
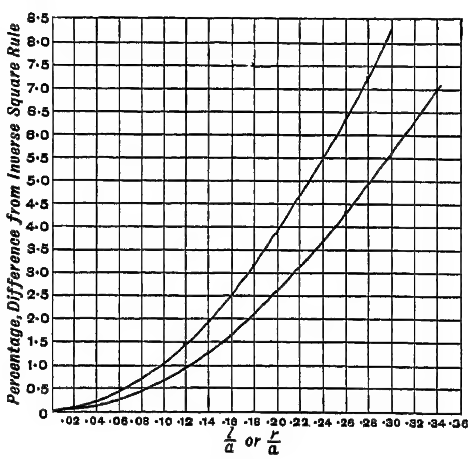

FIG. 16.

§ (23) VARIATION OF CANDLE-POWER WITH VOLTAGE.—As has been already stated above, the candle-power of electric glow lamps varies at a much more rapid rate than the voltage applied to the filament. Actually it has been found that for tungsten filament vacuum lamps, a voltage change of 1 per cent causes a 3·7 per cent change of candle-power, while for carbon filament lamps this change is as much as 5 per cent. For tungsten filament gas-filled lamps the figure is generally not much different from that for tungsten filament vacuum lamps. For tungsten the change produced by a given current variation is approximately half that produced by the same percentage change of voltage.

(i.) *Voltage Regulation.*—From this it will be seen that to attain an accuracy of one-tenth per cent in candle-power measurements it is necessary to ensure that the electrical measurements and regulation shall be accurate to at least 0·02 per cent. Either voltage or current regulation may be employed; the latter has the advantage that it is not necessary to ensure that the electrical measurements are made at the terminals of the lamp, but the former method has the advantage of greater sensitivity, and is the method generally employed in photometric laboratories.

(ii.) *Voltage and Current Measurement.*—For work where an accuracy of 1 per cent in candle-power is the best aimed at, indicating instruments of a large scale precision type are good enough if constantly checked against a standard cell and accurate potentiometer. For more accurate work, however, a potentiometer method of voltage measurement must be employed, and it is essential that the voltage of the supply shall be absolutely free from momentary fluctuations. In the most accurate work a storage battery, of reasonably high capacity for the loads to be taken, is essential. The leads from this supply are brought through adjusting resistances to the current terminals on the photometer bench. From the voltage terminals, leads are carried to the terminals of a potentiometer, which is repeatedly checked during the course of a day against a standard Weston cell. If measurements of the current passing through the lamp are also desired, it is necessary to introduce into the main circuit of the lamp an accurately measured resistance capable of carrying the current without sufficient change of temperature to affect the value of the resistance. The voltage across the ends of this standard resistance can then be measured by means of the potentiometer and the value of current deduced.

Frequently, when using two electric lamps on the bench at the same time, it is convenient to be able to have a constant indication of the voltage on each lamp, and in this case an electrostatic voltmeter may be usefully employed on the comparison lamp circuit. This lamp has normally to be run for a considerable length of time at a constant voltage, and therefore a voltmeter with a sufficiently enlarged scale (that used at the National Physical Laboratory has a scale of 12 feet radius on which one volt is represented by a length of 2½ inches)[1] may be used for maintaining a watch on its voltage. The indication of this voltmeter has to be checked at intervals throughout the day on account of the slow upward creep due to the lag of the suspension. With this arrangement, the potentiometer is

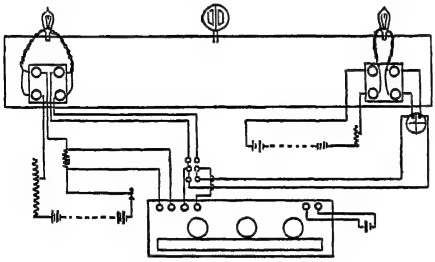

FIG. 17.

free to give a constant indication of the correctness of the voltage on the test lamp or sub-standard. A sketch diagram of the electrical connections is given in *Fig.* 17.

§ (24) OTHER TYPES OF PHOTOMETER.—The above is a general description of the methods usually followed when using a comparison photometer of any ordinary type and for the purpose of illustration; the Bunsen grease spot and the Lummer-Brodhun contrast photometers have been described. The method, however, is perfectly independent of the particular form of photometer head employed, and some of the other types which have been devised must now be described. The total number of these is very large, and it is impossible to do more than give a brief outline of a few of the best known in the space here available. For the others, a text-book on photometry, such as that of Liebenthal, *Praktische Photometrie*, or Trotter, *Illumination, Its Distribution and Measurement*, should be consulted. All of them depend, of course, on the comparison of brightness, but the arrangement of the surfaces to be compared and the form of the line of separation differ in the different instruments. Further, while the majority depend on the law of inverse squares for the variation of the illuminations, some use other means, such as polarisation, for this purpose, so that in these latter instruments the sources and the photometer are not altered in relative position while the measurements are in progress.

Of the first class, depending on the inverse square law, the Rumford, the Harcourt Gas Referees, the Ritchie, Conroy, Thomson-Starling, Joly, and Trotter types will be described, while the Martens will be taken as a model of the polarisation type.

§ (25) THE RUMFORD PHOTOMETER.—The earliest form of photometer capable of accurate work was designed by Count Rumford in 1793, and consisted of two vertical cylindrical rods R_1 R_2 (*Fig.* 18), contained in a blackened box at the meeting-point of two tables. The tables carried the two sources to be compared, and these cast shadows of the cylinders on a white surface at the back of the box. The relative positions of the cylinders were so adjusted that the two central shadows were just in contact at the centre of the white surface, while the two outer shadows were cast on a blackened surface and so lost. An opening in the centre of the front of the box enabled an observer to compare the intensities

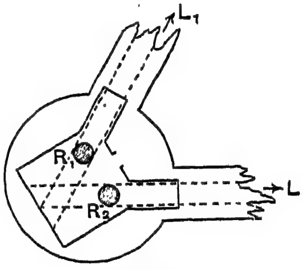

FIG. 18.

of the two shadows, and to obtain equality between them by moving one of the sources.

§ (26) THE HARCOURT PHOTOMETER.—The Harcourt photometer used by the Metropolitan Gas Referees consisted, in principle, of a box, having on one side a circular opening covered with translucent paper and on the other a diaphragm with a rectangular opening 25 mm. high and 7 mm. broad. The two sources of light to be compared were placed on the diaphragm side of the box, each slightly to one side of the line joining the diaphragm to the screen (see diagram *Fig.* 19). In this way each source caused the diaphragm to throw a bright rectangular patch on the screens, and by suitably altering the positions of the lights these two patches could be brought into juxtaposition, so that their brightness could be readily compared. When equality of brightness was obtained, the candle-powers of

[1] "Photometry at the National Physical Laboratory," *Illum. Eng.*, London, 1908, i. 845.

the two sources were in the ratio of the squares of their distances from the screen S. It was, of course, essential that the normal to the screen

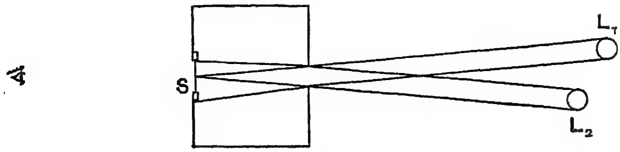

FIG. 19.

should exactly bisect the angle between the lines joining the centre of the screen to the two light sources, and in the actual instrument a mirror attachment was provided for the purpose of making this adjustment.

§ (27) THE RITCHIE WEDGE.—The photometer designed by Ritchie in 1826 consists of two inclined mirrors MM (see *Fig.* 20). These reflect the light from sources L_1, L_2, to a piece of translucent paper P. If the angle between the mirrors be rather more than 90°, the bright patches produced on the translucent paper may be brought into accurate contact, and then balance is obtained in the same way as with the Bunsen photometer by altering the distance of one or both lamps until equality of brightness between the patches is obtained. In a modification of this photometer matt white surfaces are used in place of the mirrors, and the translucent paper is removed, so that the surfaces of what has been termed the "Ritchie wedge" are directly viewed by the observer.

A very important factor in all photometers is the accurate placing in exact juxtaposition without interval or overlapping (as far as the eye is concerned) of the surfaces to be compared. Even a fine line of separation, either darker or brighter than the surfaces compared, impairs the accuracy of equality judgment, though this is of less importance in a contrast type of field. With the Ritchie wedge, therefore, the front edge must be exceedingly fine, and further, on account of the cosine law of illumination, it is most important that the light shall impinge

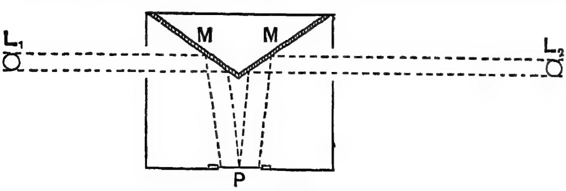

FIG. 20.

on both surfaces at exactly the same angle. Trotter has shown,[1] however, that for wedges made of dulled Bristol board the error introduced by shift of angle is not nearly as great as would be expected from the simple cosine law, owing to the special behaviour of this material when the light is incident at an angle of 30° to 35°. An angle of 60° to 70° is therefore best if the Ritchie wedge is made of this material.

Two modified forms of the Ritchie wedge photometer have been used. The first of these was introduced in 1883 by Conroy and the

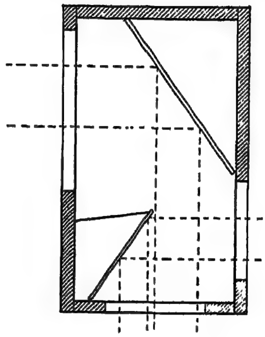

FIG. 21.

second by Starling and S. P. Thompson in 1893. They are shown in *Figs.* 21 and 22 respectively, and from these diagrams the

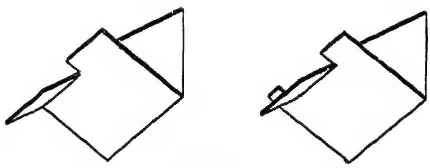

FIG. 22.

principles of the designs are self-evident. To ensure a sharp line of junction in the Thompson-Starling pattern, the edges of the cards facing the observer should be sharply bevelled.

§ (28) THE TROTTER PHOTOMETER.—Trotter's "Perforated Disc" photometer is shown in plan in *Fig.* 23 The two inclined cards A and B are of Bristol board with the glaze removed by passing over it a damp rag. A has a star-shaped hole cut in its centre, the length and height being so proportioned, and the edges bevelled so that the observer at O sees a perfectly sharp-edged and symmetrically

[1] *Illumination, Its Distribution and Measurement,* p. 95.

shaped cavity behind which appears the surface of B. A and B being illuminated by the two sources, it is possible to obtain an accurate

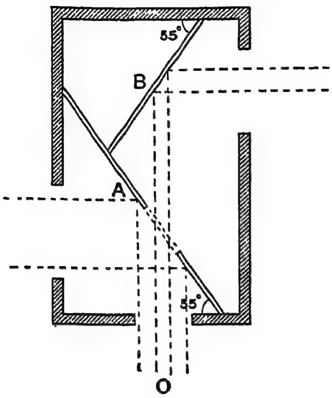

FIG. 23.

balance of brightness between them when the edge of the star becomes almost invisible. A similar design, independently proposed by Weber, is termed the "Roof" photometer, from the appearance of the cards when seen from above.

§ (29) THE JOLY PHOTOMETER.—The photometer designed by Joly in 1888 consists of two blocks of paraffin wax, or translucent glass, placed side by side. Light from the two sources falls upon the side of the blocks which appear to be suffused with light, and the brightness match is obtained between the two sides B_1, B_2 (*Fig.* 24). For an illumination of 10 lux with paraffin wax as the material, blocks about 5 mm. thick give a convenient brightness. If thicker blocks are used the illumination must be increased. When nearly balanced the less brightly illuminated block appears to have a grey band next to the dividing line, and as the point of balance is passed this band appears to shift from one side of the line to the other. The point at which this shift appears to take place gives a very sensitive criterion of the exact position of balance.

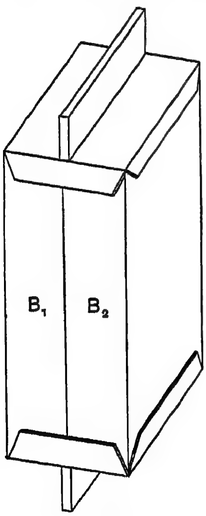

FIG. 24.

§ (30) THE MARTENS POLARISATION PHOTOMETER.—The chief example of a photometer employing polarisation as the means of varying the brightness of the comparison surfaces is Martens' Polarisation Photometer, shown in diagrammatic section in *Fig.* 25. In this instrument the light from the test lamp illuminates a plaster screen F. The light from this is reflected by two right-angled prisms P, Q through the Wollaston prism W, and the bi-prism B to the analyser N. Light from a small comparison glow lamp G illuminates an opal glass plate *b*, and this also is seen after transmission through W, B, and N. W and B are so arranged that the light from the opal plate *b* which reaches the eyepiece is polarised at right angles to that by which F is seen. Hence, equality being obtained by rotating the Nicol N, the ratio between the candle-powers of any two lamps placed successively at equal distances from F is the same as the ratio of the square of the tangents of the angles of rotation of N from the zero position. The tube T is capable of rotation about the axis passing through the centres of the prisms P, Q.

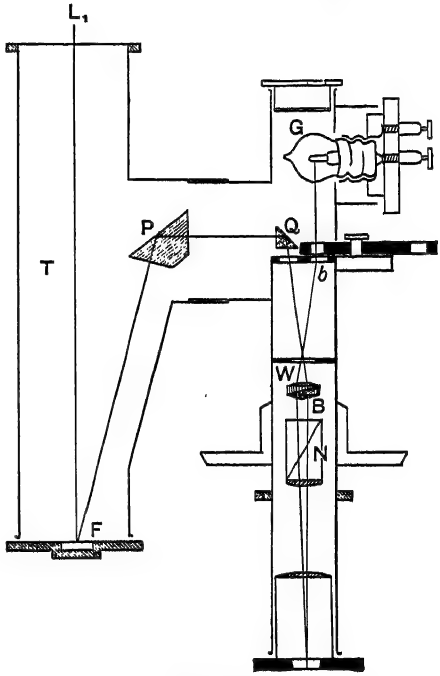

FIG. 25.

§ (31) THE ACCURACY OF MEASUREMENT.—The relative merits of the different patterns of photometer are very difficult to decide. The accuracy obtainable in photometric work depends very largely upon the individual and

each observer will obtain the best results with the particular instrument to which he is accustomed. Even the same observer differs in accuracy from day to day, and with the extent to which his eye has been fatigued by previous work. The time taken in making a reading differs with different observers, but if too long a time is taken, the precision of judgment tends to diminish after the first twenty seconds or so. The part of the apparatus which has to be moved to obtain a balance should be light enough to require very little manual effort on the part of the observer. It is often found convenient to approach the position of balance by overshooting on each side a number of times in succession, the amplitude of the overshoot being diminished each time. If the eye is allowed to see anything brighter than the field of view in the photometer, its power of accurate balance is destroyed for a time depending on the brightness of the object seen and the time for which the eye has been exposed to it.

§ (32) Physical Photometers. — All the photometers hitherto described have depended on the comparison of brightness by the human eye. It is self-evident that, in the case of all measurements of light, the eye must be the final judge of equality, but since individual eyes differ slightly from one another in their judgment it is inevitable that the results obtained by what may be called physiological photometry cannot be independent of the peculiar characteristics of the observer, and many proposals have been made to place photometry on a semi-physical basis—*i.e.* to design some instrument which will respond to light in the same way as the "normal eye" or the average of a very great number of individual eyes none of which possesses any marked abnormality as regards light perception.

The instruments proposed for the purpose of physical photometry may be grouped in three classes according as they depend on (i.) change of the electrical properties of a material when illuminated, (ii.) the electron emission of a metal surface under the action of light, or (iii.) the action of light radiation on a thermopile or bolometer.

§ (33) The Selenium Cell.—Of the first class, the most commonly used substance is selenium. It has long been known that the electrical resistance of selenium falls when illuminated, and many devices for the automatic lighting of lamps depend on the rise of resistance of a selenium cell when the daylight illumination falls.

One form of selenium cell may be made by taking a small sheet of ground glass and spreading this with a very thin layer of purified amorphous selenium by means of a hot glass rod. If now four strands of fine bare copper wire are wound round the plate so that the whole of the selenium surface is covered, and two alternate strands are then removed, the other two strands are left separated for the whole of their length by a space equal to the diameter of a wire. To make the cell sensitive to light it is heated in an oven to a temperature of 180° C. for about five minutes, when the transformation from amorphous to metallic selenium should be complete. The resistance of such a cell, formed on a plate $1 \times 3 \times 0{\cdot}1$ cm., has been found by Pfund [1] to be of the order of 2×10^7 ohms, and the sensitivity such that the resistance is decreased to 10 per cent of this value by an illumination of 150 to 200 metre-candles. The cells should be protected from moisture by being placed in a vacuum tube or waxed to a sheet of glass or mica.

A selenium cell is very selective, having a maximum of sensitivity at a wave-length of about 700 $\mu\mu$. The most sensitive cell made by Fournier d'Albe [2] was capable of detecting an illumination of the order of 10^{-5} metre-candles. He found that the change of resistance of a cell was, for a given period of recovery, approximately proportional to the square root of the illumination.

The chief disadvantage attending the use of a selenium cell is its slowness in recovering its resistance after exposure to illumination, the period taken for recovery increasing with the intensity of the illumination to which it has been exposed.

§ (34) The Photo-electric Cell. — The second class of physical photometer, generally called the "photo-electric cell," depends upon the fact, discovered by Hallwachs in 1888, that a body carrying a negative charge of electricity loses that charge when ultra-violet light falls upon it. Elster and Geitel in 1889 [3] showed that sodium and potassium exhibit this same effect when exposed to light in the visible spectrum, and they and other workers have devoted much careful experimental work to the study of this effect and the possibility of its application to physical photometry.

A convenient form of the apparatus for fairly high illumination intensities is shown in *Fig.* 26.[4] The photo-electric cell itself consists of a glass globe Z containing a mixture of helium and argon at low pressure. Into the centre of this cell projects a platinum wire which acts as the anode of the cell and is connected to the terminal K_2 of the photometer. The cathode consists of a surface of potassium which makes contact with a silver plate Ag and is connected by means

[1] *Phys. Rev.*, 1909, xxviii. 324.
[2] *Roy. Soc. Proc.*, 1913–14, lxxxix. 75.
[3] *Annal. d. Physik.*, 1889, xxxviii. 40, 497.
[4] Elster and Geitel, *Phys. Zeit.*, 1912, xiii. 740.

of a platinum wire sealed into the glass with the terminal K_1 of the photometer. A guard-ring S_1 connected to earth prevents

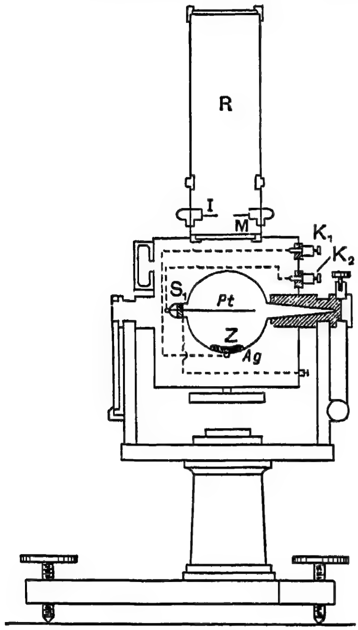

FIG. 26.

leakage over the surface of the glass between the two electrodes. The light enters by the tube R, which is closed by a cap when the photometer is not in use, so that the cell is completely shielded from light except when in operation. I is an iris diaphragm, and M a plate of matt uviol glass. The box containing the cell is blackened inside and is capable of rotation about the axis defined by the platinum wire Pt. Thus the whole instrument is mounted like a theodolite, and the tube R can be oriented in any desired direction. Using a potential difference of 40 to 60 volts between the electrodes on the cell, the current produced by sunlight illumination is of the order of 10^{-6} amperes. The current due to an illumination of 1 metre-candle is of the order of 10^{-11} amps., and it has been found that if proper precautions are taken to eliminate possible disturbing factors very accurate proportionality exists between current and illumination over great ranges of intensity of the latter (0·07 to 6000 metre-candles).[1] It has been calculated by H. S. Allen that an alkali cell of the most sensitive type, used in connection with a tilted electroscope capable of measuring currents of 10^{-15} amperes, should be capable of detecting the light from a candle at a distance of 2·7 miles.[2]

(i.) *Variation of Sensitivity with Wave-length.*—One of the chief difficulties in the use of photo-electric cells as physical photometers is the difference between the behaviour of such a cell and the human eye as regards response to light of different wave-lengths. Normally, the sensitivity of the cell should be greater the shorter the wave-length of the light, but although the alkali metals are selective in the visible spectrum, their characteristic curve is far from even approximating to that of the eye, so that the photo-electric cell in its simple form can only be used for the comparison of lights having exactly the same spectral distribution. In order to make the measurements obtained with them of absolute photometric value, it would be necessary to introduce some colour filter to reduce their curve of sensitivity at different wave-lengths to approximate equality with the sensitivity curve of the average eye.

Various metals and alloys have been tried in different gases and mixtures of gases. Both sodium and potassium have been used separately and alloyed, and the hydrogen at first employed has been replaced by a mixture of helium and argon. Elster and Geitel have prepared very sensitive cells by first heating the alkali metal in hydrogen to a temperature of about 350° C. The clear colourless crystals of hydride thus obtained are then bombarded with cathode rays, large quantities of hydrogen are evolved, and the hydride becomes brightly coloured. These coloured substances, which Ester and Geitel consider to be the metal in a colloidal state dissolved in the solid hydride, are from three to four times as sensitive as the pure metal surface prepared by distillation. The hydride crystals have to be removed from contact with hydrogen, and this is replaced by argon or helium after the colouring has been produced.

(ii.) *Photo-electric Fatigue.*—The second disadvantage attending the use of photo-electric cells is the possibility of loss of sensitiveness by what is known as "photo-electric fatigue." This fatigue may take place when the cell is standing idle and is fairly rapid in the presence of a gas. Much work has been done on both the theory and the practical effects of this fatigue when the pressure of the gas is reduced to that generally used in photo-electric cells (1 to 3 mm. of mercury), but no conclusive evidence of complete absence of fatigue in any particular form of cell has been produced so far.

§ (35) RADIOMETERS.—The third class of physical photometers, depending on radiometric measurements by some instrument such

[1] Richtmyer, *Phys. Rev.*, 1909, xxix. 71, and 1910, xxx. 385.

[2] H. S. Allen, *Photo-electricity*, p. 74.

as the thermopile, has been developed by Ives and Kingsbury in America.[1]

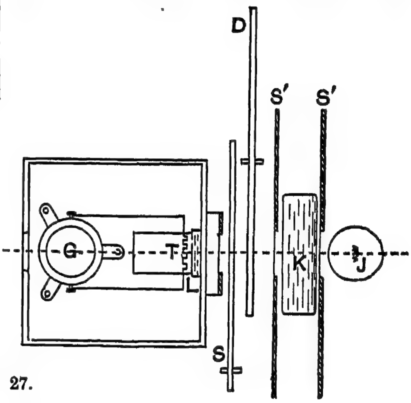
The Thermopile.—It is clear that the thermopile, since it measures total radiation, cannot be used alone to evaluate luminous flux, but that some auxiliary device is necessary to reduce the radiation in each wave-length in such a proportion that the relative effects of the different wave-lengths on the combined apparatus may be the same as their relative effects on the human eye. An approximation to this condition may be arrived at by means of a coloured solution which transmits such a proportion of the whole incident radiation in each wave-length that the effect on the thermopile is proportional throughout the spectrum to the effect of light of that particular wave-length on the human eye. The solution arrived at empirically by Ives and Kingsbury (*loc. cit.*) is as follows:

Cupric chloride . . .	60·0 gm.
Cobalt ammonium sulphate .	14·5 gm.
Potassium bichromate . .	1·9 gm.
Nitric acid (1·05 sp. gr.) . .	18·0 c.c.
Water to	1 litre.

The form of apparatus used by them is shown in *Fig.* 27. T is the thermopile, consisting of

from the Hefner lamp to an ordinary tungsten filament vacuum lamp, the agreements between the visually and physically determined values of transmission ratio of yellow and blue test solutions were identical to one-half of 1 per cent.

As an alternative to the solution method of reducing total radiation to agree with the sensitivity curve of the eye, Ives has proposed[2] the analysis of the light from the source into a spectrum band, by means of a prism. This spectrally distributed light is then transmitted through a sector disc having apertures cut in it of such a shape that the relative amounts of each wave-length transmitted by the disc are proportional to the sensitivity of the eye at that wave-length. The apparatus is shown in plan and elevation in *Fig.* 28, where L is the light source, S the slit, and P the prism producing a spectrum S′. D is the sector disc, and it will be seen from the end view, with one aperture passing over the spectrum, that the different wave-lengths can be



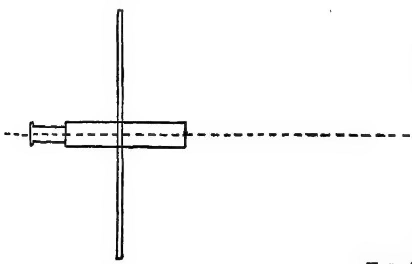


FIG. 27.

18 bismuth-silver junctions arranged linearly in series, and having a total resistance of 26 ohms. G is a d'Arsonval galvanometer with an internal resistance of 12·5 ohms and critical damping resistance of 32·5 ohms. Its sensitivity is 33 mm. per microvolt. L is the luminosity curve solution (above described) in a glass tank one centimetre thick. K is a protective water tank at least four cm. thick, to cut off infra-red radiation. S is a shutter, S′, S′ tin screens, and D a sector disc. J is the source of light, a lamp of 100 candle-power placed 25 cm. from the thermopile. It was found that with this apparatus, the lamp running at the colour of a 4 watt per candle carbon filament lamp and giving a candle-power of 45 candles, the deflection on the galvanometer was 7 cm. It was found that over the range of colour represented by the commoner illuminants and standards, *i.e.*

weighted in such a manner that the sensitivity curve of the eye is reproduced on the thermopile T when the transmitted spectrum is recombined by the lenses C, C.

The chief difficulty met with in the use of total radiation is that, owing to the very small proportion of the total radiation from the source which is in the visible spectrum (generally less than 1 per cent), the effect of scattered heat radiation is very serious, and special precautions have to be taken to ensure that this error is avoided. For details of the methods by which it has been sought to do this, the original papers above referred to should be consulted.

§ (36) SPECIAL PHOTOMETERS.—Descriptions of photometric apparatus specially designed for particular branches of photometric work (*e.g.* the flicker photometer for heterochromatic photometry, the Ulbricht

[1] *Phys. Rev.*, 1915, vi. 319.

[2] *Phys. Rev.*, 1915, vii. 334.

globe for the measurement of average candle-power, and the various forms of illumination photometers) will be found under the sections dealing with those particular branches of photometry.

IV. Light Distribution

The section on Photometric Methods dealt only with methods of measuring the candle-power of a source in one single direction, but in the case of all sources met with in practice, the candle-power varies in different directions, and it is therefore impossible to compare the performance of two sources by a single candle-power measurement unless the direction in which that measurement is made has been carefully defined. It is partly for this reason that sub-standard electric glow lamps are constructed with the filament in one plane. The candle-power in the line perpendicular to this plane is the one taken for purposes of measurement, and this arrangement has the great advantage that a slight departure from the true position has practically no effect on the candle-power in this region.

§ (37) Polar Diagrams.—It is, however, obvious that in the case, for example, of a vacuum glow lamp with a filament of the ordinary squirrel-cage type, the candle-power in the direction of the axis of the lamp is very much less than that measured in a direction perpendicular to this. It is actually found that the candle-power is by no means the same in all directions perpendicular to the axis, and *Figs.* 29 and 29A illustrate these statements. These diagrams are what are generally termed "polar diagrams of light distribution." In these curves the length of the radius vector at any angle gives the candle-power at that angle, and the curve of *Fig.* 29 shows the variation in candle-power at the different angles in a plane passing through the axis of the lamp, while *Fig.* 29A gives similar information for a plane perpendicular to this axis.

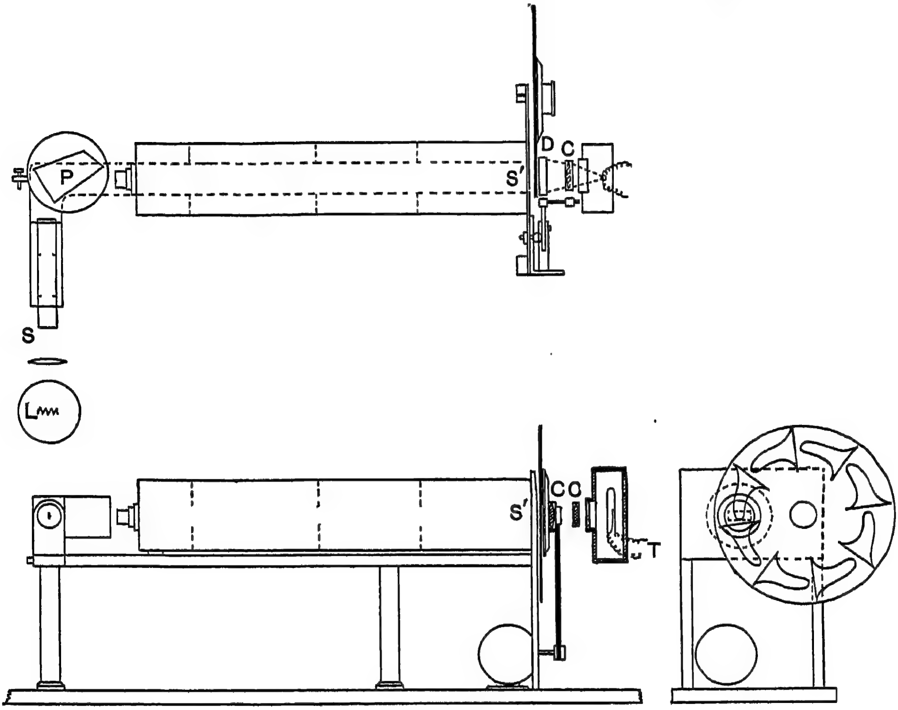

Fig. 28.

§ (38) Mean Horizontal Candle-power.—The different methods by which these polar curves are obtained will be dealt with in this section, but first it is necessary to describe a method for finding by a single measurement the average value of the candle-power in all directions in a plane perpendicular to the lamp axis. This average, called the mean horizontal candle-power (m.h.c.p.) of the lamp, is a figure very frequently used for the rating of vacuum lamps of the ordinary type.

The method consists of rotating the lamp

about its axis (placed so as to be vertical) sufficiently fast to obtain on the photometer head an average illumination. A speed of 120 revolutions per minute is generally

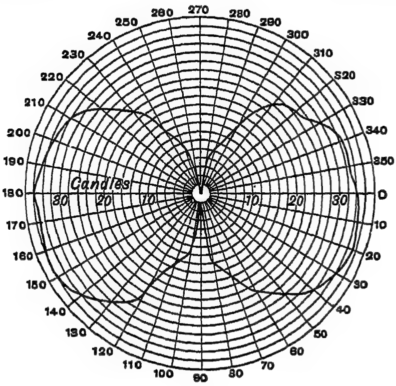

Fig. 29.

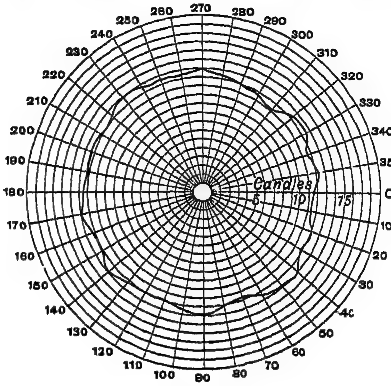

Fig. 29A.

sufficient. The candle-power corresponding to this illumination is then called the mean horizontal candle-power of the lamp. The chief difficulty of this method is to ensure a steady contact for current supply to the rotating lamp when this is being driven sufficiently fast to eliminate flicker in the photometer. This difficulty has been overcome in the form of rotator, shown in *Fig.* 30,

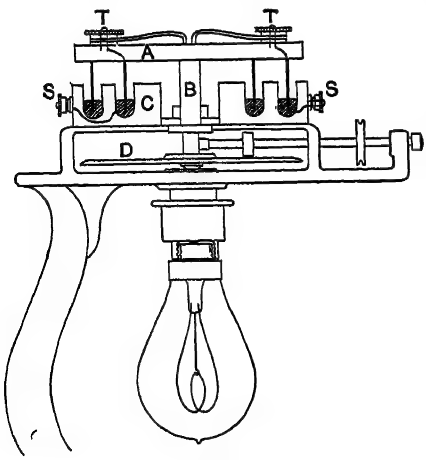

Fig. 30.

which was designed by C. C. Paterson for this purpose.

(i.) *The Lamp Rotator.*—The rotator consists essentially of two parts, one fixed rigidly to the stand, the other capable of rotation and carrying the lamp. The arrangement is best seen from the sectional diagram of *Fig.* 30. A is an ebonite disc bearing two concentric copper rings, which are respectively connected to the terminals T, T. From these terminals flexible leads are conveyed inside the vertical tube B to the lamp holder. Rigidly attached to this tube is a solid brass disc D which is friction-driven by a small wheel driven through a shaft and pulley system from a small electric motor. C is a second circular ebonite block bearing two annular grooves concentric with the copper rings of A and half filled with mercury so that these rings can rotate freely with about ¼-inch of their lower edges dipping into the mercury. The mercury in these two grooves is connected to four terminals S, S to which are attached the current supply leads and voltage measuring leads from the bench. With this apparatus, if the mercury troughs and copper rings are kept clean, there is generally no difficulty in maintaining the current through the lamp perfectly steady.

(ii.) *Step-by-step Method for Gas-filled Lamps.*—The above method of obtaining the mean horizontal candle-power can only be applied to vacuum lamps, as a gas-filled lamp may change candle-power by several per cent if it be rotated.[1] In the case of these lamps, therefore, the method of measurement at different positions round the lamp must be employed. For finding the polar curve in the horizontal plane, *i.e.* the plane perpendicular to the axis of the lamp, supposed upright or pendent, it is only necessary to rotate the lamp and its holder in the photometer carriage and take candle-power measurements every 10°. The correct positions are easily found by the aid of the degree scale on the table fitted to the carriage (see *Fig.* 10). For the determination of the polar curve in a vertical plane the lamp may be mounted

[1] Middlekauff and Skogland, *Bureau of Standards Bull.*, 1915–16, xii. 595.

in the fitting shown in *Fig.* 31. This consists of two semi-rectangular frames of iron, jointed at the open ends, so that one frame can be clamped at any desired angle with the other. A graduated dial is fixed to the lower frame (which is made to fit into a photometer carriage) so that the angle of tilt of the upper frame, bearing the lamp, can be ascertained. By this means a curve showing the distribution of candle-power of a lamp, in a plane passing through its axis, can be obtained. A curve thus obtained for an ordinary "squirrel cage" tungsten-filament vacuum lamp is shown in *Fig.* 29A.

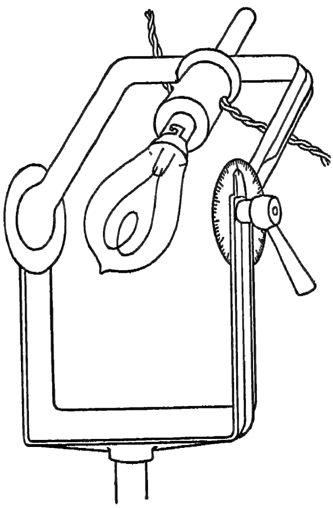

FIG. 31.

§ (39) THE MIRROR APPARATUS FOR POLAR CURVE DETERMINATION.—It is not possible, however, to tilt all light sources. Gas flames or mantles clearly cannot be tilted, and some gas-filled electric lamps change candle-power appreciably according to the position in which they are burning.[1] For such sources, therefore, it is necessary to have recourse to some arrangement of mirrors. A simple form of apparatus for this purpose is shown in *Fig.* 32. The source remains fixed at L, and the mirror M rotates about an axis passing through L. If M be tilted so as to bring the light from the source on to the photometer head (the direct light from L being screened), then the photometer readings give the candle-powers in different directions round the source in the plane of rotation of M.

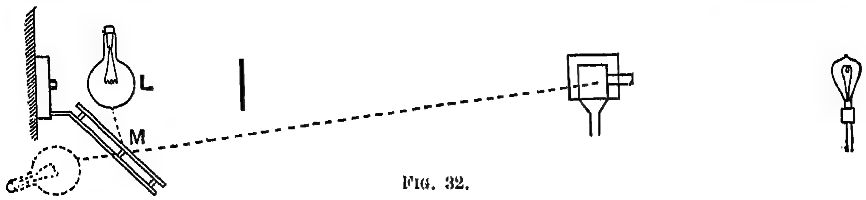

FIG. 32.

(i.) *Errors and Corrections.*—There is one source of error in this apparatus. If the radius about which M swings be not small in comparison with the distance of M from the photometer, then the light is incident obliquely on the photometer disc, so that a change in its reflection ratio as M rotates may cause a small error. Of course, the distance to be used in computing the candle-power must be that of the photometer from the image of the source as seen in the mirror. The reflection ratio of the mirror must also be allowed for, as if the mirror only reflects 80 per cent of the incident light, the measured candle-powers must be multiplied by 1·25. The reflection ratio of the mirror may be readily determined by making a candle-power measurement with the centre line of the mirror M in a horizontal plane, and then rotating L until the part which was originally seen in the mirror from the photometer now faces the photometer directly. The ratio of the candle-power in this position (the mirror being screened) to the candle-power previously obtained, gives the factor by which the mirror measurements have to be multiplied in order to obtain true values of candle-power for the curves.

(ii.) *The Three-mirror Apparatus.*—The error referred to in the preceding paragraph is avoided by the use of three mirrors arranged as shown in plan in *Fig.* 33. The principle of the method remains the same, but the light proceeds axially from the third mirror, and the candle-powers measured, after allowing for the reflection ratio of the mirror

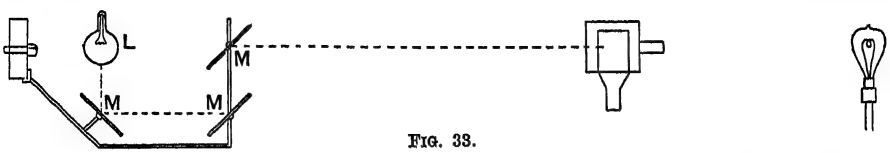

FIG. 33.

[1] Middlekauff and Skogland, *loc. cit.*

system, are not affected by changes in the reflection ratio of the photometer disc.

§ (40) Polar Curves for Large Sources.—The apparatus just described can only be used on the bench for sources of comparatively small dimensions. Very frequently, however, it is necessary to obtain polar curves for sources of large dimensions such as arc lamps, or for a lamp in a reflector fitting where lamp and fitting must be regarded as a single unit for purposes of measurement. In cases such as these, either of the methods described above may be employed, with the necessary modifications in the design of the apparatus. It is, of course, necessary to have the mirrors larger than the source or unit to be measured, and this sometimes necessitates a long swinging arm with consequent accentuation of the error referred to above in the description of the single-mirror method. At the same time, the weight of large mirrors and the difficulty of arranging a three-mirror apparatus for large sources have resulted in the use of the single-mirror method in many laboratories for sources of large dimensions. A polar diagram showing the difference of light distribution from a gas-filled lamp without reflector, and the same lamp with a large shallow reflector, is given in *Fig.* 34.

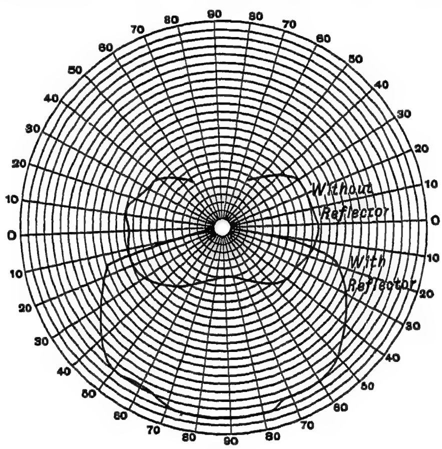

Fig. 34.

With large sources the candle-power is often considerable, and to keep within the best illumination range for accurate photometry it is necessary to have the photometer head at a great distance from the source. This is further desirable when working with a single mirror, as has been pointed out above. It is therefore often convenient to mount the source and the mirror on the wall of the room in which measurements are to be made, and to have a photometer bench of ordinary length mounted on a table on castors so that its distance from the wall can be varied. At the National Physical Laboratory, the bench is actually mounted on steel rollers which run in a track on the floor, and brass marks are fixed close to this track at intervals of a metre, so that, by means of a pointer on one leg of the photometer table, the bench can be moved an accurately known distance away from, or towards, the source.

§ (41) Unsymmetrical Sources.—In all that has been described above, it has been assumed that the source is symmetrical about a vertical axis, so that a polar curve in one vertical plane should be the same for all such planes. This, however, is not the case in practice, and therefore it must be agreed to take the vertical distribution curve in some plane, defined with respect to the source, or the source may be rotated about its vertical axis while the measurements are being made, so that the candle-power shown for any angle θ (measured from the vertical) represents the average value along all the lines forming a cone with the source as apex and semi-vertical angle θ.

When this is done, the speed at which the lamp has to be rotated may be reduced, or the flicker at any given speed may be lessened, by using two mirrors symmetrically placed with respect to the source instead of a single mirror. If this arrangement be adopted it is necessary to cut off the inner corner of each mirror so that both may be used at angles near the vertical.

§ (42) Average Candle-power or M.S.C.P. (i.) *The Rousseau Diagram.*—It might be concluded from the above description that the relative performance of two lamps or lighting units of approximately symmetrical distribution could be seen at once from their respective polar curves, obtained by one of the methods described above; but while it is true that this information can be deduced, after computation, from these curves, the appearance of the curves themselves can be most misleading. This may be very well demonstrated[1] by a consideration of the two curves shown in *Fig.* 35. All the radii vectores of the first curve are double the corresponding ones of the second, so that it is obvious that the total amounts of flux emitted by the two lamps must be in the ratio of two to one. Yet it is equally obvious that the areas of the curves are in the ratio of four to one, while the volumes of their solids of revolution about the vertical axis are in the ratio of eight to one. Clearly neither the area of the polar curve nor the volume of its solid of revolution about the vertical axis can give a mental

[1] Mrs. Ayrton, *The Electric Arc*, p. 454.

conception of the relative amounts of flux emitted by the lamps. This can only be obtained by computation of the average candle-power of the lamp measured in all directions in space. This figure, known as the average candle-power (a.c.p.) or mean spherical candle-power (m.s.c.p.) of a source, can be obtained by calculation from the polar curve in the case of a source whose candle-power performance is symmetrical about the axis of the polar curve. For, if J be the candle-power in a direction making an angle θ with the vertical, then if we suppose a sphere of radius r to surround the source, the area of the zone of this sphere from which the source appears to have the candle-power J is clearly $2\pi r^2 \sin\theta d\theta$, so that the average candle-power is $\frac{1}{2}\int_0^\pi J \sin\theta d\theta$. The value of this expression may be obtained by a simple graphical method due to Rousseau[1] and termed the Rousseau diagram. *Fig.* 36 shows on the left the polar curve of a source of light. At the ends of the radii vectores, horizontal lines are drawn through a vertical line AB, and from the point of intersection of any such horizontal a length is cut off equal

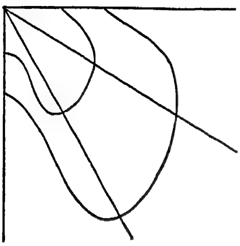

Fig. 35.

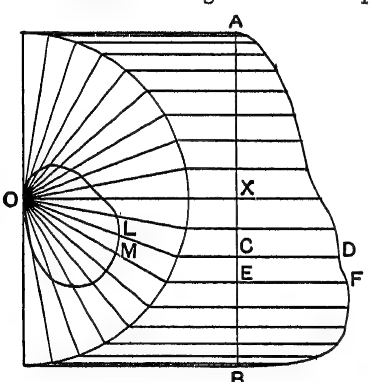

Fig. 36.

to the length of the corresponding radius vector on the polar curve. Thus CD is equal to OL, EF to OM, and so on. A smooth curve is then drawn through all the points such as D, F. From the method of construction of the diagram it will be clear that the distance CX is equal to $r \cos\theta$, so that, in the limit, CE $= r \sin\theta d\theta$, and therefore half the area of the curve ADFB gives the average candle-power of the source. This area may be obtained either by means of a planimeter, or by erecting a series of equidistant ordinates on AB as base, and using one of the forms of Simpson's rule.

(ii.) *Russell Angles.*—In the above method of obtaining the Rousseau diagram it will be seen that measurements of candle-power are made at regular intervals of 10° (or whatever interval may be selected), and that these measurements are then spaced to give them their correct respective weights in determining the area of the curve. Russell's method[2] consists of a predetermination of the angles at which measurements must be made to give equally spaced ordinates on the Rousseau diagram. The spacing of these angles is shown in *Fig.* 37, where it will be seen that the sphere

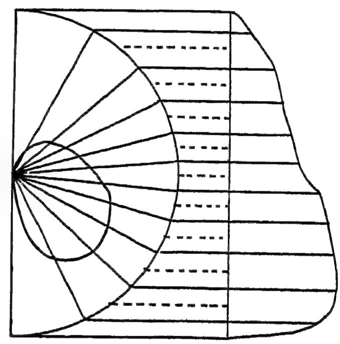

Fig. 37.

is divided by the broken lines into 10 zones of equal area, and then candle-power measurements are made at the half-way points of these zones, so that the area of the Rousseau diagram may be calculated at once by Simpson's rule without any need for the diagram to be drawn. The Russell angles to be used when the sphere is divided into 20, 10, and 5 zones respectively are as follows:

Table of Russell Angles for Calculation of Average Candle-power

§ (43) BLONDEL'S M.S.C.P. PHOTOMETERS.—The above method of determining the

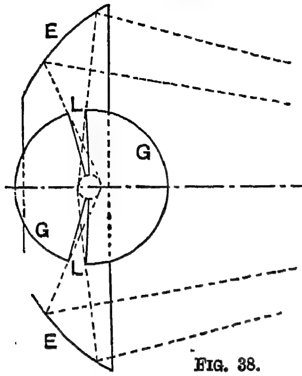

FIG. 38.

average candle-power of a source necessitates the determination of the candle-powers in a certain number of fixed directions. The same information can be obtained in a single measurement by the use of a form of apparatus which concentrates on to the photometer head the light, or a known fraction of it, from a circular ring surrounding the source. Blondel [1] has proposed two different methods of doing this. In one of these, shown in *Fig.* 38, he places the source S at the centre of a spherical blackened globe GG. This globe has cut out of it two lunar apertures LL, and the light from S passes through these and strikes an ellipsoidal mirror E, from which it is brought to a focus at P where the photometer is placed. In a modification of this method the mirror E is replaced by an annular diffusing ring. In each case the instrument is calibrated by means of a lamp of known average candle-power.

§ (44) THE MATTHEWS-DYKE PHOTOMETER.—Matthews' apparatus, as modified by Dyke,[2] is shown in plan and elevation in *Fig.* 39. Eleven pairs of adjustable mirrors M_1M_2 are carried on a semicircular support A. L is the source placed at the centre of the ring of mirrors M_1. These are so placed that the light reaching them from L is reflected to the mirrors M_2 and from the latter proceeds to the photometer head P. The case of this is cut away so that light may reach the photometer screen from all angles. It will be seen that by this method the total illumination of the photometer screen is proportional to the average candle-power of the source L, provided this is symmetrical. For light emitted by the source in a direction making an angle θ with the vertical, on reaching the photometer, makes the same angle with its surface, so that the illumination is reduced by the factor $\sin\theta$. Provided, then, that the diffuse reflection ratio of the photometer screen do not vary with the angle of incidence of the light, the photometer will give the average candle-power directly, if the apparatus be calibrated with a lamp of known average candle-power.

The apparatus was used by Dyke to determine the ratio of the average to the mean horizontal candle-power of a source. For this purpose the light from L is reflected by two other mirrors N, N to the opposite side of the photometer head. These are mounted on a stand which slides on a graduated scale T,

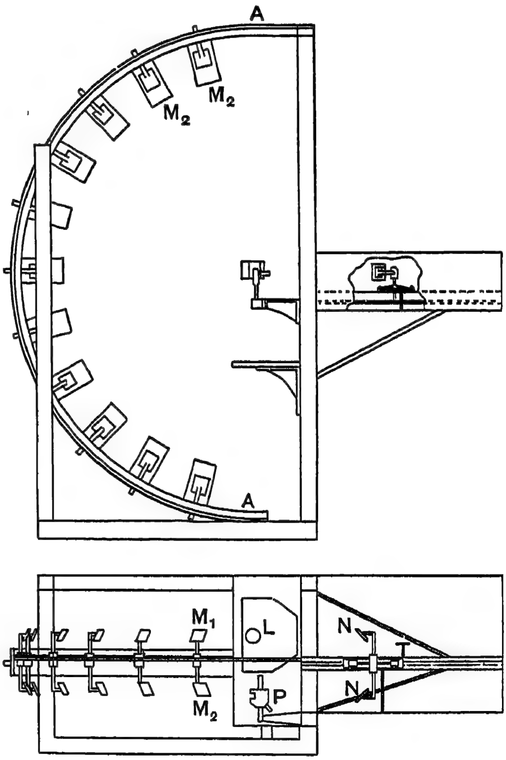

FIG. 39.

and by balancing the photometer the ratio between the mean horizontal and mean spherical candle-powers can be obtained by a single measurement. For the method of correcting for the lack of constancy of reflec-

[1] *Comptes Rendus*, 1895, cxx. 311 and 550.
[2] *Phys. Soc. Proc.* xix. 399, and *Phil. Mag.*, 1905, ix. 136.

tion ratio of the photometer screen, Dyke's original paper should be consulted.

§ (45) INTEGRATING PHOTOMETERS.—In all the above methods of determining the average candle-power it has been necessary to assume that the polar curve is the same in all planes passing through the axis of the lamp, or else that this is sufficiently nearly the case for rotation of the lamp to give a true mean. In the apparatus now to be described this assumption is not made. The distribution of light from the source may be quite irregular, and yet the correct value of average candle-power will be obtained by a single measurement, provided the theoretical conditions of the apparatus be sufficiently closely fulfilled. Actually, as will be seen, the departures from these conditions rendered necessary by practical considerations make the values inexact for very unsymmetrical sources, and the cause of these errors and their elimination will be the subject of the concluding paragraphs of this section.

§ (46) THE WHITENED SPHERE. — W. P. Sumpner first pointed out in 1892[1] that if ABCD (*Fig.* 40) be a principal section of a globe, with a perfectly matt white interior surface, then the amount of radiation reaching any point of the surface B from an element of the surface A was the same whatever the relative positions of A and B. For if O be the centre of the sphere, and F the radiation emitted from A in the direction AO, the radiation emitted in the direction AB will be F cos OAB. Also this radiation strikes the surface at B at an angle from the normal equal to OAB. The amount of radiation reaching B is therefore proportional to F $\cos^2$ OAB/AB^2. But AB $=2r$ cos OAB, and hence this expression becomes $F/4r^2$, which does not depend on the positions of A and B. Hence the radiation received from A by all parts of the interior of the sphere is the same, since any two points of a sphere can be joined by a great circle.

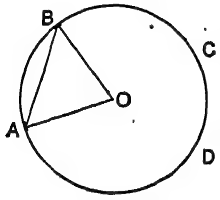

FIG. 40.

If, then, a source of light be placed inside a whitened sphere, a certain amount of light from it reaches each part of the surface of that sphere. The amount diffusely reflected by that part to every other point of the sphere is the same and is proportional to the diffuse reflection ratio of the surface (for normally incident light if the source is placed at the centre of the sphere). Thus any particular spot on the sphere receives, in addition to its own share of the direct light from the source, a constant proportion of the light received by every other point of the sphere, and thus the illumination of a given point shielded from the direct light is proportional to the light received by all the other parts of the sphere, *i.e.* to the average candle-power of the source.

The exact mathematical investigation is as follows: If ϕ be the amount of flux per unit area which reaches the point A from the source, and if R be the reflection ratio of the surface of the sphere, then the amount of flux per unit area which reaches every other part of the sphere, due to reflection from A, is $R\phi/\pi \cdot 1/4r^2$, since ϕ, the flux reflected normally by a perfectly diffusing surface, is equal to the flux received by that surface divided by π (see section on "Illumination"). It is clear, therefore, that if Φ be the total flux emitted by the source, the amount of flux received, per unit area of the sphere, by a single reflection from each other part of the sphere, is $R\Phi/\pi \cdot 1/4r^2$. Similarly, the amount received by two reflections is $R^2\Phi/\pi \cdot 1/4r^2$, and so on. Hence the total flux received by reflection at any point of the sphere is found to be $\Phi/4\pi r^2\{R+R^2+\ldots \text{to infinity}\}=\Phi R/4\pi r^2(1-R)$. But if J be the average candle-power of the source, $\Phi=4\pi J$ (see § (2), "Definitions"), so that the above expression reduces to $J/r^2 \cdot R/(1-R)$. But J/r^2 is the flux per unit area reaching the surface of the sphere, supposing all reflections absent and the source uniform in all directions. In the case of a sphere of one metre radius, a source of one candle would produce an illumination by direct light of 1 metre-candle. If the diffuse reflection ratio of the surface of the sphere be 80 per cent, the illumination by reflected light is $0{\cdot}8/(1-0{\cdot}8)=4$ times as great as this, *i.e.* 4 metre-candles.

§ (47) THE ULBRICHT GLOBE. (i.) *Description.*—The first proposal to use this principle for the determination of average candle-power was made by Ulbricht in 1900,[2] and many developments of the design and contributions to the theory of the sphere photometer have been made by him and others since that date.[3] Recently a large photometer of this type has been constructed at the Bureau of Standards. This consists of a sphere of 88 inches internal diameter, built up of reinforced concrete on a steel network, and finished off inside to a truly spherical surface.[4] There are two holes in the sphere as shown in the sectional diagram,

Fig. 41. The top hole is covered with a flat wooden disc which can be lowered from above in annular sections, so that a lamp can be suspended inside the sphere from above if

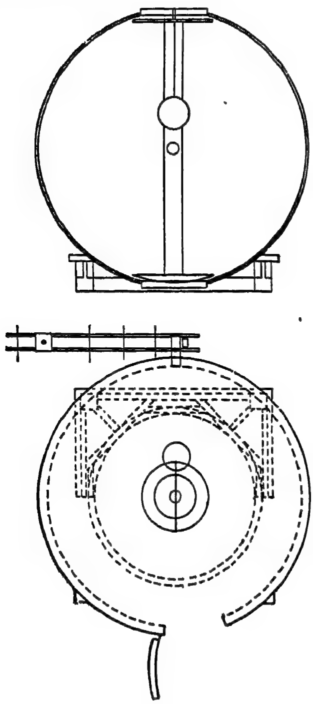

FIG. 41.

desired. On one side of the sphere is a hinged door of segmental form with maximum dimensions $37 \times 16{\cdot}5$ inches. In the wall directly opposite the door, on the equator, is a milk glass window which can be removed at will, but which is perfectly flush with the inside surface of the wall when in place. By an ingenious arrangement of hinged rods carrying the lamp socket, lamps can be brought to the door of the sphere for changing and then automatically returned to their correct position within the sphere. At a point about 27 inches in front of the window are two vertical rods which hold a runner for carrying the screens. These are of four sizes, viz. 11, 21, 30, and 37 cm. in diameter.

As has been stated already, the inside coating of the sphere must be as non-selective as possible, owing to the number of reflections which much of the light has to suffer. In many cases a pure zinc white has been found satisfactory. In the Bureau sphere the inner coating is of Keene's cement, which was found to have a reflection ratio of 92 per cent.

The photometric apparatus consists of a 1·5 metre bench with a photometer head specially designed for the direct comparison of the brightness of the sphere window with the brightness of a diffusing glass illuminated by the comparison lamp.

(ii.) *Errors.*—Tests were made to determine the magnitude of the errors introduced into average candle-power measurements by lack of uniform distribution of light from the source. The maximum error found for many sources having different types of distribution was 1·7 per cent. The percentage reduction of the measured value by the presence of black discs in the sphere was found to be 10 times their relative area (*i.e.* ratio of area of disc to area of sphere surface). For white discs, such as the screens, this reduction was about one-third of that for black discs. Tests with a source giving a beam of light showed a maximum variation, according to the orientation of the beam, of 4 per cent. The effect of the distance of the source from the window was found to be 1 per cent with the lamp half-way between the window and the centre of the sphere. With the lamp at a distance of 10 inches from the window the error was 2 per cent.

(iii.) *Calibration.*—At the Bureau of Standards, the sphere is calibrated before each period of use, by means of a lamp of accurately known average candle-power inserted in the same lamp socket as that which subsequently holds the test lamps. This is the method also adopted with the cube photometer used at the National Physical Laboratory, to be described later.

Ulbricht's original suggestion, however, was to have both test lamp and sub-standard in the sphere during both calibration and test. This arrangement is shown in *Fig.* 42, where L_1 is the sub-standard, L_2 the test lamp, and S_1

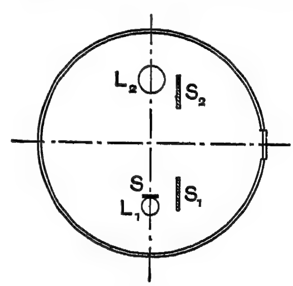

FIG. 42.

and S_2 screens shielding the window from these two sources respectively. A small screen S is also inserted to prevent specular reflection from one lamp when the other is alight. Calibration is effected by balancing the comparison lamp with L_1 on and L_2 off. The tests are then made with L_1 off and L_2 on.

If the window of the sphere does not form part of the photometer head, the two must be kept rigidly fixed in relation to each other. A useful adjunct is an iris diaphragm between the two, so that, when using the sphere for sources of very high candle-powers, the illumination on the photometer can be reduced. Of course, the diaphragm must be at the same aperture for both calibration and test.

(iv.) *Corrections.*—It will be seen from the theory outlined above that the illumination of the window is only truly proportional to the average candle-power of the source so long as the sphere is perfectly empty. The very presence in the sphere of a source of finite dimensions is a violation of this condition, and the fact that screens have to be introduced to shield the window from direct light at once introduces a further departure from the ideal conditions. The error caused by the presence of these bodies in the sphere is greater the larger their dimensions compared with those of the sphere. Ulbricht has laid it down that the diameter of the sphere should be not less than six times the diameter of the globe of the largest lamp to be measured in it. The screens, also, must be as small as possible and whitened on both sides. Where Ulbricht's arrangement is adopted the approximate error due to the screens, S and S′, provided these do not exceed 5 per cent of the area of a principal section of the sphere, has been given as $(80s-100s')$ per cent to be added to the measured value, where s and s' are the ratios of the areas of the screens S and S′ to the cross-sectional area of the sphere. Where the screens are larger than this, more complicated formulae must be employed, and for these Ulbricht's original paper should be consulted (*loc. cit.*). Where the substitution method of calibration is used, the error due to the screen may be taken as that found experimentally and given above under the description of the Bureau of Standards sphere.

§ (48) The Whitened Cube.—Various modifications of the Ulbricht globe have been suggested. One of these consists of a whitened hemisphere, another takes the form of a whitened cube. This was suggested by Sumpner [1] and has been adopted at the National Physical Laboratory.[2] Though theoretically less accurate, this form possesses the advantages of simple construction and greater ease of manipulation of the light sources inside it, and for the comparison of lamps of similar light distributions it has been found to give very accurate results. Buckley has shown [3] that for sources as dissimilar in light distribution as a tungsten-filament vacuum lamp, unshaded, and a similar lamp of which the whole of the upper hemisphere has been covered by an opaque shade, the difference introduced into the values of average candle-power measured by the cube do not exceed 4 per cent.

In all types of the globe photometer and its modifications, it is of great importance that the reflection ratio of the diffusing surface shall be uniform throughout; and if a photometer of this type is much used, especially for arc-lamp work, it must be repainted at frequent intervals, as, although frequent calibration will avoid error due to an even deterioration of the whole surface, it will not allow for a greater deterioration in one part of the surface than another.

§ (49) Average Candle-power Measurements in Specified Zones.—For certain purposes it is sometimes more important to measure the total amount of light given by a source in the lower hemisphere. This is expressed by taking the average of the candle-powers of the source measured in all directions below the horizontal plane, and is termed the average candle-power (lower hemisphere) or mean lower hemispherical candle-power. Its value may be obtained by obvious modifications of the methods described above for the determination of average candle-power. Less frequently used values are (i.) the mean upper hemispherical candle-power, and (ii.) the mean zonal candle-power, *i.e.* the average of the candle-powers of the source measured in all directions within a given zone defined in any particular case.

§ (50) General Considerations.—There can be no doubt that the use of an Ulbricht globe, or one of its modifications, will become of increasing importance owing to two facts. First, the tendency in the design of modern illuminants is to pay much more attention to the total light emitted by a source than to the particular manner in which that light is distributed, so that the average candle-power is of much more significance than the candle-power in any arbitrary direction or directions (such as the mean horizontal candle-power). Secondly, the impossibility of rotating many present-day illuminants—even the gas-filled lamp changes its candle-power value when rotated—makes a photometer such as the Blondel or Matthews useless for the determination of the average candle-power. There seems to be little doubt, therefore, that the use of the Ulbricht globe—in comparatively small sizes for the measurement of lamps of the size generally employed in interior lighting—will shortly become universal in photometric laboratories.

A very complete bibliography of the integrating photometer is given by Rosa and Taylor (*loc. cit.*) and by Ulbricht in *Das Kugelphotometer*.

V. Illumination and its Measurement

The previous sections of this article have been concerned with the measurement of the candle-power of a source of light. In the present section, however, no attention whatever is paid to the source. All that is dealt with is the actual illumination received at a surface, and this may be due to one or many sources of the same or of different kinds.

A very frequent error in terminology is the confusion of "illumination" with "brightness." The distinction has been mentioned in the definition of the latter term in the section on "Definitions," but it may be further elaborated here. Illumination is concerned only with the amount of radiation which reaches a given surface. A piece of white paper and a piece of black velvet lying side by side may well be equally illuminated, but their brightnesses will be very different. The brightness is concerned only with the luminous radiation which a surface emits in the direction of the eye, and therefore two surfaces of different reflection ratios, but equally illuminated, will have brightnesses which are proportional to their respective reflection ratios.

In illumination photometry, as in candle-power photometry, the actual comparison is always between the relative brightnesses of two surfaces, and this necessitates a brief consideration of the way in which the brightness of any given surface varies with the illumination and the angle at which it is viewed.

§ (51) Matt and Polished Surfaces.—Surfaces may be very crudely divided into two classes, polished and matt. In the case of a polished surface, such as a metal mirror, very nearly the whole of the reflected light is emitted in a single direction, viz. that making an angle with the normal equal to the angle which this normal makes with the incident light. A perfectly matt surface, however, returns light according to a cosine rule. This rule states that, for a perfectly diffusing surface, the radiation emitted in a direction making an angle θ with the normal to the surface is equal to $\phi \cos \theta$, where ϕ is the radiation emitted in the normal direction. Thus if A (*Fig.* 43) be an element of a perfectly diffusing surface, the polar curve of distribution of the light emitted from A is the circle ABC, for AC equals AB cos θ. From this rule it results that the total flux emitted by such a surface is

$$\int_0^{\frac{\pi}{2}} \Phi \cos \theta \, . \, 2\pi \sin \theta d\theta \text{ if } \Phi \text{ is the flux emitted}$$

per unit solid angle in the normal direction. This expression is equal to $\pi\Phi$, so that the average candle-power of A is $\frac{1}{2}\Phi$ or the mean hemispherical candle-power is $\frac{1}{2}\Phi$.

The brightness of a surface should generally be expressed in terms of candles per unit area, so that a square centimetre of a surface which is emitting Φ lumens per unit solid angle in the normal direction has a brightness of Φ candles per square centimetre in that direction. If the direction be not normal to the surface, the brightness must be expressed in candles per unit area of the surface projected perpendicular to the direction. For a square centimetre viewed in a direction making an angle of 60° with the normal produces an image on the retina which is only half the area of that produced by a square centimetre of surface viewed normally. Hence to obtain the illumination of the image on the retina, the criterion of brightness as far as visual effect is concerned, the radiation emitted per unit projected area must be considered.

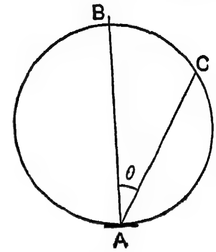

Fig. 43.

It will be seen at once that, since this projected area bears to the true area a ratio equal to the cosine of the angle of projection, it follows that a perfect diffuser appears equally bright at whatever angle it is viewed, for if the brightness be Φ candles per sq. cm. in the normal direction, the radiation emitted per unit solid angle by unit projected area (*i.e.* sec θ sq. cm.) will be Φ sec θ in the normal direction, or Φ in the direction of vision.

It is for this reason that matt surfaces, *i.e.* surfaces which approximate as closely as possible to perfect diffusers, are always employed in illumination photometry. For then the angle from which the comparison surface is viewed is less important than it would be if a glazed or semi-polished surface were employed.

§ (52) Relation between Illumination and Brightness.—It will be useful here to obtain the relation between the illumination of a perfectly diffusing surface, its reflection ratio, and the resulting brightness. If the illumination be E metre-candles, the flux received per unit area of the surface is E lumens. The total amount of flux emitted is therefore RE if R be the reflection ratio. Now if B be the brightness in candles per unit area, the flux emitted per unit solid angle in the normal direction is B lumens. Hence the total amount of flux reflected is πB lumens. Therefore $\pi B = RE$ or $B = RE/\pi$. As an example, a perfectly diffusing surface having a reflection ratio of 75 per cent and illuminated to the extent of 10 metre-candles, has a brightness of $7{\cdot}5/\pi = 2{\cdot}39$ candles per square metre.

§ (53) Photometer Screens.—It has been found that no surface behaves at all angles

as a perfect diffuser, and in some which are generally regarded as matt the departure from the cosine rule is very considerable. This departure depends not only on the direction from which the surface is viewed, but more especially on the direction of the incident light. There is always some specular reflection, and the brightness is always high where the direction of vision and the direction of the incident light make equal angles with the normal in the same plane. Trotter[1] has made a large number of measurements of this effect in the case of many surfaces. He finds that Bristol board, unglazed by passing a damp cloth over its surface, or white celluloid rendered matt by rubbing over its surface with pumice powder, gives very good results if the direction of specular reflection be avoided, a maximum error of 3 per cent being found for the last-named material.

In some photometers the comparison surfaces, or one of them, consist of sheets of matt opal glass, and for these the rule of cosine emission holds very well over quite a wide range of angles.

§ (54) Illumination Photometers.—A general account of the principle of working of illumination photometers was given at the beginning of the section on "Photometric Methods." The number of instruments which have been designed for the measurement of illumination is very large, and all that can be given here is a brief description of some of those which have been most frequently employed by workers in the field of illumination engineering.

§ (55) The Preece Photometer.—The first photometer to be designed for the purpose of making illumination measurements was that of Preece described in 1883.[2] This consisted of a box containing an electric glow-lamp and furnished at the top with a Bunsen grease-spot screen. The current through the lamp was varied until the grease spot disappeared, and the illumination of the screen was then known from previous calibration against the illumination produced by a standard source of light at various known distances. In a modification of this instrument, due to Trotter, the variation in the illumination of the under side of the grease-spot screen was effected by altering the position of the lamp instead of its candle-power.

§ (56) The Trotter Illumination Photometer.—The latest form of the Trotter Illumination Photometer is shown in vertical section in *Fig.* 44. L is a small 4-volt glow-lamp mounted in a screw socket which is carried on a bracket sliding on a vertical bar B. By this means the distance of L from a mirror M can be varied to suit the candle-power of the particular lamp used in the photometer at any time. The light is reflected by M to a matt white celluloid screen C which is capable of rotation about an axis perpendicular to the plane of the paper. This rotation is effected by means of the snail cam A which bears on a pin D. This cam is so shaped that

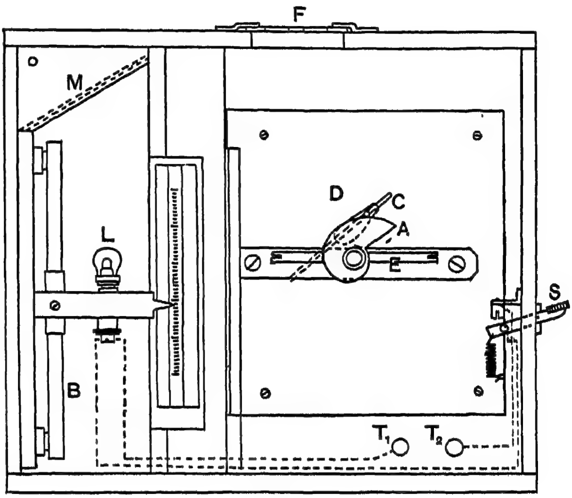

Fig. 44.

the angular motion of the celluloid surface is much slower than that of the cam at the positions where the light from M falls very obliquely on to C. For at these positions it follows from the cosine law that the illumination will vary very rapidly with the inclination of C, so that unless a cam such as that shown is provided, the scale becomes very compressed at the lower values of illumination. A light leaf spring E gives just enough friction to hold the screen in any position while yet allowing a very free movement of the cam. The pin D is held in close contact with the cam by means of a flat spiral spring fixed to C. S is a knife-switch by means of which the lamp L can be lighted from a 2-cell accumulator connected to the terminals T_1, T_2 of the photometer. At the top of the box is a second matt white celluloid surface F, and the photometer is placed so that this surface is in the spot at which it is desired to measure

[1] *Illumination: its Distribution and Measurement*, p. 93, and *Illum. Eng.*, London, 1919, xii. 243.
[2] *Roy. Soc. Proc.*, 1884, xxxvi. 270.

the illumination. A plan view of F is shown in *Fig.* 44A, and the measurement is made by viewing C through the slit in F and adjusting the brightness of the former by tilting it with the cam handle, until F and C appear equally bright. Illumination at F is then given by the position of a pointer connected with the handle by which C is turned. The scale is obtained by previous calibration with known illuminations provided by a standard lamp at different fixed distances. To ensure that F is always viewed at a constant angle, C is provided with two small black pointers. These must be just visible at the ends of the slot in F (as in *Fig.* 44A) when the measurement is being made. The direction actually used is 20° from the vertical. Even with this precaution of constant angle of vision, if the sheet F is not perfectly matt and the light is incident upon it at an angle of about 20°, there is danger that specular reflection may cause an appreciable error. It is best, therefore, to view the photometer in a plane perpendicular to that of the incident light, as shown in *Fig.* 44B, which also gives a view of the complete instrument.

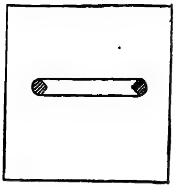

FIG. 44A.

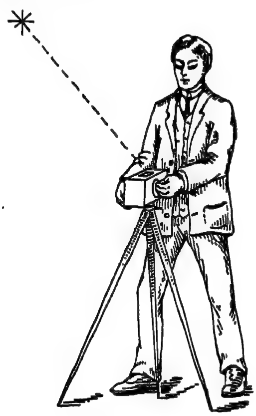

FIG. 44B.

§ (57) THE HARRISON PHOTOMETER.—In the Harrison photometer, the surface illuminated by the outside lights consists of a disc from which two diametrically opposite quadrants have been removed. This disc is set spinning pneumatically, and thus the instrument acts on the flicker principle and is adapted for use with lights of colours different from that of the comparison lamp contained in the photometer box (see section on "Colour Photometry").

§ (58) THE WEBER PHOTOMETER.—The Weber photometer was one of the first illumination photometers designed.[1] It is shown in vertical section in *Fig.* 45. L is a benzine lamp which acts as a source of standard candle-power, S is a translucent screen movable along the tube T_1, its position being marked by a pointer moving over a scale engraved on the outside of this tube. C is a Lummer-Brodhun cube, and P is a total reflection prism for use when the tube T_2, which is capable of rotation about the axis of T_1, is used in the vertical position (as

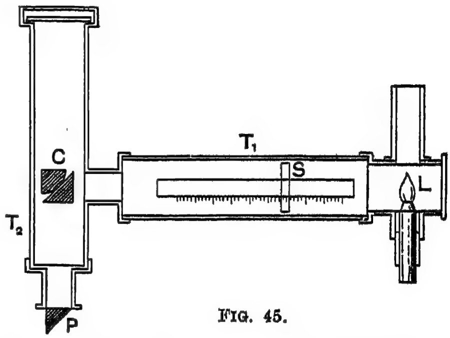

FIG. 45.

shown). The upper end of T_2 is closed by an opal glass disc, and this forms the surface the illumination of which is to be measured.

§ (59) THE SHARP-MILLAR PHOTOMETER.—A much more elaborate photometer on a somewhat similar principle is that of Sharp and Millar, described by the latter in a critical paper on illumination photometers.[2] The plan of this instrument is seen in *Fig.* 46. L is the lamp, a 4-volt glow-lamp, which is capable of movement along the box by means of an endless wire moved by the handle H. The position of the lamp is indicated by the

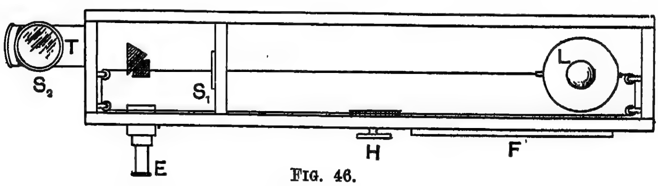

FIG. 46.

[1] *Wied. Ann.*, 1883, xx. 326.
[2] *Am. Illum. Eng. Soc. Trans.*, 1907, ii. 475.

shadow of a pointer on a translucent celluloid scale at F. This lamp illuminates an opal screen S_1, and the brightness of this is compared, by means of a Lummer-Brodhun cube viewed through the eyepiece E, with the brightness of a second opal glass screen S_2 reflected in a 45° mirror, contained in an elbow tube of which T is the plan. The illumination to be measured is that at S_2, and the range of the instrument is increased by the insertion of neutral glasses, with known transmission ratios, between C and either S_1 or S_2.

This photometer possesses the great advantage that the test plate S_2 is viewed from below, so that its illumination is completely unobstructed by the person of the observer or any part of the apparatus. This is of considerable importance, since, when the number of sources contributing to the illumination is large, it is often difficult for the observer to avoid shading one or more of them from the test plate when this is viewed, as is usually the case in illumination photometers, from above.

It is also claimed for this photometer that the brightness of the comparison disc S_1 varies exactly as the inverse square of the distance from it of the lamp L. This is probably the case unless this distance is made too short, when the inevitable effect of interior reflections will be such as to cause departure from the exact inverse square scale.

§ (60) THE MARTENS PHOTOMETER. — The Martens photometer is shown in side elevation in *Fig.* 47 and in section along the line AB in *Fig.* 47A. L is a benzine lamp which is used as a comparison source, and which illuminates a ground glass plate G by

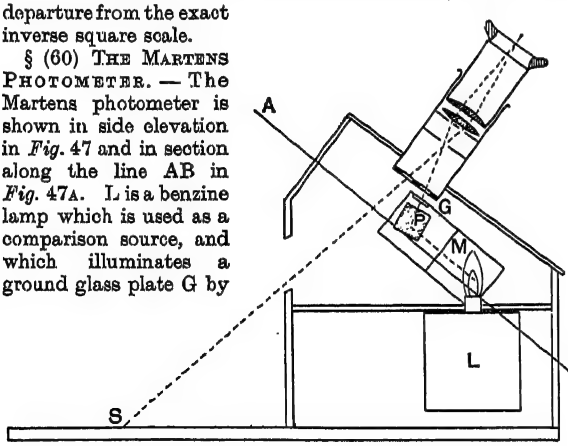

FIG. 47.

reflection in the mirrors M and a total reflection prism P. S is a white screen, the illumination at which is desired, and comparison is made in the eyepiece between the brightnesses of S and G.

A slight modification of the Martens polarisation photometer described in § (30) enables this instrument to be used as an illumination photometer. The plaster screen F is replaced

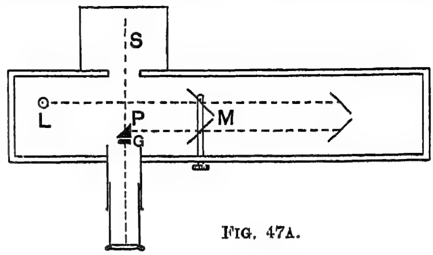

FIG. 47A.

by an opal glass screen, and the tube T is turned so that this screen occupies the position where it is desired to measure the illumination.

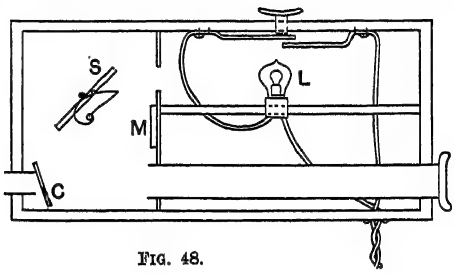

FIG. 48.

§ (61) THE LUXOMETER.—Two very portable instruments employing a test screen which may be quite separate from the photometer are the Luxometer, which is a modification of the Trotter photometer, and the Lumeter due to Dow and Mackinney.[1] The first of these is shown in section in *Fig.* 48. L is a small 2-volt glow-lamp which illuminates the tilting screen S. This screen is reflected in the mirror M and is seen in the plate C which is silvered over one-half of its surface. The test plate T is seen by direct vision through the unsilvered half of C, and the two halves of the field are brought to equality of brightness by tilting S.

§ (62) THE LUMETER.—The lumeter is seen in plan in *Fig.* 49. The 2-volt glow-lamp L illuminates an opal glass plate G. Behind this plate a cylindrical shutter C with a carefully graduated opening is moved by a handle carrying a pointer which travels over a scale on the outside of the instrument,

[1] *Opt. Soc. Trans.*, 1910–11, xii. 66. [This paper describes the original form of the instrument which has now been revived. The description here given refers to a modified form introduced about 1912.]

The light from the part of G exposed by C illuminates the screen S, which consists of an exterior ring of white opaque material, and an inner clear circle. This screen is viewed through the eyepiece, the exterior test plate P being seen through the clear central portion of S, while the brightness of the opaque portion is varied to equality with S by altering the position of C. The shape of the opening in C is seen in the lower part of the figure. The breadth of the larger portion is ten times that of the smaller, so that at the transition point the scale is enlarged ten times. Theoretically the scales should be linear, but in practice errors up to 5 per cent and more are found with a linearly divided scale. Just at the point where the larger opening begins to come into operation, the error is, naturally, very large.

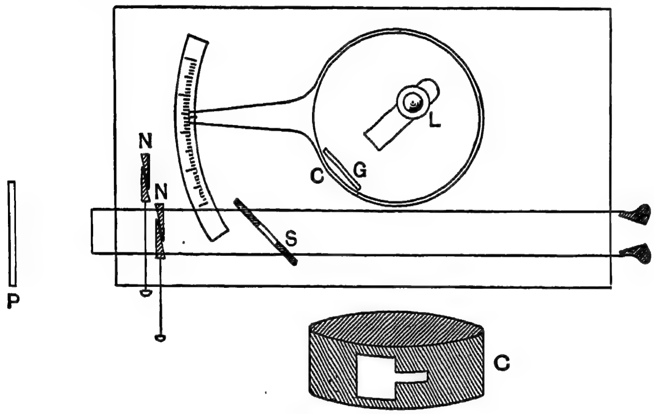

FIG. 49.

Both these instruments are adapted for measuring low illuminations by the provision of neutral glasses N, N, of known transmission ratios, which can be inserted at will between the test surface and the eyepiece. In the lumeter these consist of double wedges, so that adjustment to convenient ratios, such as 0·1 and 0·01, is possible.

§ (63) THE SHARP FOOT-CANDLE METER.—For rapid approximate measurement of illumination a portable photometer has been devised by Sharp and modified by Sackwitz.[1]

It consists of a box containing a trough, over which lies a white screen with a line of translucent circles in it, this screen being illuminated from beneath by a lamp placed at the end of the trough. The brightness of the circles diminishes gradually from one end of the screen to the other, and when the box is placed in any position, one of the circles is found to disappear, those on the right still showing bright, while those on the left now appear dark. Previous calibration gives the value of illumination at which each circle vanishes in this way, and thus the instrument can be used for obtaining quickly an approximate value of the illumination at any point.

The lamp is supplied from a dry cell contained in the box, and a small voltmeter and regulating resistance are supplied to enable the fall of voltage of the cell to be compensated.

A somewhat similar instrument was described[2] by H. T. Harrison in 1910.

§ (64) THE MEASUREMENT OF BRIGHTNESS.—In both the luxometer and the lumeter, the test surface is quite separate from the photometer, and in fact these instruments may be used for measuring brightness as well as illumination. For, if the reflection ratio of the white card be R, then an illumination of n metre-candles gives it a brightness of nR/π candles per square metre. Thus if the balance be obtained by means of the instrument when the test card is replaced by some other surface, the reading of the instrument multiplied by the factor R/π will give the brightness of the surface in candles per square metre. Similarly, if the instrument be calibrated (as is usually the case) in foot-candles, multiplication by R/π gives the brightness in candles per square foot.

It has frequently been the custom to express brightness in equivalent foot-candles, *i.e.* in terms of the brightness of a perfectly diffusing surface of 100 per cent reflection ratio, illuminated to the extent of one foot-candle. This figure is obtained at once from the readings of an illumination photometer multiplied by the simple factor R. Unfortunately this system has given rise to much confusion between illumination and brightness, and it is desirable that the latter should always be expressed in candles per unit area.

§ (65) VOLTAGE REGULATION.—It will have been noticed that a number of illumination photometers depend, for their standard of comparison, on a small 2- or 4-volt electric glow-lamp fed from a portable battery. Now, as has been already stated, the candle-power of an electric lamp varies as the fourth or fifth power of the voltage, so that constancy

[1] Sharp, *Elect. World*, 1916, lxviii. 569; Sackwitz, *Am. Illum. Eng. Soc. Trans.*, 1918, xiii. 292.

[2] *Illuminating Engineer*, London, 1910, iii. 373.

of battery voltage is of first importance. Most such photometers are provided with a switch so that the lamp can be switched on only when the readings are being taken. The discharge of the battery is thereby much reduced, and, as the current of the lamp does not generally exceed half an ampere, a storage cell of 10 to 20 ampere-hour capacity will maintain a constant supply voltage over a considerable period of use. The voltage of the battery on discharge must be frequently checked, and recharging should be commenced as soon as the voltage has dropped 5 per cent of its value. During this time the readings of the photometer must be reduced by 3·7 or 5 per cent for every 1 per cent drop in voltage, according as the lamp filament is of tungsten or carbon. The cell when first taken off charge should be discharged at about half an ampere for at least an hour before being used on the photometer. This avoids the initial over-voltage.

§ (66) Precautions in using a Portable Photometer.—The most frequent source of trouble in portable photometers employing an electric lamp, is faulty contact at some part of the circuit. At the very low voltage used, the slightest fault in a contact causes a noticeable decrease or fluctuation in the light. The leads to the battery should be tightly screwed down on to perfectly clean terminals, and it is inadvisable to undo them during the taking of a set of readings. All contacts inside the photometer should be soldered, and the lamp socket must be of the screw type with the lamp well screwed down into the socket. If a switch is provided for the lamp, it is necessary to ensure that it makes good and constant contact when in the "on" position.

All portable photometers require frequent checking at two or three points of their scale, against known illuminations provided by a standard lamp at definite distances from the test plate. When all the precautions detailed above have been observed, the best of these instruments may be relied upon to an accuracy of about 2 to 3 per cent over the most favourable part of its scale.

The measurement of illumination, both by daylight and artificial light, is becoming increasingly frequent and important. In several countries codes of illumination required for particular kinds of workshop and factory processes are enforced by legislation. Extensive rules have also been framed for the lighting of schoolrooms, and the illumination of shop windows, public halls, churches, theatres, and other buildings has lately received considerable attention.[1]

§ (67) The Measurement of Illumination.—The method of making illumination measurements is to place the test plate at the position where the illumination is required, and to determine this by means of a photometer similar to one of those above described, taking care that the body of the observer shields as little light as possible from the test plate. Unless otherwise stated or clearly implied, it is usual to assume that the test plate is placed horizontally, and very frequently the floor level or the 1-metre level is adopted for all the measurements. More frequently, however, the plate is placed horizontally on the desk, loom, bench, lathe, etc., where it is desired to know the illumination. Sometimes, as in planning a picture gallery, the illumination of a vertical surface is of primary importance. In such cases, of course, the vertical position is adopted for the test plate.

§ (68) The Calculation of Illumination.—If it be desired to predict by calculation the distribution of illumination which will result from any given arrangement of light sources, this may be done from the polar curves of the sources to be used. For (*Fig.* 50) the illumination of a horizontal plane at A, due to a source at L of which the candle-power in the direction LA is J, will be $J\cos\theta/LA^2$ or $J\cos^3\theta/h^2$, where h is the vertical height of L above the horizontal plane through A. Thus the total illumination at A will be $\Sigma J\cos^3\theta/h^2$, the summation being made for all the sources which send light directly towards A.

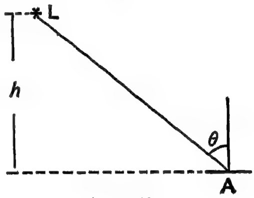

Fig. 50.

In illumination calculations it is usual to assume some simple form of polar distribution which approximates to that of the actual light source to be used. The great variety of the polar curves of present-day sources make it useless to do more than give a single example of such calculations. For other examples the reader is referred to some book on illumination engineering, such as Gaster and Dow, *Modern Illuminants and Illuminating Engineering*; Trotter, *Illumination: its Distribution and Measurement*; Bohle, *Electrical Photometry and Illumination*; Uppenborn, *Lehrbuch der Photometrie*; Steinmetz, *Radiation, Light and Illumination*; etc.

§ (69) The Illumination Curve.—If we have a number of equal light sources of known polar distribution placed in line at a given height, the curve showing the variation of illumination along the line vertically beneath the sources can be very readily obtained. From the expression given

[1] Vide *Illuminating Engineer*, London; *Transactions of the Illuminating Engineering Society of New York*; *Lighting Journal*, and other publications.

above, it is easy to obtain, from the polar curve of the source, the diagram connecting the illumination at a point P, due to a single source, with the horizontal distance of P from the source. This has been done in *Fig.* 51, where the heavy line is the curve of

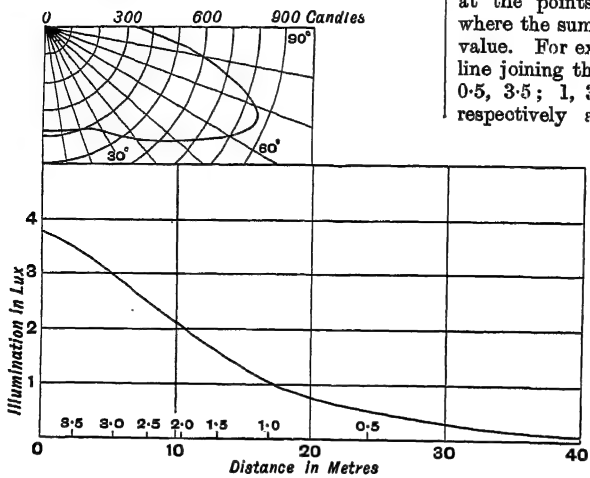

FIG. 51.

illumination along a line 10 metres below a source having the polar diagram shown. If now the sources be spaced 20 metres apart as shown in *Fig.* 52, a curve like that in *Fig.* 51 is placed in its proper position under each source and the ordinates are added to produce the full line curve which shows the distribution of illumination due to all the sources together. It will be obvious that the method may be applied to other arrangements of sources or to a variety of different sources, though the calculations will not be quite so simple as in the case of the example given above.

The curve of *Fig.* 52 is termed an illumination curve. It shows only the distribution of illumination along a single line. If it be desired to show the distribution over an area, this is most conveniently done by means of an iso-lux diagram, or contour map of equal illumination. Trotter[1] has described the method of constructing such a map. The simplest case is that of two sources. Strips of paper are marked off with a scale representing the illuminations due to a single source at various horizontal distances from that source. Such a scale corresponding to the curve of *Fig.* 51 is shown at the base of that figure. Two such scales are pinned to a sheet at points representing the positions of the two sources (see *Fig.* 53) and marks are made at the points of intersection of the scales where the sum of the graduations has a given value. For example, the 4-lux contour is the line joining the points where the scale marks 0·5, 3·5; 1, 3; 1·5, 2·5 on the two scales respectively are coincident. The complete contour map is shown in *Fig.* 53. The larger the number of sources, the more complicated become the necessary calculations. A large number of such maps are given by Trotter (*loc. cit.*), Blondel, Uppenborn,[2] Steinmetz,[3] and Maréchal.[4]

It will be seen that, although either an illumination curve or an iso-lux diagram may be used to obtain a mental conception of the effect of a given system of light sources of known distribution, yet it is still necessary to have some definite figure by which the illumination performances of two lighting systems may be compared. This is analogous to the comparison of the light-giving power of two sources by means of their average candle-powers instead of by the more detailed but comparatively cumbrous polar diagrams.

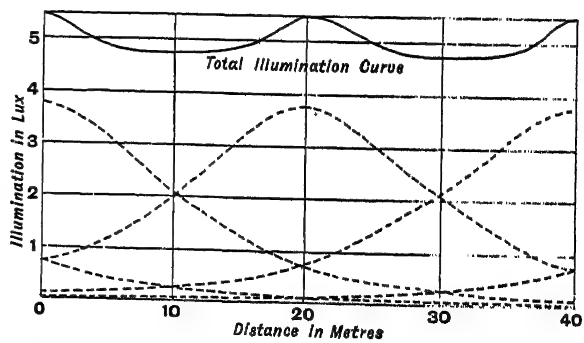

FIG. 52.

§ (70) THE AVERAGE ILLUMINATION. — Various suggestions have been made for a basis of comparison of different illumination systems. On the whole the average illumination, or, what is equivalent to it, the average

[1] *Illumination: its Distribution and Measurement*, p. 46.

[2] Uppenborn and Monasch, *loc. cit.*

[3] Steinmetz, *loc. cit.*

[4] *L'Éclairage à Paris.*

flux per unit area (generally expressed in lumens per square metre or per square foot), has been most generally adopted for indoor

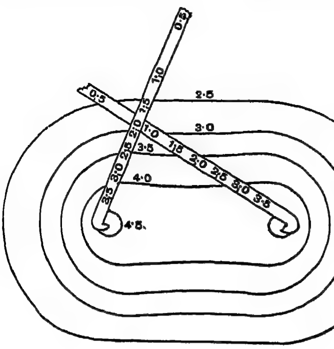

FIG. 53.

illumination. This means that, for a direct lighting system where the reflection from walls and ceiling can be neglected to the approximation desired, the average illumination in metre-candles will be equal to the total mean lower hemispherical candle-powers of all the sources in the room, multiplied by 2π and divided by the area of the room in square metres.

(i.) *The Variation Factor.*—This system gives no indication as to the distribution of illumination over the room. If there be only a few sources of high candle-power the illumination will be concentrated in the regions underneath a source, leaving the outer parts of the room in comparative darkness. For this reason a second figure, giving the ratio of maximum to minimum illumination in the useful area of the room, has been proposed as an addition to the average illumination. This figure may be termed the "variation factor."

(ii.) *Trotter's "Characteristic Curve."*—Another method of describing an illumination system has been called by Trotter[1] a characteristic curve. This is a curve having for its abscissae areas, and for ordinates the values of the minimum illumination over those areas. Thus, referring once more to the illumination diagram shown in *Fig.* 51, it will be seen that the illumination at all points within a circular area of radius 10 metres equals or exceeds 2·1 metre-candles. The area of this circle is 314 square metres, and therefore the point (314, 2·1) is a point on the characteristic curve which is shown in *Fig.* 54. Since the abscissae of this curve represent areas, the mean ordinate of this diagram, as far as any given ordinate, is equal to the illumination over the circle having an area represented by that ordinate. Thus the average illumination over a circle 1000 sq. metres in area is equal to the mean ordinate of the area OABC on the diagram, *i.e.* to 1·86 metre-candles.

(iii.) *Bloch's Method of calculating Average Illumination.*—Two methods which have been proposed for the approximate calculation of the average outdoor illumination due to lamps having a given distribution will be shortly described. In the first, due to Bloch,[2] the area is divided into a number of rectangles so that there is a lamp in the centre of each rectangle. The radius of the circle which has an area equal to that of the rectangle is then found, and the average illumination over this circle is obtained from the polar diagram of the source. This is equal to the total radiation emitted by the source within the cone having

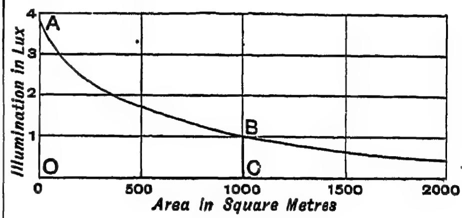

FIG. 54.

the lamp as apex and the circle as base, divided by the area of the circle.

In this method the effect of neighbouring lamps is neglected, making the calculated value too low; but, on the other hand, the conversion of the rectangle into a circle makes the value too high, so that these errors tend to neutralise each other. Bloch proposes that for street lighting the value so obtained shall be multiplied by the factor $(1{\cdot}2 - 0{\cdot}1\gamma)$, where γ is the ratio of the distance between the lamps to the width of the street.

(iv.) *Högner's Method of calculating Average Illumination.*—Högner's method is more accurate, but rather more laborious. The rectangular area surrounding a source is divided into four smaller rectangles with their common corner at the point vertically below the lamp. Each of these four rectangles is then further subdivided into still smaller areas by the construction shown in *Fig.* 55. Points X_1, X_2 . . . Y_1, Y_2 . . . are marked off on AB and AC, so that the lines X_1L, X_2L . . . and Y_1L, Y_2L . . . make angles of 10°, 20° . . . with the vertical. Mutually perpendicular ordinates drawn through X_1, X_2 . . . and Y_1, Y_2 . . . divide the area into a number of small rectangles such as PQRS. Now each of these rectangles is regarded as forming the base of a pyramid having L as apex, and the solid angle ω, and the inclination to the vertical θ, of the line joining its centre

[1] *Loc. cit.* p. 58.

[2] *Elektrot. Zeits.*, 1906, xxvii. 493.

to L has been found and tabulated for each such rectangle. It only remains, therefore, to find the candle-power of the lamp at any angle θ, and to multiply this by the value of ω (in steradians), to find the total flux reaching the base of the pyramid. The total flux over the whole area being thus found by addition, the average illumination can be calculated.

It will be clear that the illumination due to a given system of sources cannot be altered in distribution if the candle-power of all the sources be altered in the same ratio. It therefore follows that to determine the candle-power required for a given illumination E_1, using sources of known distribution arranged in a certain way, it is only necessary to calculate the illumination due to such a system of sources of candle-power J. Suppose this illumination is found to be E_2. Then the candle-power required is JE_2/E_1. This refers equally to illumination at a point and to average illumination over an area.

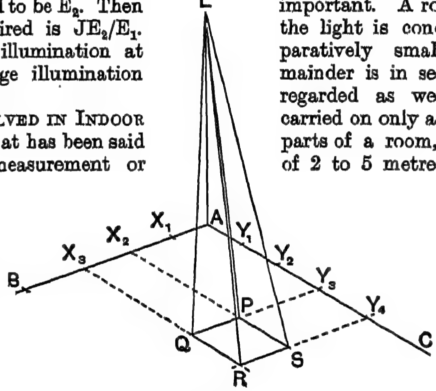

FIG. 55.

§ (71) FACTORS INVOLVED IN INDOOR LIGHTING DESIGN.—What has been said above refers to the measurement or calculation of the actual illumination at a point, or the average illumination over an area, due to a given system of light sources. But it will be obvious that in designing any system of lighting the degree of illumination produced is only one out of several factors, all of which have to receive consideration. Every particular case will present its own special problems, and only the most general rules can be given here as an indication of the principal factors which enter into the design of all lighting systems.

The problems of indoor illumination must be treated quite separately from those of street lighting and outside illumination generally. The requirements of an indoor system may be briefly summarised as (1) adequate intensity, (2) proper distribution, (3) absence of glare, (4) avoidance of excessive contrasts—and these will be dealt with in turn. For a discussion of the particular problems presented by the many classes of indoor illumination, and of the manner in which these may be dealt with, the reader is referred to chapter ix. of *Modern Illuminants and Illuminating Engineering*, by Gaster and Dow.

§ (72) ILLUMINATION REQUIRED FOR VARIOUS PROCESSES. (i.) *The Amount.*—The necessary illumination for various types of room, workshop, etc., depends almost entirely on the nature of the work. For reading, writing, and similar work an illumination of 30 to 60 metre-candles has been proposed. For such places as foundries, where the illumination has to be general and no fine work is done, 10 to 20 metre-candles is generally regarded as sufficient, while for a drawing-office 80 metre-candles is needed, and in the special case of a shop window, where display is required and the goods to be shown are of a dark colour, as much as 200 metre-candles may be used with advantage. Tables of the intensities suggested for various purposes have been frequently put forward.[1] It has been found that for similar work with materials of different reflection ratios the illumination required is inversely proportional to the reflection ratio.[2]

(ii.) *Distribution of Illumination.* — The proper distribution of the light is most important. A room in which nearly all the light is concentrated in one comparatively small area, while the remainder is in semi-darkness, cannot be regarded as well lighted. If work is carried on only at one or more particular parts of a room, a general illumination of 2 to 5 metre-candles should be provided, with the addition of local lights to give the necessary illumination at the points where it is specially needed. For reading, the light should preferably come from behind, while for writing it should come from the left front.

(iii.) *Avoidance of Glare.* — The avoidance of glare is of the utmost importance if eye-strain is to be avoided and the light provided is to be properly appreciated by the eye. Even sources of low intrinsic brilliancy should be shielded from direct vision, and it has been generally agreed that an intrinsic brilliancy of 3 to 5 candles per square inch should not be exceeded in any source, shade, or reflector which the eye is liable to see by direct vision. It is a matter of common experience that exposure to a very brightly illuminated surface renders the eye less capable of properly appreciating the forms of objects having a lower intrinsic brilliancy, so that if glare be not avoided a much higher general illumination is required.

Excessive contrasts, generally in the form of deep shadows, are annoying to the eye in domestic lighting, and may be sources of the utmost danger in street or factory lighting.

[1] Gaster and Dow, *loc. cit.* p. 329.
[2] *Report of Departmental Committee on Lighting in Factories and Workshops*, i. 37.

On the other hand, an almost complete absence of shadow is most unsuitable for work requiring perception of fine detail, such as sewing, watchmaking, etc.[1] The attainment of the above requirements in any particular case is a matter requiring much experience of illumination engineering.

(iv.) *Direct and Indirect Lighting.*—For the sake of convenience, systems of indoor lighting have been classified as direct, indirect, and semi-indirect. In the first-named system, the light from the source reaches the area to be illuminated by a direct path and does not suffer any change of direction once it has left the lighting unit. In an indirect system, on the other hand, the light is all cast upwards to the ceiling, or to a reflector placed above the source, so that the light reaching the lower part of the room has suffered at least one reflection on its way. In the semi-indirect system of lighting, part of the light from the source illuminates the room directly, the remainder by reflection. In addition to the ceiling, the upper part of the walls has a considerable share in the distribution of the light from an indirect or semi-indirect system. Both of these systems, owing to the great area from which the light is received by the lower part of the room, avoid all possibility of glare, and cause a very great softening of shadows. With a totally indirect system, the lack of shadow may be so pronounced as to cause inconvenience if the room is used for certain kinds of work.

Combination of indirect general lighting with direct local lighting is frequent and possesses many of the advantages of both systems. With indirect or semi-indirect systems and, to a less extent, with direct systems of lighting the reflection ratio of walls and ceilings has a marked effect on the intensity of the sources required to produce a given illumination. Walls with a very high reflection ratio may increase the illumination by 40 to 50 per cent over that obtainable with very dark walls.[2] In general it may be assumed that with a white ceiling the sources used in an indirect system of lighting require to have double the intensity of those used for a direct system. Useful tables of the consumption of power by various illuminants, when producing an illumination of one foot-candle on the working plane, have been given by Gaster and Dow [3] and by Uppenborn.[4]

§ (73) Outdoor Illumination.—The requirements in the case of outdoor illumination are somewhat different. In street lighting the need is for as even an illumination as possible with the comparatively wide spacing necessary. This is partly accomplished, either by specially designed reflectors which concentrate the light in a direction only slightly below the horizontal, or by placing the lighting units at a considerable distance above the roadway. A *minimum* illumination of 1 metre-candle is regarded as necessary for important thoroughfares.[5]

Other problems which come under the head of outdoor lighting are the illumination of railway platforms and goods-yards, parks, bridges, and open spaces. The illumination of signboards and building exteriors for spectacular purposes are also cases requiring special treatment. For these a work on illumination engineering should be consulted.

§ (74) Daylight.—What has been said so far has been with reference to illumination by artificial light. But it will be obvious that the methods of illumination measurement, and the photometers which have been described, may be employed equally well for the measurement of daylight illumination. The chief difficulty met with, that of the great colour difference between daylight and the light from the comparison source used in a photometer, may be overcome to a certain extent by the use of a blue glass or gelatine filter between the comparison lamp and the surface it illuminates (see § (101) in "Colour Photometry"). This has the disadvantage of reducing the illumination of the comparison surface, whereas the illumination to be measured is generally high in the case of daylight. This has led to the use of a yellow filter placed between the test surface and the eyepiece, but this has the disadvantage that the transmission ratio of the filter may vary with the colour of the daylight to be measured.

(i.) *Daylight Factor.*—A further complication in the case of measurements of interior illumination by daylight arises from the fact that the daylight is constantly varying in intensity. A simple measurement of the illumination at a point inside a room on a particular occasion, therefore, does not give the information required, for clearly this will depend on the illumination prevailing outside the building, and hence a knowledge of simultaneous values of indoor and outdoor illuminations is essential if any information of permanent value is to be obtained. On a dull day with a grey sky, the illumination at a point inside a building bears a very nearly constant ratio to the illumination at a point outside. This ratio, expressed as a percentage, has been termed the daylight factor at the point and is taken as giving some indication of the illumination at the point when the outside illumination is known.

(ii.) *Variations of Daylight.*—It is seldom

[1] *Departmental Committee on Lighting in Factories and Workshops, loc. cit.*
[2] Gaster and Dow, *loc. cit.* p. 326.
[3] *Loc. cit.* p. 323.
[4] *Lehrbuch der Photometrie*, p. 179.
[5] Gaster and Dow, *loc. cit.* p. 419.

realised how rapid and how great are the variations which take place in daylight illumination. Some experiments on these have been described by C. C. Paterson and the author.[1]

The conditions exerting the greatest influence on daylight illumination are three, viz. (i.) time of day, (ii.) time of year, (iii.) meteorological conditions.

(iii.) *Variation with Time of Day.*—As to the first, experiment has shown that the gradual rise of illumination at sunrise closely corresponds with the fall at sunset, and that the change of illumination takes place at a more uniform rate when there is a dull grey sky than when the sky is blue and cloudless. The sunset and sunrise illuminations do not vary with the time of year, but only with the meteorological conditions, and may be assumed to lie, generally, between 100 and 500 metre-candles; 250 metre-candles may be taken as a fair average value.

(iv.) *Variation with Time of Year.*—As to the variation with time of year, the average results of a very large number of observations extending over nine months gave the curves shown in *Fig.* 56 for the variation of

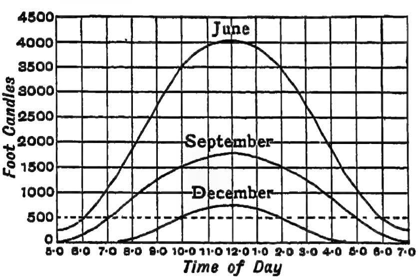

FIG. 56.

daylight from 5 A.M. to 7 P.M. on average days at different times of the year. On this diagram the horizontal scale represents the time of day, and the vertical scale foot-candles of illumination under an open sky. There are three curves, representing average days in June, September, and December respectively. A horizontal line has been drawn through the curves at the 500 foot-candle level for the purpose of illustration, and it will be seen that the line cuts the December curve at 10 A.M. and 2 P.M. It follows that any room in a building for which the daylight factor is below 0·2 per cent will have less than 1 foot-candle of daylight illumination before 10 A.M. and after 2 P.M. on an average day in December, while in June the corresponding times are 6 A.M. and 6 P.M. respectively.

It may be said, further, that there is, on the average, an outside illumination of about 100 foot-candles 30 minutes after sunrise and before sunset, so that a position in any building with 1 per cent daylight factor has, on the average, an illumination of 1 foot-candle 30 minutes after sunrise and before sunset.

Although the sunrise and sunset illuminations do not vary appreciably from summer to winter, the mid-day illumination falls from an average of about 4000 foot-candles in June to 700 foot-candles in December, the intermediate distribution being of the nature of that shown in *Fig.* 57.

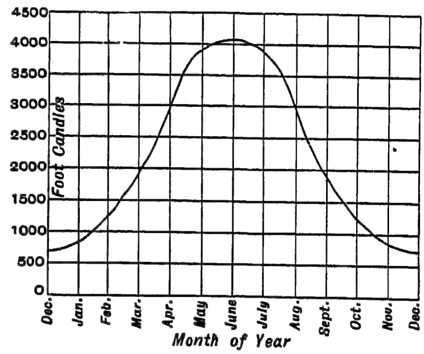

FIG. 57.

(v.) *Variation with Meteorological Conditions.*—The variations in the daylight illumination arising from even small changes in atmospheric or cloud conditions are often surprisingly great and take place with extreme rapidity. The diagrams in *Fig.* 58 show the magnitude of

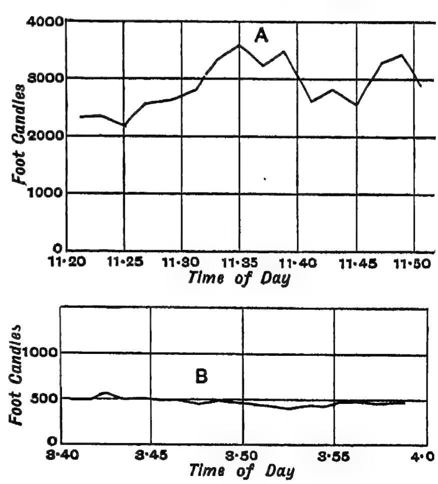

FIG. 58.

such variations on representative days. The first gives an approximate record of the day-

[1] *First Report of the Departmental Committee on Lighting in Factories and Workshops*, 1915, i. 63.

light illumination observed on a bright day in March (17th), when there was a large number of grey and white clouds over the sky. The second shows the comparative steadiness found on a day with a very uniform and dull grey sky at the same time of year (March 30th).

It will be seen from the first example that the illumination may vary by upwards of 80 per cent within a few minutes. Also two days of a different type, though in the same month, may give widely different average illumination values at the same time of day. Thus the midday illumination on one day when it was very dull and drizzling was 150 foot-candles, while three days later, at the same time of day, it was 1200 foot-candles. Of the various factors affecting the illumination, the number and brightness of the clouds are, perhaps, the most important. A bright cloud upon which the sun is shining has a brightness far exceeding that of the surrounding blue sky, and as such a cloud changes its position in the heavens its brightness, as well as its capacity to produce illumination at any particular position, will both change considerably. With a large number of such clouds in the sky it is not surprising that the illumination should fluctuate rapidly. The clearness of the atmosphere, too, has naturally a considerable influence on the illumination, but this effect is not capable of such rapid variations as that due to clouds. The probable limits between which the daylight illumination at any time may be expected to lie are indicated in the table. The values there given are based on 9½ months' observations taken at the National Physical Laboratory from March to December 1914. Observations over a more extended period might lead to some modification of the averages given. The values of illumination considered throughout are those measured on a horizontal plane placed in an open field with a practically unobstructed horizon. The direct sunlight was always shielded from the test cards.

TABLE

Month.	Midday Illumination (Foot-candles).		
	Highest.	Lowest.	Mean.
1914.			
April	5340	710	3200
May	5430	1050	3200
June	5160	2420	4100
July, August	Sufficient observations not available.		
September	3030	870	1180
October	2610	152	1300
November	2500	130	1100
December	1160	360	720

§ (75) MEASUREMENT OF DAYLIGHT FACTOR.—In view of what has been said above as to the variability of daylight, it would appear that the only satisfactory method of specifying the daylight illumination of a room is by its daylight factor, either the minimum, or an average for the whole room, being taken. This involves simultaneous measurements of illumination inside and outside the building.

A convenient method of arranging this is to have one observer taking readings at regular one-minute intervals on a test plate so situated that it receives unobstructed light from the whole sky. At the same time, another observer inside the building takes readings at convenient intervals (consisting of an integral number of minutes), and the daylight factors are subsequently calculated from the two sets of data. This was the method adopted by the author in making 4000 measurements of daylight factors for the Home Office Committee on Lighting in Factories and Workshops. (*Report*, vol. iii.)

§ (76) TROTTER PHOTOMETER DAYLIGHT ATTACHMENT.—There is one difficulty in applying the method to buildings in crowded areas, viz. that of finding a sufficiently open space for the outside measurements. This may be partially overcome by the adoption of a device described by Trotter and Waldram. It may be readily shown that if E be the illumination of a test plate which is receiving unobstructed light from a complete hemisphere of sky of brightness B, then $E = \pi B$. If now a vertical tube be placed over the test plate, and if an opening at the upper end of this tube be of such a size that the solid angle it subtends at the centre of the test plate is $2\pi/1000$, then the illumination of the test plate will be only $2E/1000$, so that by providing the top of the tube with discs of various known apertures, the brightness of the test plate can be reduced to a corresponding fraction of the illumination it would have received from the whole sky. The method of applying this to the Trotter photometer is shown in *Fig.* 59. Thus only a very small proportion of unobstructed sky is needed, but of course the assumption is made that the sky is uniformly bright all over, and this is usually very far from being the case except with a dull grey sky.

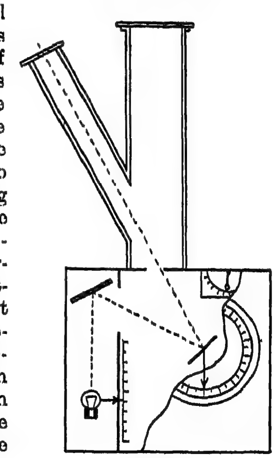

FIG. 59.

It is usual, in making daylight illumination

measurements, to shield direct sunlight from the test card, though the fact that this has been done is generally stated. The average daylight factor for side-lighted rooms of usual construction varies from 0·25 to 1 per cent. A room where the average daylight factor is 4 per cent or over may be considered to possess exceptionally good natural lighting.

VI. Life Testing of Incandescent Lamps

§ (77) Connection between Life and Efficiency.—There are, in the main, two characteristics of an electric glow-lamp which determine the quality of its performance from the economic point of view. The first of these is its efficiency—*i.e.* the candle-power which it gives per watt of electrical energy consumed—while the second is its life, *i.e.* the number of hours for which it may be expected to give this candle-power within certain specified limits. These two characteristics are so intimately connected that if the efficiency be increased by raising the voltage applied to the lamp terminals the life is inevitably reduced. This fact will at once explain both the great importance of the life testing of electric lamps and the necessity for ensuring that such a life test is carried out under the efficiency conditions at which the lamps are to operate in practice.

§ (78) Fall of Candle-power, and "Smashing-point."—In general, it is found that the candle-power of an electric glow-lamp of either the carbon or tungsten filament type falls gradually as the lamp is run (after a short initial period of somewhat uncertain behaviour, generally including a preliminary rise), and this fall of candle-power continues until the filament is fractured either by accidental mechanical shock or by some apparently spontaneous action while in use. It may frequently happen that the fall in efficiency of the lamp, after a certain period of time, reaches the point at which the additional power necessary to give the requisite amount of light is more expensive than the replacement of the lamp by a new one. The point at which this occurs is often termed the "smashing-point" of the lamp, and it is for this reason that it is necessary carefully to define the term "useful life" as applied to an electric lamp. Very frequently this is defined as the time which elapses before the candle-power falls to 80 per cent of its initial value (the voltage being maintained constant throughout the run), or to previous failure, provided this does not take place by accidental means (*i.e.* when the lamp is not burning).

§ (79) Life-test Conditions.—A life test may be made under several different sets of conditions, and these conditions must be carefully specified in order that the desired information may be afforded by the test. The simplest form of test is that in which the lamps are run throughout at constant (generally rated) voltage, all the photometric measurements being made at this voltage. Such a test does not, however, give the most reliable information as to the life performance of a set of lamps. Since life testing must necessarily be by sample, it is essential that the conditions under which the sample lamp is run shall be such as to give the nearest approximation to the average life of the lamps which it represents. This is best attained by a test at definite efficiency, *i.e.* the average working efficiency of the batch of lamps represented by the life-test lamps. This of course involves the adjustment of the voltages on each of these lamps to the values at which they give this definite efficiency. In general, therefore, each life-test lamp must run at a voltage peculiar to itself, and provision must be made for this arrangement in designing any equipment for the life testing of electric lamps. A less satisfactory alternative, when this correct procedure is not possible, is to select as life-test lamps those whose efficiency at rated voltage happens to be nearest to the mean or rated value. These lamps are then tested for life at rated voltage.

§ (80) Forced Life Test.—The life of most modern electric lamps at normal working efficiency is from 500 to 2000 hours, and many attempts have been made to avoid the long delay occasioned by tests such as those described above, and to substitute tests at a higher efficiency. By this means a shorter life is obtained, and then some form of correction factor is applied in order to calculate the life at normal efficiency. Such a test is termed a "forced" life test. The chief difficulty of this method lies in the fact that correction factors differ widely for lamps of different construction, and reliable factors can only be obtained as the result of life tests of large numbers of similar lamps under normal and "forced" conditions. Even with this information the correction factor can only be applied over a comparatively small range of efficiency, but nevertheless a considerable amount of time is saved by adopting this procedure where accuracy is of less importance than speed. The subject of the correction factors applied in forced life tests will be referred to again in the concluding paragraphs of this section.

§ (81) Life-test Installation.—From what has been said above, it will be clear that in any life-test installation two requirements of first importance are (1) a current supply of which the voltage is carefully regulated, and (2) arrangements for applying any desired voltage to each particular lamp on test. The apparatus used for this purpose at the large testing laboratories are generally similar

differing only in details of arrangement. The description here given is of the installation at the National Physical Laboratory,[1] but that of the Bureau of Standards [2] is not greatly different in general principle.

§ (82) VOLTAGE REGULATION.—An alternating current supply of 55 cycles and 240 volts from a dynamo, coupled with a Tirrill regulator, feeds an autotransformer from which leads are taken to a number of racks supported in an iron framework. A diagram of the wiring of one of these racks is shown in *Fig.* 60. The pick-off points of the transformer

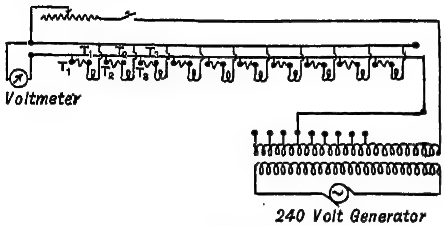

FIG. 60.

permit of any desired voltage in steps of 5 volts being applied to the leads of any rack. This voltage is further adjustable by means of a series resistance so that if lamps are being run at specified voltage they can be put in the sockets on the rack, and the terminals T_1T_1, T_2T_2, etc., can be connected by short pieces of copper wire. More frequently, however, the voltage at the terminals of each lamp on the rack is different, and then small resistances of the form shown at R in *Fig.* 61

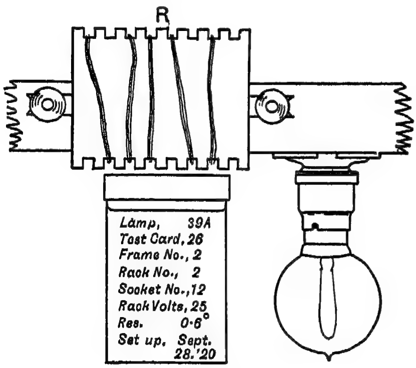

FIG. 61.

are inserted between the terminals T_1T_1, T_2T_2, etc. Each of these resistances is, to the nearest tenth of an ohm, that required to give, with the current taken by the lamp to which it applies, the necessary voltage drop between the rack leads and the lamp terminals.

§ (83) CANDLE-POWER MEASUREMENTS.—Before the lamp is put on life test, measurements of candle-power and current at various voltages are made in the usual way (see § (20)), and the voltage at which the desired efficiency is obtained is then deduced. This voltage then becomes the life-test voltage of the lamp, and no attempt is made to alter this voltage as the efficiency of the lamp falls with lapse of time. Further, the candle-power measurements at stated intervals during the run are made either at this life-test voltage or, more frequently, at rated voltage. These measurements are often made at the expiration of 0, 50, 100, 200, and each subsequent 200 hours after the commencement of the test. In the case of a forced test the intervals at which candle-power measurements are made may be much shorter than this, as the total life is reduced in length.

§ (84) POSITION OF THE LAMPS.—The card shown in *Fig.* 61, close to a lamp, is a very useful auxiliary in practical working. It shows, for the lamp in question, the reference number of the lamp, its position on the life-test rack, the voltage applied across the rack leads, and the resistance necessary to reduce this voltage to the life-test voltage of the lamp. The racks are so arranged on their framework that the lamps can be burnt upright or pendent, the latter being the more usual condition. The racks are inspected at frequent intervals and failures are noted, as far as possible, to the nearest hour. It is the usual practice to regard any lamp, the filament of which fractures when no current is passing through it, as having been accidentally broken. The results on such a lamp are then not included in determining the average life of the group to which it belongs. If the filament of a lamp break, and fall across another portion so as to complete the circuit through the lamp and cause it to burn, that lamp is nevertheless regarded as broken, and removed from the test.

§ (85) LIFE-TEST CURVES.—Lamps are generally run until failure of the filament occurs, or until the candle-power, measured at one of the intervals mentioned above, shows more than 20 per cent drop below the initial value. The interpretation of life-test results is a matter requiring very careful consideration. It is usual to draw the candle-power time curve for each individual lamp, and then to draw two curves showing respectively the average candle-power and the average value of watts per candle for the whole number of lamps burning at any time. Thus in drawing these latter curves, lamps removed from the test, either on account of breakage or candle-power fall, are not included in computing the averages for times subsequent to their removal.

[1] Paterson and Rayner, *Illum. Eng.*, London, 1908, i. 845.
[2] Middlekauff, Mulligan, and Skogland, *Bureau of Standards Bull.*, 1916, xii. 607.

A set of such curves for a batch of six lamps is shown in *Fig.* 62, where the individual candle-power curves are shown on the left, and the mean candle-power and average watts-per-candle curves are shown respectively above and below on the right. The removal of a lamp from the test is indicated by an arrow at the appropriate point on the time scale.

§ (86) Interpretation of Results.—For specification purposes, however, it is desirable to have, in addition to the full information afforded by the curves, some figure of merit for the life-test lamps by which it may be possible to judge of the probable performance of the lamps they represent. The figure adopted by the British Engineering Standards Association in this country is the "test life," defined as the average number of hours burnt by all the lamps in a group throughout a specified running period. It is therefore the total number of hours burnt by all the lamps in a group, throughout each running period, divided by the number of lamps.

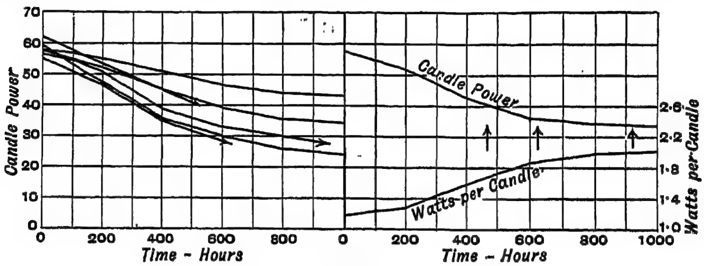

Fig. 62.

§ (87) Forced Life Efficiencies.—The advantages of speed and economy of power possessed by a forced life test were pointed out earlier in this article, as well as the difficulties attending the correct interpretation of such tests. These difficulties are diminished in proportion as the extent of the "forcing" is reduced. The extensive life tests carried out at the Bureau of Standards[1] are made at efficiencies corresponding to about 0·9 to 0·95 watts per candle for tungsten lamps rated at from 1 to 1·15 watts per candle, and in many other cases the use of forced life tests is customary.

The determination of the conditions at which a forced test is to be run may be made in two different ways. The first method is to measure the voltage at some stated watts per candle, and to multiply this by a constant factor to determine the forced test voltage. A forced test voltage in common use with this method in America is 130 per cent of the voltage at which the lamp absorbs 1·23 watts per candle.[2]

The second method is to run the lamps at the voltage which gives them, initially, some specified watts per candle higher in efficiency than the normal by a constant amount.

The life-test voltage having been determined as above, it is usual to make the photometric measurements at rated voltage for the sake of consistency and simplicity in records. Since the life test is considerably shortened in length of time taken, the intervals between the photometric measurements are correspondingly reduced.

§ (88) Reduction of Forced Life Results.—It is usual to reduce the life results of a forced life test to those of a test at normal efficiency by means of a relationship such as the following:

$$(\text{Life}) = (\text{constant}) \times (\text{watts per candle})^n.$$

For although Cady[3] and Edwards[4] have shown that n is not constant over a wide range of variation of the efficiency, yet within the limits of 15 per cent in voltage above and below normal the error in the computed life will not be serious if the departure of the efficiency from the normal value is not too great. Lewinson has shown[5] how much the value of the exponent n depends on the construction and type of the lamp under test. For 100-watt lamps of various constructions this exponent varied from 6·2 to 8·2 with a mean of 7·4. For lamps of various sizes the value of n was also found to vary according to the following table:

Watts.	n.	Watts.	n.
15	6·8	40	7·4
20	7·2	60	7·5
25	7·3	100	7·8

Middlekauff, Mulligan, and Skogland[6] use

[2] Lewinson, *Am. Illum. Eng. Soc. Trans.*, 1916, xi. 817.

[3] *Am. Illum. Eng. Soc. Trans.*, 1908, iii. 459.

[4] *Gen. Electric Rev.*, 1914, xvii. 282.

[5] *Loc. cit.* p. 822.

[6] *Loc. cit.* p. 826.

the value 7·4 for all sizes of tungsten lamps from 25 watts upwards, and the value 5·83 for carbon lamps.

The same value of n cannot be applied to all interpretations of a forced life test. The figures given above refer to a "useful life" interpretation, *i.e.* life to 80 per cent of initial candle-power or earlier burn-out. For the 60-watt lamp the value of n given by Lewinson for a "total" life interpretation—*i.e.* life to burn-out—is 6·6, while for an 80-per-cent life—*i.e.* life to 80 per cent of initial candle-power with all burn-outs eliminated—it is 7·6 instead of the figure of 7·5 given in the table above.

An important factor in the loss of candle-power during the life of a lamp is the blackening of the bulb, especially if this be small compared with the size of the filament. Some lamps contain bulb-blackening preventives, which depend for their effective operation on the temperature of the bulb. It will be clear that if the variation of the action of this preventive with change of temperature is different in two classes of lamps the life efficiency factor will be different also, and this effect requires consideration when forced life tests are being made.

§ (89) Special Life-test Conditions.—What has been said above applies, in the main, to life tests of all classes of lamps, but in the case of lamps required for use under special conditions it is often desirable that the life test should be carried out as nearly as possible under the conditions of use of the lamps represented. Thus, for example, lamps to be used in confined spaces should be represented on life tests by lamps burning in similar-sized spaces. Lamps to be run off small-capacity portable accumulators, where the lamp may be subjected to appreciable over-voltage at the beginning of each run, may be required to be tested for life on a circuit in which this over-voltage is imitated. Special life tests of this nature require special arrangements of the electrical circuits.

§ (90) Number of Lamps required for Life Test.—It is also desirable that the number of life-test lamps should be a larger percentage of the total number of lamps represented than is the case with more normal tests. The standard specification of the British Engineering Standards Association calls for a life test on at least one-half of one per cent of the lamps in a batch, with a minimum of five lamps, in the case of ordinary tests, and this number should be doubled or trebled in the case of special or of forced tests.

§ (91) Dependence of Life on Voltage.—When setting up lamps on life test it is, of course, necessary to ensure that failure of one lamp does not entail excess voltage on any of the others. Thus life-test lamps must not be set up in parallel on a circuit containing any appreciable external series resistance, otherwise the failure of one lamp will increase the effective resistance of the lamp portion of the circuit, with consequent rise of voltage, to act adversely on the life performance of the remaining lamps. Constancy of voltage is, in fact, one of the chief requirements of a reliable life test, and the B.E.S.A. Specification, referred to above, calls for a limit of variation which shall not exceed 1 per cent as regards momentary fluctuations, or what is appreciable on an ordinary large-scale type indicating voltmeter as regards permanent error in the voltage at which the lamps are run. The reason for this requirement is readily understood from the high value of the life efficiency characteristic when it is remembered that this means a life-voltage exponent of between 15 and 20 for a vacuum-type tungsten-filament lamp. The degree of dependence of life upon efficiency for gas-filled lamps has not yet been determined, and it will probably prove to be extremely variable owing to the large number of independently variable conditions in this type of lamp.

§ (92) Effect of Alternating or Continuous Current.—It has been customary to consider that a life test may be run on either continuous or alternating current, and experiments by Mongini [1] show that the results obtained by both methods are practically identical. The same conclusion is reached by Merrill, Cooper, and Blake,[2] who found that actual switching on and off did not appreciably affect the life of the lamps. If, therefore, it be assumed that the only effect which might have a tendency to decrease the life on alternating current is that of the rush of current which takes place when a metal filament lamp is first switched on (due to the lower resistance of the filament when cold), the smallness of the effect on the life found for actual switching on and off can only be diminished when the current impulses follow one another so rapidly that the degree of cooling in the filament is comparatively slight.

VII. Heterochromatic Photometry

§ (93) Effect of Colour Difference in Photometry.—In the other sections on photometry it has been assumed throughout that the two surfaces whose brightnesses are being compared appear to the observer to be of the same colour. Such a condition is, however, the exception rather than the rule in practical photometry, except in cases where the work is confined to the measurement of sources which are very uniform in character. The eye is a very sensitive judge of colour difference, and when two exactly similar

[1] *Atti dell' Assoc. Elettr. Ital.*, 1913, xvii. 690.
[2] *Am. I.E.E. Proc.*, 1910, xxix. 945.

surfaces are seen side by side in a photometer (as, for example, in the Lummer-Brodhun head), if they are illuminated by two tungsten lamps operating at efficiencies differing by as little as 2 per cent, a colour difference is just perceptible to the eye of a practised observer.

Actually, in such a case, the light given by the less efficient lamp is very slightly yellower than that given by the other, but the appearance in the photometer head is, by contrast, that of a slightly pink patch on a bluish field and *vice versa.* Even such a very slight colour difference as this is sufficient to reduce quite seriously the accuracy of a photometric balance. The colour difference makes it impossible to obtain exact equality between the two halves of the field, and the eye has to allow for the difference in *hue* when endeavouring to obtain a balance of *brightness.* Of course much more serious differences are met with in practice when comparing electric glow-lamps with flame standards, or when measuring gas or acetylene sources by means of electric glow-lamp sub-standards. When it is a case of measuring daylight illumination, or the light from a high-intensity electric arc by means of tungsten-filament sub-standards, direct comparison becomes very inaccurate indeed, and the majority of observers will, on different occasions, obtain readings differing by as much as 20 per cent. Further, different observers do not obtain results in agreement with one another, and it is therefore necessary that special methods shall be adopted for the comparison of lights in which the colour difference exceeds even a small amount.

§ (94) Methods of Heterochromatic Photometry. — Theoretically no physical equality can ever be obtained between lights of different colours, because the things being compared differ in kind as well as in degree. But physiologically it is a matter of experience that, provided the difference in kind be not too great, equivalence in degree can be established within assignable limits by observers having normal vision For even when signal-green and ruby-red lights are being compared, it is possible to raise the brightness of the green to such a degree that no doubt is left in the observer's mind that the green is definitely the brighter of the two, while similarly there is a much lower intensity at which the red can quite confidently be asserted to be the brighter. The aim of heterochromatic photometry is to reduce these limits as much as possible for the cases met with in practical photometry, and this problem has been attacked, in the main, along three lines, viz.: (i.) the flicker method, (ii.) the use of coloured glass or gelatine filters or solutions, and (iii.) the division of the colour difference to be dealt with into a number of smaller colour steps.

§ (95) The Flicker Photometer. — The flicker method depends upon the phenomenon of visual diffusivity in the human eye (see article on "The Eye," § (19)). When two bright surfaces are presented to the eye in rapid alternation a flicker is perceived, the degree of which depends both on the rapidity of the alternation and also on the identity of the two surfaces as regards brightness and colour. The more nearly identical the surfaces the slower the speed at which flicker ceases to be perceptible, and the principle of the flicker photometer lies in producing a rapid alternate presentation of the two comparison surfaces to the eye of the observer, and the adjustment of their relative brightnesses until no flicker is observed at a comparatively low frequency of alternation.

§ (96) The Whitman Photometer. — Several instruments have been designed on this principle. That of Whitman [1] is shown in plan in *Fig.* 63. C is one comparison

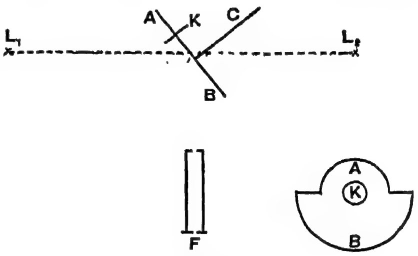

Fig. 63.

surface, and AB the other. AB consists of a disc of the shape shown in the right-hand bottom corner of the figure. Rotation of AB about the axis K causes the eye at F to see first one and then the other comparison surface in succession. A photometric balance can be repeated with this instrument to about 2 per cent when using lights of the same hue. The accuracy is of course less with different coloured lights.

§ (97) The Bechstein Photometer. — Rood employed a plano-concave cylindrical lens oscillating in front of a Ritchie wedge so that first one side and then the other was brought into the field of view. This principle has been developed by Bechstein,[2] who uses the lens and prism system shown at L in *Fig.* 64. In the position shown in the figure the eye at A sees a circular field of which the outer annular portion is due to the right-hand side of the prism P, while the inner circular portion is due to the left-hand side of P. If now L be rotated as a whole through 180° the

[1] *Phys. Rev.*, 1895–96, iii. 241.
[2] *Zeits. Instrumentenk.*, 1916, xxvi. 249

outer and inner parts of the field are respectively illuminated by the left- and right-hand sides of P, so that as L is rotated by a small

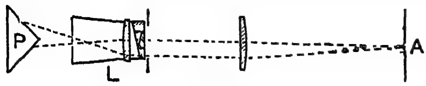

FIG. 64.

electric motor an alternation of contrast is obtained in the field of the photometer.

§ (98) THE SIMMANCE-ABADY PHOTOMETER.—In the flicker photometer of Simmance and Abady [1] a plaster disc consisting of a combination of two truncated cones is used. Its formation may be best understood from *Fig.* 65. ABCD and EFGH are two exactly similar truncated cones, divided respectively by the planes AC and EG. The portions ABC and EGH are removed, and EFG is then placed on ACD so that the resulting solid has the form shown in *Fig.* 66, which represents it as seen edge-on in four positions 90° apart. It will be clear that if the two sides of such a disc be illuminated by the two sources to be compared, the line of demarcation will swing back and forth across the field of view for every rotation of the disc, and thus a

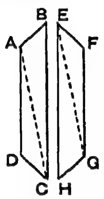

FIG. 65.

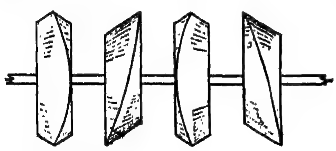

FIG. 66.

flickering field will be obtained as before. Discs designed on an exactly similar principle, and giving 4 or 8 alternations instead of 2 for each rotation, have been designed by Krüss.[2]

§ (99) THE WILD PHOTOMETER.—The flicker photometer designed by Wild [3] consists of a Bunsen disc in which a semicircle or two quadrants are waxed, the remainder of the disc being plain. It is mounted so as to be perpendicular to the direction of the beams of light to be compared, and both sides of the disc are viewed simultaneously by means of mirrors. Rotation of the disc by clockwork, or by a small electric motor, produces the field alternation. The criterion in this photometer is not absence of flicker, but equality of flicker on both sides of the field. It therefore possesses the advantage that the appearance of the field, when out of balance, indicates the direction in which the head has to be moved. This instrument has been stated to have a sensitiveness of 0·5 per cent with lights of the same colour and 0·9 per cent when comparing red and green lights.

§ (100) EFFECT OF SPEED ON SENSITIVITY OF FLICKER.—The speed of a flicker photometer has a very noticeable influence on its sensitivity. Dow [4] has investigated this problem and finds that for lights of different colours the speed giving maximum sensitivity is much higher than it is for lights of the same colour. The range of speed over which maximum sensitivity is obtained is also more restricted in the case of different coloured lights. The most favourable speed varies both with the illumination and with the difference of colour of the two fields, the results obtained when comparing green and white lights being shown graphically in *Fig.* 67. The abscissae are frequencies of field

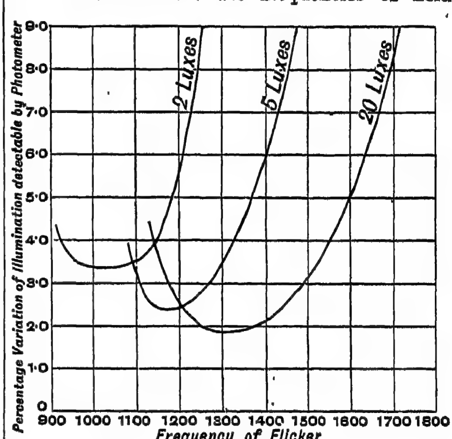

FIG. 67.

alternation (*i.e.* the number of changes per minute), while the ordinates show the percentage change of illumination which can be made without flicker, *i.e.* the difference between the illumination ratios at the two positions at which flicker just begins to appear. The accuracy of setting can be made much closer than this, since the mean of the two positions at which flicker is just perceptible may be taken as the position of balance. For illuminations greater than 20 metre-candles the range of sensitivity is approximately the same as for that illumination, while it can also be assumed that a colour difference less than that of the experiments will give a greater range of speed for maximum sensitivity, and that the actual speeds will be lower, tending to limits of 500

[1] *Phys. Soc. Proc.*, 1903, xix. 39.
[2] *Zeits. Instrumentenk.*, 1905, xxv. 98.
[3] *Illum. Eng.*, London, 1908, i. 825.
[4] *Electrician*, 1907, lix. 255.

to 100 for lights of the same colour when the illumination is 2 metre-candles.

§ (101) THE COLOUR-FILTER METHOD.—A second method by which it has been proposed that lights of different colours should be compared is that involving the use of some coloured medium which will either (*a*) bring the hue of one light to approximate equality with that of the other, or (*b*) enable a comparison to be made of the relative intensities of both lights at some particular part of the spectrum. To the former class belong the "photometric" gelatine filters devised by C. K. Mees.[1] In § (6) "Visibility" of the article "The Eye" (*q.v.*) it has been stated that a curve may be constructed showing the relative brightnesses which the average eye will assign to equal quantities of energy at different parts of the visible spectrum. This curve, called the visibility curve, is shown in *Fig.* 2 of that article, and if its ordinates be multiplied by

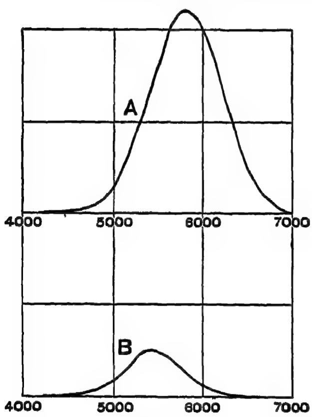

FIG. 68.

the relative energy emissions in the different wave-lengths, of a given source of light, a curve will be obtained showing the relative contributions of the different parts of the spectrum given by this source to its total luminosity. Such a curve for a black body at a temperature of 2000° K is shown in *Fig.* 68, curve A.

Now by means of a spectrophotometer (see article on "Spectrophotometry") the transmission ratio of a coloured transparent medium may be measured for light of any wave-length. If, then, the ordinates of curve A in *Fig.* 68 be multiplied by the corresponding transmission ratios of a colour filter, a curve will be obtained showing the luminosity reaching the eye through the filter. Such a curve is shown in *Fig.* 68, curve B. The ratio of the areas of the two curves A and B gives the over-all transmission ratio of the filter for light of the spectral distribution assumed, and hence this value of transmission ratio can be assumed for all sources the spectral distribution of the light from which approximates to that of the curve used for the calculations.

§ (102) COMPARISON OF DIFFERENT COLOURED LIGHTS.—In this way a tungsten-filament lamp, or even daylight, may be compared with a flame standard by using a blue colour filter, which, when placed between the standard and the photometer, will produce a colour match in the photometer head. A knowledge of the energy distribution curve of the standard and the visibility curve of the average eye gives at once the luminosity curve of the standard. This and the transmission ratio curve of the filter give the over-all transmission ratio of the filter for the light from the standard, and hence the candle-power of the combination of standard and filter. Instead of a blue filter in front of the standard it is often desirable to use a yellow filter in front of the light of higher efficiency. In this way an undue reduction of candle-power on one side of the photometer may be avoided.

The above process of finding the transmission ratio of a colour filter is very laborious, and a less fundamental but much simpler method is that employed at the Bureau of Standards and at the Physikalisch-Technische Reichsanstalt. In this method it is assumed that the mean value of candle-power obtained by a large number of observers with a direct comparison photometer, such as the Lummer-Brodhun, approximates very closely to the true value even when the colour difference involved in the comparison is considerable. The transmission ratio of a colour filter is determined by comparing the candle-power of a given lamp (of Hefner flame colour) with a standard (*a*) without the filter and (*b*) with the filter placed between the lamp and the photometer head. The ratio of the candle-power in case (*b*) to that in case (*a*) is then assumed to be the transmission ratio of the filter for light of that colour, and the combination is used for the determination of candle-power of test lamps as usual.

The advantage of this method over a direct comparison involving colour difference in every case is that the determination of transmission ratio can be made by a large number of observers, and when this has been done, the photometry of test lamps involves no further colour difference, so that a much smaller number of observers is sufficient.

§ (103) THE CROVA WAVE-LENGTH METHOD.—The second alternative, of using a colour filter having only a narrow band of transmission in the yellow part of the spectrum, was suggested by Crova in 1881.[2] He found

[1] *Amer. Illum. Eng. Soc. Trans.*, 1914, ix. 990.

[2] *Comptes Rendus*, 1881, xciii. 512.

that if the visibility curves of various sources having approximately the same spectral distribution as a black body at various temperatures were plotted with equal total areas, these curves all intersected, *i.e.* had equal ordinates, at the wave-length 0·582 μ. It therefore followed that a comparison of such lights at this wave-length gave a correct comparison of their total candle-powers. This wave-length, termed the Crova wave-length, has been redetermined and probably lies more nearly in the region 0·557 μ to 0·562 μ. One great advantage of this method lies in the fact that any filter which has only a narrow band of transmission must necessarily reduce the intensity of the light very greatly. Crova suggested the use of a combination of solutions of perchloride of iron and chloride of nickel in a glass vessel 7 mm. thick. This combination transmits between the wave-lengths 0·630 μ and 0·534 μ with a maximum at 0·582 μ.

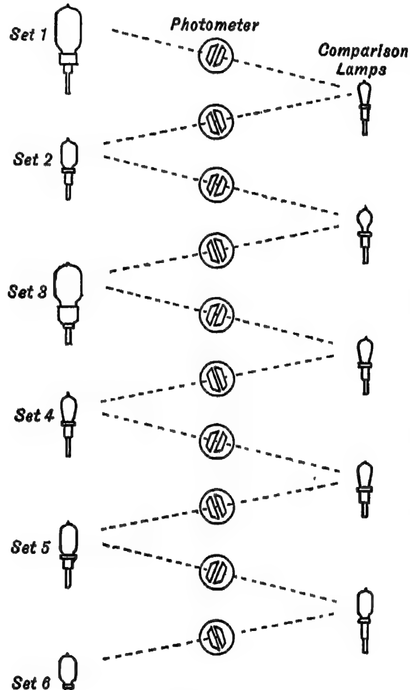

FIG. 69.

§ (104) THE CASCADE METHOD. — The third method of colour photometry does not attempt to eliminate the colour difference, but simply divides it into a number of small steps. This is the method employed for the measurement of the electric sub-standards used at the National Physical Laboratory. Between the flame standard, in this case the Vernon-Harcourt pentane lamp, and the highest efficiency sub-standards used, viz. those operating at 0·67 candles per watt, four sets of tungsten or carbon filament sub-standards are interposed, as shown diagrammatically in *Fig.* 69. The lowest efficiency set consists of tungsten-filament lamps operating at 0·11 mean horizontal candles per watt and the light from these matches that from a pentane lamp; the other lamps are respectively (1) single carbon loop-filament lamps operating at 0·20 m.h.c. per watt; (2) double horse-shoe carbon filament lamps operating at 0·26 m.h.c. per watt; (3) metallised carbon filament lamps operating at 0·33 m.h.c. per watt; (4) tungsten grid filament lamps operating at 0·52 m.h.c. per watt, and (5) tungsten grid filament lamps operating at 0·67 m.h.c. per watt.

These efficiencies are such that the colour difference between any two neighbouring sets is approximately the same throughout the series, and each set of lamps is compared with the set below it by not less than six observers, each taking at least 30 observations on each lamp. The observers work in pairs, every one of the possible combinations of observers being employed. Thus the values obtained by each observer on each lamp are taken on five different days. By this method the effect of colour difference on the comparison is minimised, and a direct comparison of set 6 with set 1, made in an exactly similar way to that described above, shows that, in fact, the sum of the probable errors of the different steps in the comparison by what is called the "cascade" method is slightly less than the probable error of the direct comparison.

There is, however, another much greater practical advantage in the cascade method. Ordinary photometric comparison is made by not more than two observers, so that in the case of a considerable colour difference the chance of any two observers obtaining a result in agreement with that obtained by a much larger number has to be considered. The intercomparison of the sub-standards, on the other hand, is carried out by at least six observers, and then for any subsequent photometry a sub-standard is available of a colour quite close to that of the test lamp. The small remaining colour difference is then all that remains to be considered when assigning the accuracy of comparison by two observers.

§ (105) THE COMPARISON LAMP IN CASCADE. —It is often the practice, when working with small colour differences, to use a comparison lamp giving light of a hue midway between that of the test lamp and that of the nearest available sub-standard. In this way the colour difference is halved, but as the same difference appears on opposite sides of the photometer in standardisation and in the test-lamp

measurement, it is doubtful whether any increase in accuracy results from this procedure. When working with sources far bluer than the highest efficiency sub-standard a "half-way" colour filter may be used on the comparison lamp side, or the method adopted by the Bureau of Standards (§ (102)) must be used.

§ (106) Other Methods of Heterochromatic Photometry.—Other methods, not depending on any of the three principles above described, have been proposed and may be briefly noticed. Macé de Lépinay suggested placing in front of eyepiece of the photometer first a green and then a red solution. The ratio of the intensities found in these two cases gave, by means of a table, the intensity for the whole spectrum. Wybauw used a "compensation" photometer in which the light from the (more powerful) source to be measured illuminated one side of the photometer, while the other side received light from the standard and, in addition, a fraction of the light from the source to be measured. Thus the hue difference was reduced, but the sensitiveness of the measurement was also diminished.

§ (107) The Visual Acuity Method.—Another method, which has been proposed by Weber and others, depends on the amount of light necessary for the visual perception of detail. Patterns consisting of concentric black circles of different thicknesses, or a series of fine dots of progressively diminishing size, are illuminated in turn by means of the lights to be compared, and it is assumed that equal ease of discrimination corresponds with equality of illumination for the different lights. The theoretical soundness of this form of colour photometer has been frequently called in question, and it appears more than doubtful whether visual acuity can be used in this way as a judge of equality of brightness without reference to the colour of the light used.

§ (108) The Contrast Pattern Method.—A colour photometer devised by Von Czudnochowski [1] depends upon the production of two sets of shadows formed by mutually perpendicular wire gratings, each set being illuminated by one of the sources to be compared. The field produced consists of two shadow patterns which appear grey on a white background, with dead black intersections. If one of the sources is moved sensibly out of balance one of the patterns becomes coloured.

§ (109) Effect of various Factors on Flicker Sensitivity.—The various phenomena underlying the comparison of lights of different colours have been the subject of investigation by many workers. Notably J. S. Dow [2] has shown that, while a single observer may obtain very consistent results on a single occasion when using an equality of brightness photometer to compare lights of different colours, yet the same observer, after a few hours' rest, may obtain another series of readings, equally consistent among themselves, but differing from the first set by 5 or even 10 per cent. Dow also finds that the readings are affected by the size of the image produced on the retina by the photometric field. It results from this that the size of the surfaces used for the purpose of comparison, as well as the distance of the eye from these surfaces, are of importance in heterochromatic photometry. He found in a particular case of comparison between red and green lights that there was a 25 per cent difference in setting according as the telescope of a Lummer-Brodhun photometer head was in its extreme "in" or "out" position. He also investigated the effect of the Purkinje phenomenon in colour photometry, and found that this had no appreciable effect on illuminations above 1 metre-candle, so that it may be neglected in ordinary photometry. The experiments, however, seemed to show that the effect was less with the flicker than with the equality of brightness photometer.[3]

§ (110) Comparison of Flicker and Equality of Brightness Methods.—Ives carefully investigated the relative merits of the different methods of colour photometry,[4] and came to the conclusion that the flicker method was more sensitive than the equality of brightness method, and that the results obtained by its means were more reproducible in the case of lights differing considerably in hue. This opinion was confirmed by Crittenden and Richtmyer,[5] but they found that for sources having a relatively high intensity at the blue end of the spectrum, the values given by the flicker photometer departed appreciably from those given by the contrast type, the difference being estimated at as much as 3 per cent for such sources as the gas-filled lamp. They also came to the conclusion that for individual observers, or for small groups, the flicker photometer gave a result which was closer to the mean than that found with the contrast instrument. Reference [6] should also be made to the work of Middlekauff and Skogland.

A critical discussion of the relative merits of the two methods has been given by Hyde,[7] who, in his determination of the visibility curve of the human eye, preferred the equality of contrast method as being the most suitable.

§ (111) Colour Difference in Illumination Measurements.—The above description has been practically confined to ordinary

[1] *Illum. Eng.*, London, 1908, i. 283.
[2] *Phil. Mag.*, 1906, xii. 120.
[3] *Phil. Mag.*, 1910, xix. 66.
[4] *Ibid.*, 1912, xxiv. 149.
[5] *Amer. Illum. Eng. Soc. Trans.*, 1916, xi. 353.
[6] *Bureau of Standards Bull.*, 1918, xiii. 287.
[7] *Astrophys. J.*, 1918, xlviii. 65.

photometry, but in the measurement of illumination the problem of colour difference is even more important on account of the many different types of illuminants met with, often in the same building. Further, the brightness of the test surface may sometimes fall below the limit at which the Purkinje effect cannot be neglected, so that colour difference between the light to be measured and the comparison source may cause considerable errors at these lower values of illumination. Above all, the colour differences met with in ordinary photometry never approach the difference experienced when measuring daylight illumination by means of a portable photometer in which the comparison lamp is an ordinary tungsten-filament vacuum glow-lamp. The use of a colour filter is almost universal for daylight illumination measurements. This may take the form of a yellow filter placed between the test surface and the photometer, or a blue filter used in front of the comparison lamp. The latter scheme has the disadvantage that it reduces the upper limit of working of the photometer. Instead of interposing a yellow filter between the test surface and the photometer, a yellow test surface is sometimes used. The constant of such a surface, or filter, can be found on the photometer bench by a number of observers, and it may then be used in the portable instrument by a single observer. The transmission ratio of a yellow filter must, of course, be determined for light of daylight colour. It should be noticed, in this connection, that the colour of daylight is by no means constant. The colour of the light from a clear blue north sky is much richer in blue rays than the light derived directly from the sun or from white clouds illuminated by it. The difference, however, is not sufficient to invalidate the transmission ratio of a yellow filter determined for light of the colour of sunlight.

§ (112) Determination of Filament Temperature.—The ease with which the eye can distinguish colour difference in an ordinary equality of brightness photometer has been used by C. C. Paterson and B. P. Dudding [1] for the determination of the true temperature of an incandescent body. They found that the light from an ordinary tungsten or carbon filament vacuum lamp approximated very closely in spectral distribution to that of a "black body," and that a close and invariable relationship existed between its efficiency, expressed in candles per watt, and its temperature. Thus if one side of a photometer be illuminated by such a lamp while the other side receives light from an incandescent body whose radiation has the same spectral distribution as a "black body," the efficiency of the lamp may be altered, by changing the voltage applied to it, until the two sides of the photometer appear to be of exactly the same colour. An exact equality of brightness must be maintained by moving the photometer between the sources during the process of obtaining this colour match, and the temperature of the incandescent body may then be assumed to be very closely the same as that of the lamp filament. The lamp filament may be calibrated by an exactly similar method against a standard "black body," but the authors above quoted (*loc. cit.*) have found that for all drawn tungsten-filament lamps of ordinary vacuum type and disposition of filament, the relation between temperature and efficiency follows the relationship

$$\log\frac{L}{W}=C-m\log_{10}T-185\log_{10}\left(1+\frac{115}{T}\right),$$

where L/W expresses the efficiency of the lamp in lumens per watt, T is the absolute temperature, and C and m are constants having the values 21·51, 4·58 and 23·31, 5·1 respectively for carbon and tungsten filaments. They have also found that the watts consumed by a lamp vary with the absolute temperature according to the relation $\log_{10}W=C_1+4{\cdot}58\log_{10}T$ and $\log_{10}W=C_2+5{\cdot}1\log_{10}T$ for carbon and tungsten filaments respectively.

VIII. The Photometry of Projectors

The photometry of light-projection apparatus falls into a class by itself on account of the many difficulties involved and the special means which have to be employed in order to overcome them. At the same time it is of the utmost importance to obtain information as to the relative performance of different types or patterns of apparatus such, for instance, as searchlights, motor-car headlights, signal lights for marine or land service, and similar special optical devices.

§ (113) Difficulties due to Beam Concentration.—The chief difficulties met with in these tests arise from the fact that the light does not diverge from a source of which the dimensions may be neglected in comparison with the distance from it at which the measurements are made. In all the cases mentioned above, the light from the source is redistributed by optical devices, and it is therefore necessary to ensure that the measurements are made at such a distance from the apparatus that the inverse square law may be assumed to hold within the accuracy desired. It is not necessary, of course, that distances should be measured from the source itself, and often it is assumed that the optical centre of the device lies at the meeting point of the

[1] "The Estimation of High Temperatures by the Method of Colour Identity," *Phys. Soc. Proc.*, 1915, xxvii. 230.

extreme rays of the projected beam. This assumption, however, is generally no more than a convenient approximation to the truth, for it cannot always be assumed that the light is emitted in all directions from a single point. Often the light emitted in two different directions may behave as if it emanated from points which are separated by a distance far from negligible in comparison with the distance at which measurements have to be made.

§ (114) Minimum Distance for Photometric Measurements.—It may be generally assumed that the inverse square law holds for distances greater than fifty to four hundred times the diameter of the optical aperture with beams of 20° to 2° total divergence. As a very approximate guide it may be assumed that the inner limit of distance at which the beam has attained its final distribution is given by Kd/θ, where θ is the total angle, measured in degrees, of the cone of light formed by the beam, d is the diameter of the aperture, and K is a constant lying between 600 and 1000.

This rule leads to the result that for such apparatus as motor-car headlights, where the diameter of the mirror is of the order of 10 inches and the divergence may be as little as 5°, photometric measurements should always be made at least 100 feet away from the headlight. On the other hand, for a lens such as that used in a ship's navigation light, where the divergence may be as much as 20° with a lens height of 7 inches, a distance of about 20 feet is sufficient. In both these cases the chief difficulty is that of obtaining sufficient light to enable measurements to be made at these comparatively great distances, and very often a compromise has to be effected by making measurements at two shorter distances, and obtaining an approximation to the desired result by an extrapolation.

§ (115) "Effective" Candle-power.—The information usually desired is that given by a curve of distribution of illumination on a screen placed so as to be perpendicular to the axis of the beam at a convenient distance from the source. This distribution may often be conveniently found by actual measurement of brightness at different portions of a white screen placed in the path of the light, using a form of portable illumination photometer (see p. 441). It is often more convenient, however, to keep the photometric apparatus fixed in position and to move the source either in altitude or azimuth. Measurements of illumination can then be made by means of a photometer head fixed in a given position, with a comparison lamp movable along a bench directed away from the source. Alternatively, the test surface of a portable photometer (see p. 441) may be fixed in a convenient position, and measurements of illumination at this position may then be made for any desired orientation of the projector. The results may be expressed either directly in terms of illumination, or, by calculation, in terms of the candle-power which would be required of a point source placed in the position of the projector in order that it might produce at the screen the illumination actually measured there. The latter figure is generally termed the "effective candle-power" of the source in the direction considered.

§ (116) Distribution Curve for Beams.—Whichever method of expressing the results is employed, the distance from the source at which the measurements have been made should always be stated. The results may be exhibited graphically by means of a curve in which the abscissae represent either illumination at a given distance or effective candle-power, while the ordinates are the corresponding angles of deviation from the axis of the apparatus. Such a curve, for a motor headlight beam of small divergence, is shown in the upper diagram of *Fig.* 70. The lower

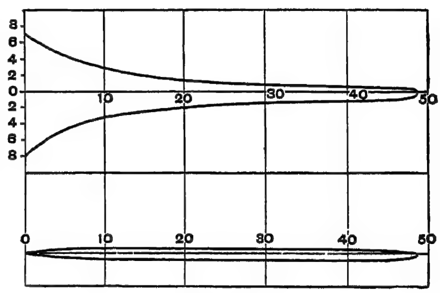

Fig. 70.

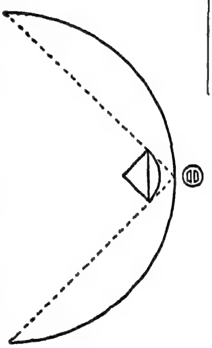
diagram is a polar curve for the same beam, and illustrates strikingly the failure of a polar diagram to give an intelligible representation of light distribution from any form of projection apparatus.

For photometry of small projection apparatus, such as motor headlights, ships' light lenses and hand signalling lamps, the distances required by the formula given above do not generally exceed 100 feet, and consequently measurements can be carried on in the laboratory, where all that is required in addition to ordinary photometric equipment is a tilting table for movement in altitude, and a horizontal turn-table for variation of angle of azimuth. If the beam is roughly symmetrical about its centre, sufficient information is generally given by a curve, such as that shown in *Fig.* 70, representing the mean of measurements made across the horizontal and vertical diameters of the beam. If the beam is not symmetrical in shape, similar curves are obtained along other specified lines of

traverse. Occasionally the patch of screen illuminated by the beam is divided into squares, and the illumination on each of these squares is measured and noted on a figure representing the appearance of the patch.

§ (117) Atmospheric Absorption.—In the photometry of searchlight projectors matters are very different. The divergence of the beam may be as little as 2 to 3°, while the diameter of the mirror is from 2 to 4 feet. Consequently, distances of at least 500 to 1000 feet are necessary for accurate beam tests, and in practice it is customary to employ distances of one-half to two miles. At such distances as these, attainable only in the open, atmospheric absorption cannot be neglected. Even a slight ground mist may cause errors of as much as fifty per cent, which are by no means constant from hour to hour, or even from minute to minute.

The effect of atmospheric absorption may be allowed for in one of three ways. First, a "standard" searchlight beam of known constant characteristics may be used. This beam directed towards the distant measuring station at intervals throughout a test will give, by measurement of its candle-power, the correction to be applied on any given night to the observations made on the other searchlight beams tested during that night. Such a beam may be that given by a large size tungsten arc, or a steady carbon arc burning under standard conditions. In either case the source of light must be used in conjunction with a given parabolic reflector as no two reflectors can be relied upon to give exactly the same distribution of light in the beam.



§ (118) The Telephotometer.—A second method depends on the use of a telephotometer, in which a simple double convex lens forms an image of a large screen (situated at the observing station) on the centre of a Lummer-Brodhun cube. This cube forms part of a photometer of ordinary construction at the station where the searchlight is placed. Simultaneous readings of the brightness of the screen as measured by the telephotometer and by an ordinary portable photometer at the observing station give at once the atmospheric absorption when the calibration of the telephotometer is known.

§ (119) The Two-station Method.—The third method is more direct than either of the foregoing. In this, two observing stations are used at known distances d_1 and d_2 from the searchlight. The light is directed first to one station and then to the other, and measurements of the illuminations are made. If these be I_1 and I_2, and t the transmission coefficient of the atmosphere per unit length (assumed to be the same throughout the region over which the measurements are made), while C is the effective candle-power of the searchlight, then

$$I_1 = \frac{C}{d_1^2} t^{d_1} \quad \text{and } I_2 = \frac{C}{d_2^2} t^{d_2},$$

so that

$$\frac{I_1 d_1^2}{I_2 d_2^2} = t^{(d_1 - d_2)}.$$

If for convenience $d_1 = 2d_2$, then $C = I_2^2 d_2^2 / 4I_1$.

§ (120) The Integrating Hemisphere.—Atmospheric absorption is only one out of many difficulties attending the measurement of candle-power distribution in the beam of a searchlight,[1] and for many purposes sufficient information is obtained by a measurement of the total luminous radiation in the beam. For this purpose some form of integrating photometer must be employed. Either the arc may be placed out of focus, so as to cause the beam to converge on to a white reflecting surface placed inside an integrator of the sphere or cube type, or the beam may be directed on to a hemispherical integrator as illustrated on the left-hand side of *Fig.* 71. This

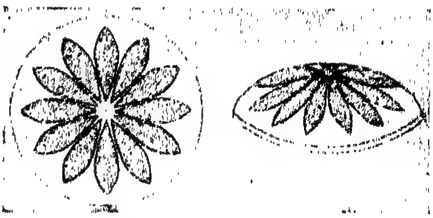


Fig. 71.

integrator consists of a hemispherical matt white surface, furnished at its centre with an aperture and photometer, and having in front of the aperture a convex mirror with foliated black screens as shown enlarged on the right of the figure. These screens are so designed as to produce on the photometer window an illumination proportional to the total flux received by the hemisphere. A full description of the method has been given by Benford.[2]

§ (121) The Focometer.—Another difficulty in the beam testing of searchlights is the necessity for ensuring that the arc crater is kept constantly in the same position with respect to the mirror. This can be done either with a special focometer fitted to the side of

[1] Paterson, Walsh, Taylor and Barnett, *Inst. Elect. Eng. Journ.*, 1920, lviii. 83. F. A. Benford, *Gen. El. Rev.*, 1919, xxii. 668.

[2] *Am. Illum. Eng. Soc. Trans.*, 1920, xv. 19.

the projector case, or by observation of the divergence of the resulting beam. The measurement of the surface brightness of the positive crater of a carbon arc is of very great importance, since, for a given angle of divergence, this quantity determines the brightness of the illumination produced by the beam at a given position. A method by which this quantity may be measured has been indicated in Part II. on "Photometric Standards" (§ 11). All searchlight photometry is affected by difficulties of colour difference, and the use of coloured glasses is general on this account (see § (102)).

IX. The Photometry of Fluctuating Sources of High Candle-power

§ (122) Photometer for Instantaneous Reading.—It is sometimes desirable to obtain an approximate estimate of the candle-power of intermittent or rapidly fluctuating sources such as flares, parachute lights, landing lights, etc. The photometry of such sources presents the special difficulty that photometric balance cannot be obtained except for a brief instant of time. Consequently any photometer involving the use of moving parts for adjustment to equality of two comparison surfaces is out of the question. The problem has been dealt with by a committee of the Illuminating Engineering Society,[1] who used a photometer of the form shown in *Fig.* 72. This consists

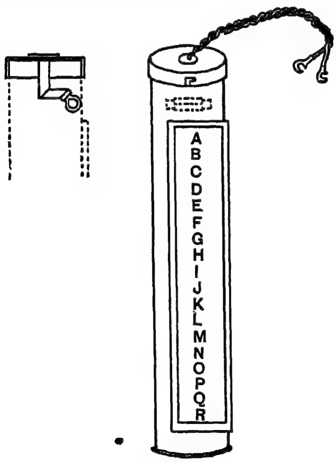

Fig. 72.

of a tube 25 in. long and 3 in. in diameter. The interior is whitened and illuminated by a small electric glow-lamp placed at one end as shown in broken line. A slot extending for nearly the whole length of the tube is covered by a strip of thin metal painted white and having in it perforations in the form of letters of the alphabet. Since the illumination inside the tube decreases gradually from top to bottom, the top letters appear brighter and the bottom letters darker than the surface surrounding them. An intermediate letter can be found at which the illumination of the interior of the tube is the same as that of the outside of the strip. This particular letter becomes practically invisible with a steady light, but with a flickering light the point of balance is continually moving up and down. Letters of the alphabet were chosen because they were monosyllabic and therefore quickly transmitted from the observer who had to watch the photometer continuously, and the assistant who wrote down the observations at close and regular intervals.

§ (123) Candle-power of Flares.—The flares on which tests were made by the committee burned for various intervals of the order of half a minute, and a typical curve showing the variation of candle-power during this time is given in *Fig.* 73. Candle-powers as high as 130,000 were dealt with. The results can be most conveniently expressed, for comparative purposes, in candle-power seconds per gram of composition, a particular example of flare being found to have the value 4000 for this quantity.

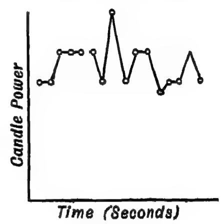

Fig. 73.

X. Measurements of Low Intrinsic Brightness

A third class of photometric measurement demanding special treatment is that in which the brightness of the luminous surface to be measured is very low (below 1 metre-candle). This problem arises, principally, in connection with the study and use of self-luminous compounds, either those depending on photo-luminescence or those in which the exciting agent is some radioactive material, generally radium and its disintegration products.

§ (124) The Colour Problem and Purkinje Effect.—It is impossible by any optical means to increase the brightness of a surface, so that as these luminous compounds, either in bulk or as applied to surfaces in the form of figures or other markings, have luminosities varying from 0·5 to 0·001 metre-candles or even less, the problem of accurate brightness measurement becomes a very difficult one. The difficulty is increased by the fact that the light given by these compounds is often

[1] A. P. Trotter, *Illum. Eng.*, London, 1918, xi. 253.

restricted to one part of the spectrum. Thus, for example, the light given by a compound in which a specially treated zinc sulphide is rendered luminescent by the action of radium is a very decided green (see article on "Radioactivity," § (15)), and as the brightness is below the limit of the Purkinje effect, it is necessary to ensure that the surfaces whose brightnesses are being compared are as nearly as possible of the same colour. It is also especially desirable, in the case of low brightness photometry, to ensure that the dividing line between the surfaces being compared shall be as fine and imperceptible as possible.

In the case of a luminous compound, the problem of photometric measurement requires different treatment according as the brightness of the compound in bulk or that of the markings of the finished design are in question.

§ (125) PHOTOMETRY OF LUMINOUS COMPOUND IN BULK.—In the first case the measurement may be readily made by means of the apparatus shown in *Fig.* 74. S is a sheet of

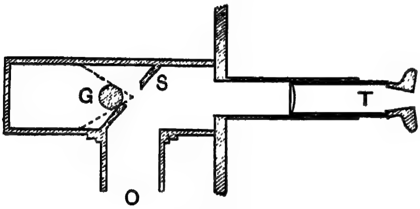

FIG. 74.

matt white celluloid, having at its centre an oblong aperture, so proportioned that when looked at through the telescope T it has the appearance of a small square. This aperture is cut with a sharp bevel to ensure as little separation as possible at the edges. The luminescent compound is contained in a glass tube G, and wedge-shaped guides are arranged inside the box to assist in placing it centrally behind the aperture in S, no matter what the diameter of the tube. The celluloid sheet S is illuminated by a standardised lamp, the light from which, after passing through a green glass or gelatine filter, enters the box at O. The illumination at S is calculated from the candle-power and distance of the lamp, the transmission ratio of the green filter being determined by measurement of the brightness of a given sample of compound by a number of observers with and without the filter in use.

The only filter remaining is that relating the brightness of S, as seen in the direction of the telescope, with its illumination from the direction of O. This may be determined by measuring, with a surface-brightness photometer (see § (64)), the brightness of S as seen in the direction of T, and the brightness of a similar piece of white celluloid placed in the position of S but normal to the incident light. The factor obtained in this way embodies both the reflection ratio of the card under the particular conditions of use, as well as the reduction of illumination according to the cosine law. This form of apparatus is that used at the National Physical Laboratory,[1] but somewhat similar forms of apparatus, designed for the same purpose, have been described by Blok [2] and Clinton.[3] A method in which a circular disc of the material under test placed side by side with a disc of variable brightness has been described by Andrews,[4] while Dorsey [5] places the tube of compound in front of a surface of variable brightness.

§ (126) ADAPTATION OF THE EYE.—In all measurements of low intrinsic brightness the observer's eye must be "dark-adapted" by a lengthened stay (of at least a quarter of an hour, or more if the general illumination to which the eye has been previously exposed be very great) in the photometer-room. Further, as many radioactive luminescent substances are also photo-luminescent, the compound to be measured should be kept away from daylight or strong artificial light for at least half an hour before measurements are made. Luminous compound is generally measured while enclosed in a glass containing vessel. If new, the absorption of the intervening glass wall may be assumed as 9 to 10 per cent, but the action of the rays from the radioactive material is such as to cause a darkening of the glass with lapse of time so that the absorption may increase by as much as 1 per cent per month even when the glass is thin.

§ (127) PHOTOMETRY OF LUMINOUS-PAINTED DIALS.—The measurement of the brightness of the markings on a dial painted with luminous compound is again a special problem in photometry. No constant relation exists between the brightness of the original compound and the luminosity of the markings, and two dials painted with the same compound may have very different luminosities.

The apparatus used at the National Physical Laboratory [6] for the purpose of luminosity measurements of dial markings is shown in *Fig.* 75. L is an electric lamp, the light from which, variable at R, passes through a green filter F and illuminates two screens S, S, each consisting of two thicknesses of thin white paper with a space between them. This

[1] Paterson, Walsh, and Higgins, *Phys. Soc. Proc.*, 1917, xxix. 219.

[6] Paterson, Walsh, and Higgins, *loc. cit.*

arrangement ensures perfect diffusion of the light and an even brightness over the whole surface of the second sheet. In front of the

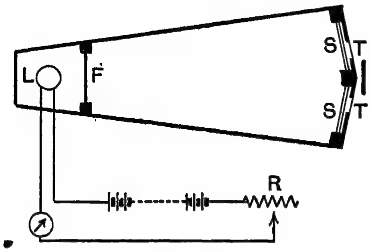

FIG. 75.

screens are placed two stencils T, T, each consisting of a sheet of thin brass with figures or markings cut out on an engraving machine so as to be identical with the luminous markings of the dials under examination. Two comparison dials are used, one on each side of the test dial, so as to overcome errors due to inequalities in sensitivity to green light on different parts of the retina. The instrument is calibrated by measuring, for different values of the current passing through the lamp, the brightness of the surfaces immediately behind T, T, using for this purpose a surface-brightness photometer. The surface brightness of the luminous markings of dials such as those used for aircraft instruments is between 0·2 and 0·05 metre-candles when the compound has been freshly mixed. The luminosity falls off with lapse of time, however, and dials which have been painted for six months or a year may have deteriorated in brightness so much as to be practically useless [1] for their intended purpose.

PIANOFORTE, THE

THE piano belongs to the percussion class of musical instruments in which the sound is produced by giving a sudden impulse to the vibrating system and then leaving it to itself —as contrasted with wind instruments, for instance, in which the vibration is maintained as long as desired by the continuous supply of energy. The sustaining power of percussion instruments is determined by the amount of energy that can be supplied initially and the way in which this energy is dissipated.

The piano is a development from the harp in which the strings were plucked by hand, the next stage being the spinet and harpsichord, in which the wires were plucked by quills. But this method of setting the wires in motion gave none of the light and shade so necessary for the artistic rendering of a musical composition. Hence the complications of the later harpsichord, in some of which by means of stops, as on an organ, the number of wires that were plucked when a key was depressed could be varied; also to some there was added a venetian shutter, which could be opened or closed by a pedal in the same way as the swell box of the organ. All this was done away with and control of the sound was restored to the performer by the substitution of a hammer for the quill, which was first effected by Christofori, an Italian, about 1709. From this original and very primitive instrument the pianoforte has developed by very many steps, generally small, the most important of which have been the inventions of the actions now used in the upright and grand pianos and the introduction of the iron frame. We shall return to these later.

§ (1) THE WIRES.—The original vibrators in the piano are the wires, or *strings* as they are called. There are three to each note from the treble down to about the 32nd note from the bass end (say to E in the bass clef). In long grands they continue another octave. Hence the term *trichord.* Each of these is a simple wire of high tensile steel, left hard from the last one or two drawings so as to give it as high an elasticity as possible. The breaking strain of a good pianoforte wire exceeds 140 tons per sq. in. The nineteen notes from D♯ down to about A in the bass have two covered wires to each note of steel about 1 mm. diameter wrapped with soft copper wire of ·6 mm. diameter. The last twelve notes have only one wire to each note; these are also of steel ranging from about 1·1 mm. to about 1·5 mm. diameter, but wrapped with copper of increasing size from 1·016 mm. diameter to 2 mm. diameter. The lowest notes of all pianos, except of some of the long grands, have two layers of the copper wire, and the total diameter of the wire may be as great as 7 mm.

When a wire is stretched between two fixed supports and set in vibration it will, as is shown in the text-books on sound, execute p vibrations a second, where $p=\sqrt{T/m}/2l$; l being the length of the vibrating segment in cm., T the stretching force in dynes, and

[1] See "Luminous Compounds," § (6) iv.

m the mass in grams of the wire per cm. length. The wire may, however, vibrate not only as a whole—in which case l will be the whole length L of the wire between the two supports—but can also vibrate in 2, 3, 4, or more segments, and then l will become L/2, L/3, L/4. Thus (neglecting rigidity) the same wire may be caused to give any one of a series of notes of which the frequencies are p, $2p$, $3p$, $4p$, p being the frequency of the wire when it vibrates as a whole. In all ordinary cases when a wire is plucked or struck with a hammer it does actually move in such a way as to be equivalent to the superposed effect of all these frequencies. Its equation at any time t is thus given by $y=\sum_1^n A_n \sin(2\pi nt/\mathfrak{T}) \sin(\pi nx/L)$, $\mathfrak{T}$ being the periodic time of the fundamental; the quality of the sound it will produce depends upon the relative amplitudes of the component terms in this series.

The maximum energy that can be given to a wire is dependent on the mass of the wire set into vibration; it can therefore be increased by using larger and longer wires. The three wires of each note are tuned to unison and struck simultaneously by the hammer; this is obviously a device for multiplying the energy which can be given to the wires and by them dispersed *via* the soundboard as a musical sound. The introduction of the iron frame, by making it possible to increase the tension on the wires, and therefore to use longer and heavier ones, is one of the chief factors which distinguishes the modern piano from that of say fifty years ago. But the increase in strength of the frame would have been useless unless the tensile strength of the wire had been increased to correspond, and if this strength can be still further increased it may be possible to get a still greater sustaining power.

The series above given only represents the motion of the wire to a first approximation, for the rigidity of the wires influences the pitch of the higher notes and of the upper partials of all the notes, causing the frequency to be higher than that given by the formula; for the restoring force due to the tension of the wire is augmented by that due to its stiffness, and although the latter has little effect on the long vibrating segments of the lower partials, it obviously will play an increasingly important rôle as these segments become shorter. Thus the higher partials of any string in vibration will be sharpened. The effect on the pitch is the same as if the wire were perfectly flexible and the stretching force increased by $\pi^3 r^4 Y/4l^2$ dynes, where r is the radius of the wire, l the length of the vibrating segment, and Y is Young's modulus of elasticity. This sharpening is not in general noticeable, for the amplitudes of the partials after the third or fourth is very small, and they can only be heard with difficulty. But should the cross-section of a wire be an ellipse instead of a circle, the rise in pitch due to the rigidity will be greater for vibrations executed in the plane containing the major axis of the ellipse than for those executed in the plane at right angles to this. Thus, as usually the wire will not be vibrating wholly in one of these planes, each partial will yield two frequencies differing slightly from one another, which will therefore beat with one another. This beating is easily heard, although the partials which give rise to it would otherwise have been too weak to be perceived, and, as it makes the wire sound out of tune, such a wire is described as "false." The only remedy is the replacement of the wire by another. It can thus be seen that the perfect circularity and uniformity of a piano wire is of great importance.

It is evident from the formula that as the frequency depends on the three factors—length, tension, and mass—any two of the three may be taken as independent variables and be chosen arbitrarily, and then the third can be determined to obtain the pitch required. In practice the tension is made uniform for all the strings of a piano; for pianos in which the tension is the same throughout have been found to keep in tune best, no doubt because with a uniformly distributed load, temperature variations affect the instrument as a whole and do not throw the notes out of tune with one another. The tension adopted by various makers range from 160 to 190 lbs. on each string. This is well below the limit of elasticity of all but the smallest gauge wires, as can be seen from the following table which has been extracted from figures given in Wolfenden's *Art of Piano Construction.*

Note and Number.	Length in Mm.	Diameter of Wire in Mm.	Breaking Strain in Lbs.	Actual Tension in Lbs.
C 88	5·40	·800	275	173
C 76	10·20	·850	306	173
C 64	19·25	·900	332	173
C 52	36·40	·950	366	173
C 40	68·80	1·000	384	173
C 28	131	1·050	410	173

The tension of the intermediate notes varies from 173 lbs., for the same gauge wire is always used for several successive notes, and as the lengths are increased in a regular manner, the sudden variation in the sizes of the wire has to be compensated by corresponding changes in the tension.

It might at first sight seem possible to keep to one size wire throughout and to use the length only as the factor to obtain the change in pitch. The wire for any note would then be double the length of the wire belonging to the octave above. This is nearly done for the upper octaves, but it must not be forgotten that rigidity plays an important part, and if this relation were adhered to, it would make the top notes too short and too stiff, and those of the lower octaves would be too limp as well as unmanageably long. The length of the wire is therefore graduated to the extent of reducing the ratio to 17 : 9 for all but the lower octaves. In order to allow of the use of wires of lengths following this ratio as far down towards the base as possible, the practice has arisen of "overstringing," that is to say, the bass wires are carried more or less diagonally across the tenor wires, the latter wires sloping some 20° to the vertical downwards to the left, while the former slope an equal or greater amount to the right. The change from the last wire sloping one way to the first sloping the other is called a "break," and as these wires pass over different and widely separated bridges on the soundboard, there is liable to be a serious difference between the sound yielded by those two notes, and it requires judgment and skill to minimise this. Other changes are for this reason usually avoided at this point; for instance, the change from the simple steel wire to the covered wire is often made four or five notes above this point.

Even with the extra length that overstringing gives, the lower octaves cannot continue to increase in length in the same ratio, in fact the wires of the last octave are practically all one length, the change in pitch being produced by the additional thickness of the copper wire which is wrapped round the central steel core. Sometimes in cheap pianos the makers lower the tension in this octave to reduce the weight of the costly heavy copper wire. In any case, except in the long concert grand, the resultant quality of the octave is usually poor; but these notes are of comparatively small importance as they are much less frequently used prominently, and are generally accompanied by the octave above, which helps to mask their poor quality.

Strips of felt are threaded in and out between the wires above the top bridge, and between the bottom bridge and the hitch-pin, to prevent these portions of the wire from vibrating; one or two makers have endeavoured to make the lower end of the wire equal in length to the part between the bridges, in the hope that this would form an additional resonator. It is difficult to see how such a wire can add to the initial energy, but it might help to avoid a useless dissipation of energy in the felt just referrred to.

§ (2) The Soundboard.—Although the wires are the original vibrators in the piano, their vibrations are themselves to all intents and purposes inaudible; for as the wire swings to and fro, the air in front of the moving wire slips round to fill the space left behind it by its motion, and no compressions and rarefactions of appreciable amplitude are produced in the air. To a slight extent the pressure of the wire on the fixed upper bridge transmits the vibration to the iron frame, thence it passes to the case of the instrument and the floor of the room, and these in turn transmit it to the air. But in the main the transmission of the vibrations of the wire to the air is by the medium of the soundboard, this thus plays almost as important a part in the speaking quality of a piano as does the body of the violin in the tone yielded by that instrument. The *soundboard* of the piano (as of the violin) is made of a wood in which the ratio of the elasticity to the density is as high as possible. Pine fulfils this best, and "belly-wood," as it is called, is usually Norway spruce, *Picea excelsa*, or sometimes *Abies pectinata*. The best trees are those growing in high altitudes on a mountain side where the growth is slow and regular. Before the war the best came from the Roumanian forests; some is now being obtained from British Columbia. The wood is cut on the quarter (*i.e.* radially) into strips 7 to 10 cm. wide and about 1 cm. thick, and these are carefully jointed up to form a more or less rectangular board with the grain running approximately parallel to the long bridge, that is from the top right-hand corner to the bottom left-hand corner at an angle of about 40° to the horizontal. This board is stiffened at the back by about ten parallel wooden bars, 2 to 3 cm. square, usually tapered off at the ends, which are glued across the soundboard at right angles to the grain of the latter. In gluing them on the makers attach great importance to "bucking" the soundboard—that is to say, making the front surface convex. The centre should be about 1 cm. above the edge. This curvature is produced in one or more of three ways:

(1) By planing the bars to a curve so that when they are glued on they shall tend to draw the board round to their own curvature.

(2) By the use of a concave table on which the board is laid while the bars are being glued on, and into which it is forced by the pressure of a large number of *go-bars* which are sprung in between the bars and the roof, as

shown in *Fig.* 1, where BB is the hollow-top table on which the soundboard CC is placed; AA is a firm wooden roof; DD are the bars to be glued on the back of the soundboard; GG, G′G′ are the *go-bars* which are sprung in between DD and the roof; E is a block of wood to prevent the go-bar from denting the bar.

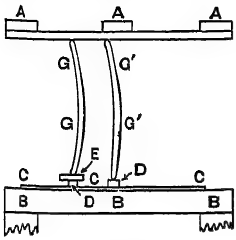

Fig. 1.

(3) By heating both the bars and the soundboard for some time before gluing. This causes the bars to expand lengthwise, and (by drying it) causes a contraction of the soundboard across the grain. So when the whole is cold and it has reabsorbed a little moisture it tends to curve.

This curvature helps the soundboard to sustain the pressure which is caused by the *down-bearing*, or the resolved part normal to the surface of the soundboard of the tensions in the wire; for in order to keep the wire well down on the bridge during its vibration the top of the bridge is left at such a height that it raises the wire a little (2 to 5 mm.) above its natural position. The pressure of the wires forces the bridge down, but it is considered fatal if it should be forced down so much that the soundboard becomes concave. The down-bearing is usually measured by the angle the two segments of the wire make with one another. This may be as great as 1½°.

The edges of the soundboard are fixed very firmly by hard wood fillets to the wooden framework or *back* of the piano, which back also carries the iron frame and is the foundation of the case of the instrument. Any want of rigidity round the edges of the soundboard will not only lead to a dissipation of energy in friction which should have been given out as sound, but may also cause noises which are difficult to locate and eliminate.

By placing the piano with its soundboard horizontal, scattering sand upon it, and then striking a string with a hammer, nodal lines are often obtained. This shows that to some extent stationary waves are formed, and that the soundboard does not vibrate as a whole, but that some parts of it are in a different phase to the rest. This partly explains a fact which at first sight seems curious, namely, that it has been found advantageous to limit the size of the soundboard. Usually the lower right-hand corner, and sometimes also the top left-hand corner, are either cut away or are prevented from vibrating by a heavy wooden bar glued on behind called a *dumb-bar*.

Just as the varnish on a fiddle is supposed to be of great importance, so some have held that the varnishing of the soundboard is also of great importance. But it seems doubtful if the varnish plays any other part than that of preserving it from damp.

Most makers seem to have had at some time the idea that by imitating the violin and using a double soundboard, with or without apertures, it would be possible to improve the piano; but all such attempts have been failures.

In order to give the greatest possible length to the bass strings, and at the same time to avoid the want of response which would be caused by placing the bridge close to the edge of the soundboard, the short bridge on which the overstrung wires are carried is usually a *floating bridge*. The meaning of this is shown in the diagram, where B is the fillet at the edge of the soundboard A, W the overstrung wire which passes over the bridge C and

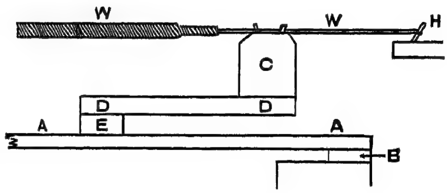

Fig. 2.

terminates at the hitchpin H. The bridge C, instead of being glued directly on the soundboard A, is carried on a thin board D, which is glued to a block E attached to the soundboard at some distance from its edges. This device enables the vibrations to be communicated to a flexible part of the soundboard and greatly improves the quality of the tone produced.

§ (3) The Hammer.—The oldest hammers were of wood covered with leather. The old hand-covered hammers were of wood covered with a number of layers, of which the inner ones were hard felt and the outer ones softer felt. The modern "machine-covered" hammer has only one layer of felt over the wood. The whole set for a piano is covered in one operation. The felt when first made is 10 to 15 cm. thick, but it is shrunk by the makers until it is about 2 cm. thick at the bass end, 3 to 4 mm. thick at the other. It is then cut to a roof shape as shown at BB, *Fig.* 3. It is glued and bent up round the row of hammers AA, being pressed upon them by hot metal moulds in a machine. Any degree of hardness required can be obtained by suitably regulating the pressure on the

moulds. When the glue is dry, the hammers are cut apart with a sharp knife. In this way a very regular gradation of weight, thickness, and elasticity from bass to treble can be obtained. Moreover, the density of the felt in any hammer is greatest in the centre of the felt next the wood, and gets less as the outer surface is approached. This is a very important matter, for it determines the relative intensities of the fundamental and the upper partials, or in other words, it determines the quality of the sound produced.

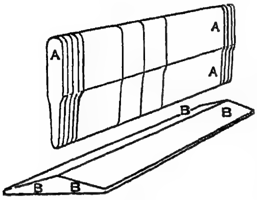

Fig. 3.

To understand the action of the hammer, stretch a wire thirty or more feet long with a small force—say a pound weight—gently pluck it near one end, and put a finger lightly upon it. The plucking will produce a pulse which will travel to and fro along the wire and can easily be felt each time it arrives at the finger. If it be struck with a rod a sort of momentary dent will be formed which will travel away along the wire in both directions from the point struck. When it reaches the end the dent will be inverted and return as a hump. In so doing it is evident that it will give the support an impulse, just as a man who is exercising with a pair of heavy dumb-bells can shake the floor by bringing them down or up suddenly. It is this reversal of the pulse in the wire each time it arrives at the bridge that is mainly responsible for the communication of the vibration of the wire to the soundboard. To return to our experiment, it is evident that while a smart blow with a metal rod will cause a sharp dent, a blow with a soft felt hammer (such as a bass drumstick) will cause a smooth dent of much less curvature. If the hammer were of such weight and consistency that the blow lasted for half the natural period of the stretched wire, while its strength gradually increased to a maximum and then died gradually away as the hammer rebounded, the pulse produced would have a length equal to the length of the wire; thus an analysis into the Fourrier series to which it is equivalent and which expresses the motion, would result in a series in which the amplitude of the fundamental was predominant; a similar analysis of the pulse produced by a metal rod would require a larger number of terms to represent it with any closeness. Thus if the sound produced when the piano wire is struck by the hammer is to be largely composed of the fundamental and the first one or two partials, the hammer must have suitable weight and elasticity. It should strike a blow which commences gently, rises to a maximum in a time which will vary with the pitch of the note, and then dies away as regularly. A moment's thought will show that if the outer layer be soft and curved so that it touches first at a point, the blow will commence gently, then as the blow proceeds, if the deeper layers are harder, the pressure will increase rapidly attaining a maximum at the moment of greatest compression of the felt when the hammer and wire are relatively at rest; after this as the hammer rebounds the pressure will die away. As the coefficient of restitution of felt is not very high, the force will be less during the rebound and the pressure-time curve will not be quite symmetrical.

The point of impact of the hammer on the string is of great importance. From about the 40th note from the bass end downwards to the bass end the string is struck at about one-eighth of the length of the speaking part of the string (that is the distance between the two bridges) from the upper bridge. From this note upwards towards the treble, the fraction of the length from the top bridge gradually changes until at the top it becomes one-fourteenth or even one-sixteenth of the speaking length. Helmholtz showed that when a string was struck at any given point every partial which had a node at that point should be absent, and he thought that by striking the string at one-seventh or one-ninth of the distance from the end these partials which are inharmonic would be eliminated; but it is obvious that this cannot be the controlling factor, since at one-eighth the partials eliminated would be in tune, and this is the fraction chosen for all those notes for which such partials would be most obvious. Now it is a fact that the amplitudes of the partials above the third and fourth in a good piano are relatively small, and though their existence can be proved by means of resonators, they are almost inaudible without such aid and are probably negligible. Thus it is much more probable that the point found most suitable is really determined by the motion of the hammer. The makers say that the treble notes become more brilliant when the wires are struck nearer the end. Towards the top notes of the piano the *thud* produced by the blow of the hammer is audible if the point of contact is not nearer the end of the string than one-eighth of its length, and this may, therefore, be another reason for the point of contact chosen for those notes.

§ (4) The Action.—The action now universally adopted for all upright pianos is developed from the action patented by an Englishman named Wornum in 1826.

Wornum's action is virtually an adaptation of an earlier one of Backer's for a horizontal piano. It was very nearly the same as the action illustrated, except that he continued the use of an inclined plane to throw the jack out of the notch of the hammer-butt. The bell-crank lever was first embodied by Erard in his grand action, and was not used in the upright action till much later. Wornum found it impossible to induce the English makers to adopt his action, and it was the French who took it up, so that it became known as the *French action.* Most English makers continued to use the old "sticker" action until nearly the end of the nineteenth century—long after Wornum's action had been adopted universally abroad. A good action (1) must give the performer full control of the blow, so that he can vary the intensity of the sound produced with ease and certainty; (2) must withdraw the hammer from the string immediately—even if the performer hold the note down—or the motion of the string will be damped by the hammer; (3) must not allow the hammer to bounce back and hit the string twice, unless a second movement is imparted to the key; (4) must enable the performer to obtain rapid repetition of the blow when desired, and (5) this repetition should be obtainable without waiting for the key to rise to its initial position. All this the Wornum action provides. When the front of the key K is pressed down the pilot P, which is screwed into the back end of the key, presses against the rocker A, which is pivoted at T. To the rocker is pivoted the jack J. The top of the long end of the jack rests in a notch in the butt B or hinge of the hammer, and thus pushes this up, causing the hammer to move towards the string FF′. Just before the hammer strikes the string, however, the rocker A brings the toe of the jack up against the set-off Q, and this causes the jack to rotate clockwise, and so lifts its top forward out of the notch of the butt B, leaving the latter free. This should happen when the hammer is 2 to 3 mm. from the wire, so that it is only the inertia of the hammer which causes it to strike the wire. It will then rebound and would fall back on the rail R were it not for the check C, which comes against E, which has been raised by the motion of A to which it is attached. In this way the hammer is held up a short distance from the string as long as E is held against the check C, *i.e.* as long as the performer keeps the key down. This has two important results: (*a*) it catches the hammer and prevents it bouncing back to strike the string a second time; (*b*) it holds the butt up so that as the key is raised the jack can fall back into the notch almost as soon as it is free of the set-off, and this enables the performer to cause the hammer to strike again without having first to let the key rise up to the top, as he would otherwise have to do. The damper D is carried on a wire inserted in a wooden lever hinged at M, and the lower end of this lever is pressed to the left by the spoon S when the rocker A is rotated.

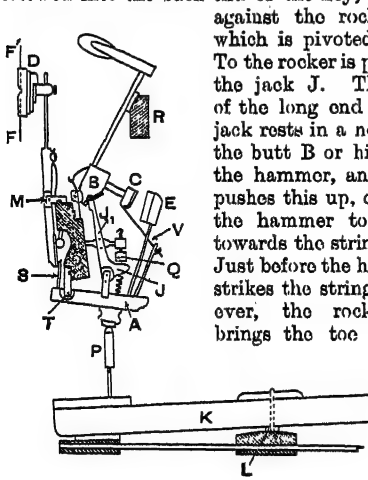

FIG. 4.

The hinges or *centres*, as they are called, of this action are made by brass wires passing through a hole bushed with thin cloth. This yields a smooth working hinge free from back-lash and noise. The bearing surfaces of the several parts of the action are covered with soft fabrics to avoid noise. The top of the notch in B into which the jack falls is lined with doe-skin, as it has to transmit the blow, but the back of the notch is lined with soft felt, as it merely has to receive the end of the jack and stop it as noiselessly as possible.

An interesting point arises in regard to the best position for the interface between the pilot P and the foot of the rocker A. In order to reduce wear at this surface it is obvious that there should be no sliding motion between P and A, and that it should be a pure rolling one if possible. Now P is rotating about the fulcrum of the key K, while the rocker rotates about the centre T, so that to produce a rolling motion the point of contact between P and A should lie throughout the motion on the line joining T and L. This determines the depth of the foot of the rocker. (It should also determine its curvature, but this is usually ignored.) The same consideration applies to the point of contact between M and S which should lie on the line joining the centres M and T; also to the contact between J and Q which should lie on the line joining T and the centre or hinge of the jack.

An important feature of this action is the tie V, which has two objects: firstly, as the hammer is only about 3° from the vertical when it strikes the wire its weight cannot help it to come away after the blow, and if the blow were a gentle one it might be too slow in returning after the blow; and secondly, the jack might get below the butt instead of merely falling into the notch. Hence Wornum provided the string to connect the hammer

block with the rocker, and so to prevent any such undue separation.

§ (5) THE GRAND ACTION.—This beautiful action was invented by Sebastian Erard in 1827 and is now used almost universally. The underlying principles are the same as those of the upright action, already described, but the mechanism by which the results are achieved was quite original. *Fig.* 5 shows a modern form of this action which is almost identical with the action as Erard left it. The wippen 2

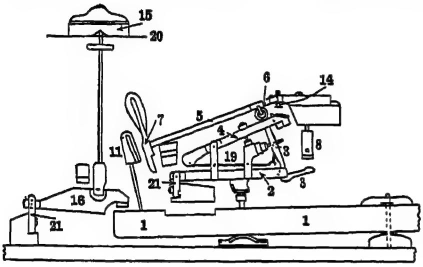

FIG. 5.

which is pivoted at its rear end to the flange 21 carries the jack 3, which presses against the roller 6 attached to the hammer shank 5, and so causes the hammer head 7 to strike the string 20 when the key 1 raises the wippen 2. Just before this happens, the toe of the jack 3 comes into contact with the button 8, and this rotates the jack clockwise and removes it from below the roller 6; so that the hammer is quite free when it strikes the wire. After the blow it falls back upon the check 11. The repetition lever 4, which is pivoted near its middle to an upright fixed on the wippen 2 (and therefore moves with it), assists the check in holding up the hammer for a repetition of the blow. This it does because its front extremity comes into contact with the rail 14 before the jack reaches the button 8, and being held up by spring 19 it remains in contact until after the jack has left the button. The damper 15 rests on the top of the string, and is lifted by the lever 16, which is pivoted to the flange 21 and lifted by the far end of the key 1.

R. S. C.

PIANOFORTE: a stringed musical instrument in which the sounds are excited by felt-faced hammers striking the strings and then leaving them to vibrate. See "Sound," § (29); also previous Article.

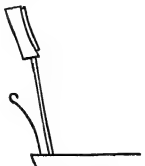
PIANO-PLAYER, THE

§ (1) DEVELOPMENT.—The piano-player has developed from the old barrel-organ, in which the music to be played was produced by opening the pallets by stiff wires set in a wooden or metal barrel. A patent was taken out in 1694 for a machine for playing on any keyed instrument, including the virginal and harpsichord, so that mechanical players are of some antiquity. The pierced paper rolls appear to have first been used for wind instruments. The openings in the rolls were passed over other openings communicating with chambers in which harmonium reeds were placed. The air was able to pass through the reed and cause it to sound when the opening in the paper came over a hole. The paper rolls evidently could not be used to strike a note on a piano directly, but it is obvious that the admission of the air through a cut in the paper could be used to operate a bellows to strike a note. In 1863 Fourneaux in France took out a patent for striking a note on a piano by the aid of air; but it was Gally of New York in 1881, Bishop and Down in England in 1885, and Kuster of New York in 1887 that really developed the pneumatic player. The player was sold as an independent instrument up to 1902, and even after that date many separate players were sold. Gradually, however, its incorporation into the piano itself has become universal.

§ (2) PNEUMATIC ACTION.—The main principles of the pneumatic action had been developed by the pipe-organ builders; it was the provision of means for varying the force of the blow, traversing the music roll over the tracker-bar, adjusting and varying the tempo, and emphasising the melody, which required to be developed in order to make the player a satisfactory instrument.

The mode of action of the player is shown in its simplest form in the accompanying figure (1). A long sheet of thick perforated paper 2 travels from the music roll 3 to the take-up spool 1 over the tracker-bar 4. This bar is pierced with a row of 88 narrow slots about 3 mm. apart, each hole corresponding with one note on the piano which it is to actuate. When a perforation in the paper passes over one of these slots, it allows a little air to enter the duct 5, which communicates by the tube 6 with the primary chamber 7. This chamber is divided into two parts by the thin flexible circular diaphragm 8. The upper part of this chamber 9 is maintained partially exhausted of air, so the sudden difference of pressure between the upper and lower parts of this chamber lifts the diaphragm. Just above this diaphragm is the lower end or disc of the dumb-bell-shaped primary valve, which is therefore also lifted. The movement of the valve closes the communication between the valve tube 12 and the exhausted primary chamber 9, and puts it into connection with the atmosphere by the lifting of the upper end 11 of the valve. Air is now able to pass through the valve-tube 12 into one side, 14*a*, of the secondary pneumatic chamber 14. This chamber is also divided into two parts by

the secondary diaphragm 13; the part 14*b* is kept partially exhausted of air, and thus, when air is admitted to the other side of the diaphragm, the difference of pressure causes it to move, carrying with it the secondary valve 15, 16 to which the diaphragm is joined. This movement closes the opening from the open air to the channel 17, and puts this channel



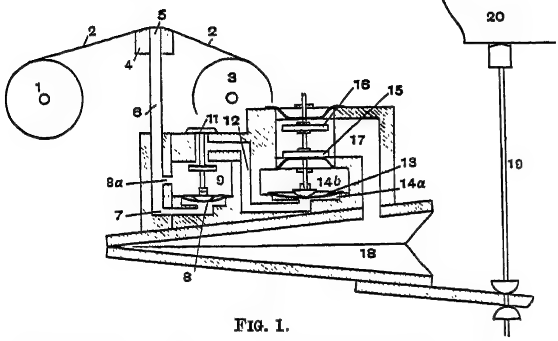


FIG. 1.

into connection with the exhausted chamber 14*b*, so that air is withdrawn from the pneumatic 18, causing it to collapse, and to lift the action 20 by means of the connecting rod 19. There is a tiny hole 8*a* called a bleed-hole connecting the chamber 9 with the tube 6; so that when the perforation has passed across the aperture in the tracker-bar and the slot is once more closed the pressure becomes equalised on both sides of the diaphragm 8. This then falls and allows the primary valve to fall also. The air is therefore sucked out of the tube 12, the valve 13 is drawn back, and the pneumatic 18 is allowed to open, ready to give another blow. All this is very similar to the operation of the pneumatic action in the larger pipe-organs.

§ (3) BELLOWS AND RESERVOIR.—The two chambers 9 and 14 of *Fig.* 1 are kept ex-

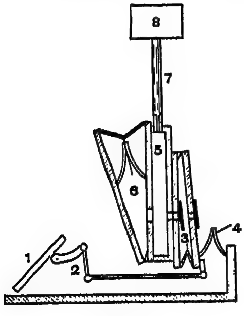

FIG. 2.

hausted by being connected through the action-box 8 (*Fig.* 2), trunk 7, and the bellows-board 5 to the reservoir 6.

The reservoir is a bellows kept open by a spring; the air has to be continuously removed from it by working the foot-pedals 1, which through the pedal-bars 2 force open the bellows 3 against the pressure of the spring 4. The pneumatics of a pipe-organ are worked by air, which is at a pressure of about 30 cm. of water above that of the atmosphere; but while it is obvious that both primary and secondary pneumatics might be arranged to work with an air pressure which is either above or below the atmospheric pressure, the latter is now always used in players, as the reduced pressure holds the music roll down against the tracker-bar, and leakage is avoided.

§ (4) MOTOR.—To carry the music roll from the roll 3 on to the take-up spool 1 of *Fig.* 1, the latter is rotated by a pneumatic motor, which is also driven by air passing to the reservoir 6. The motor consists of five simple bellows

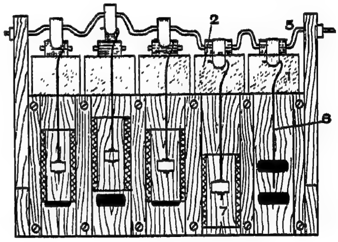

FIG. 3.

1, 2, etc. (*Figs.* 3 and 4), each joined by a connecting rod 4 to a five-throw crank-shaft 5, the cranks being at 72° to one another. The same shaft works slide-valves 7 by arms 6, which alternately admit air to each of the bellows and put it into communication with the reservoir through the exhaust 8.

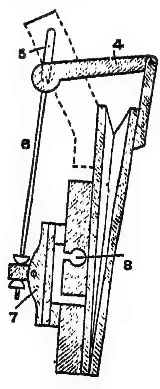

FIG. 4.

§ (5) EXPRESSION.—The player as it has so far been described would run at a constant speed, strike every note with the same force, and altogether fail to pick out a melody. Thus although its execution might be perfect, it would give none of the light and shade and no variety of tempo (except such as might be incorporated

into the original cutting of the original music roll). In fact, it would, artistically, be a failure; for although the soft pedal in the modern piano throws the action forward and so shortens the blow, this alone would be insufficient. A much greater range of power can be produced by the rate at which the bellows are worked; but the change of air pressure so produced would, of course, alter the speed as well as the blow. Some means of adjusting the air pressure of the motor independently, and also that of the chamber 14 (of *Fig.* 1) of the secondary pneumatic which actuates the final pneumatic 18, is therefore essential. This is achieved by the pressure-control valve of which the action is illustrated in *Fig.* 5. There is a chamber 2 communicating both with a small bellows 3 and with the reservoir through the rectangular aperture 1. A spring connects the top of the bellows with a lever 6. The top of the bellows is also connected with a knife-valve 5

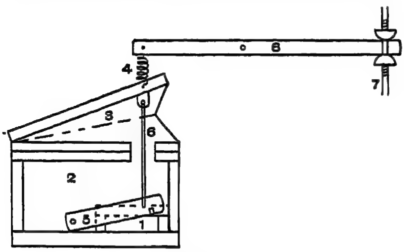

FIG. 5.

by the rod 6. As the pressure diminishes in 2 the pressure of the atmosphere on the outside of the bellows causes it to collapse and to close the valve 5, so stopping the exit of the air. Thus the pressure of the air in 2 is maintained constant; the actual pressure depends upon the position of the lever 6, which latter is joined by the rod 7 to a lever under the control of the operator—generally at the front of the keyboard. One of these valves is put between the motor and the reservoir. It controls the tempo at which the piece is to be played and is set at the beginning of each roll. A second one is put in series with this to enable the operator to produce accelerations, or retardations, or even pauses, in the piece at pleasure. One or more similar valves control the supply of air to the final pneumatic 18 (*Fig.* 1). Frequently there is one to affect all the upper notes on the piano and another to operate upon the lower notes.

§ (6) SOLO DEVICE.—For playing some chords louder than others, or a melody louder than the accompaniment, there are numerous devices. Only two can be described here. In one of these the note or notes to be emphasised are cut a little behind the other notes that should be played together, as shown in *Fig.* 6, where 5, 6, are to be played quietly, but 2, 3, 4, are to be emphasised. The slots of the latter being a little behind those of the former, the corresponding pneumatics will act a fraction of a second later. At the edge of the music roll there is an extra perforation 1, which

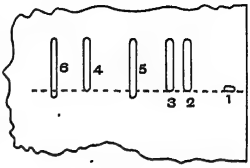

FIG. 6.

actuates a special pneumatic whose function it is to change over the secondary pneumatic chamber 14 (*Fig.* 1) from communication with one of the control-valves just described (*Fig.* 4) set at a lower exhaustion, to a second valve set at a high exhaustion. Thus after the blows have been given by 5 and 6 with a small pressure difference, the other notes are struck with a greater force. The pneumatics for the louder notes will be actuated a little later than the rest. Though this later speech of the emphasised notes might not necessarily be disagreeable, it is possible that the notes are actually struck almost simultaneously, for although the hammers of these notes will start an instant later, yet as they are given a greater velocity they may reach the wires and strike the notes at the same time as the quieter ones.

The second method makes use of a group of perforations at the side of the tracker-bar as shown in *Fig.* 7. The perforations of the

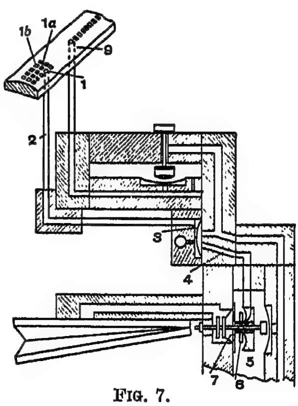

FIG. 7.

notes themselves which are to be emphasised are not altered in any way. Each of the side perforations 1 admits air through a tube 2 to a primary pneumatic 3, which in the usual way actuates through 4 a secondary diaphragm 5. This diaphragm lets a plate 6 come down upon the opening 7 and closes it. The plate

is pierced with a small hole only, and when it closes the opening 7 it obstructs the passage of the air, and only allows the pneumatic 8 (which will be actuated if a perforation arrives over the opening 9 in the tracker-bar) to close gently. Thus if the aperture 9 is opened while 1 is closed, the note is struck gently, but if 1 is open the note is struck loudly. It might be thought that as the perforation which is to open 1 has to pass over the other holes 1*a*, 1*b*, it might cause other notes to be louder than those desired; but if the distance between 1 and 1*a* is less than the time interval between two notes on the roll, this cannot happen. For it will not affect the note if 1 is open either before or after its note is struck, it is only operative if 9 is opened while 1 is open. It is obvious that this is a more complicated way of producing emphasis, but it is a positive method. To some extent it does involve taking liberties with the timing of the notes, in order occasionally to avoid emphasising a note that does happen to require a perforation that would have acted just when the side perforation was passing over its solo hole.

§ (7) Tracker Device. — It is of course essential that the paper roll shall register correctly with the tracker-bar, so that the slots cut in the music roll may pass exactly over the holes they are intended to open. To accomplish this, two holes (1 and 2, *Fig.* 8)

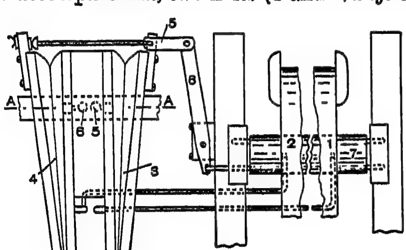

Fig. 8.

are added to the bar; they are close to the edge of the roll and are covered by the roll when it is in its correct position. The holes are connected with the bellows 3 and 4 by tubes as shown. The bellows are normally kept exhausted by small bleed-holes (5 and 6) connected to the air reservoir. When the paper does not go quite straight, it opens one of the holes, 1 or 2, and the corresponding bellows begins to close slowly. By means of the bar 5 (which joins the bellows together, and so has been balancing their pulls) and the lever 6 the tracker-bar is caused to slide along, until it once more registers with the music roll.

§ (8) Electric Players.—These have also been made, a brush making contact with a metallic plate through the perforations. In the earlier machines the current energised an electromagnet which acted directly upon the piano action. This was very unsatisfactory, as if it was attempted to reduce the blow by reducing the current the armature might not be moved at all, on account of the rapid decrease of attractive force with the distance. In an interesting player a metal cylinder is kept in continual rotation. The armatures are arranged a little below and in front of this cylinder. Loose straps pass from the armature over the cylinder to the piano action. When the armature is energised the strap is gently tightened, and the friction of the revolving cylinder rubbing against the strap lifts the action and strikes the blow. Power is of course supplied by motors, which can be controlled either by varying the current or by brakes.

§ (9) Automatic Recording. — Electricity has been very successfully applied to recording the actual performance of a pianist. Contacts on the piano keys are connected to electromagnets in a punching machine, so that the exact instant when the note is struck, the length of time that the key is held down, the use of the pedals, and the minutest variations in tempo are all recorded. In reproducing such a record the operator has therefore only to concern himself with the intensity of the blow.

Many records have the music printed upon them, so that the operator can render the expression more intelligently. This is especially necessary in records which are intended to be used as accompaniments to the voice or violin.

POLARIMETRY

§ (1) DESCRIPTIVE AND HISTORICAL.—When certain crystals and liquids are placed between crossed Nicol prisms, the light will not in general remain extinguished. If the light source is homogeneous, or approximately so, by rotating the analyser (*i.e.* the polarising prism nearer to the eye, the farther one being called the polariser) a new position is found where complete extinction is again obtained. This can be explained by regarding the crystal or liquid as having rotated the plane of polarisation of the light as it passed through the substance.

The phenomenon can be illustrated schematically by means of *Fig.* 1. Consider the case

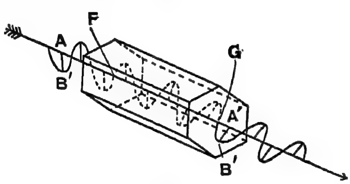

FIG. 1.

of a plane polarised beam of light passing through a crystal of quartz along its optic axis, the beam before entering the quartz being polarised in the azimuth perpendicular to AB. The plane of vibration is in the plane of AB. When the light enters the quartz, this plane is gradually orientated by an amount that is proportional to the thickness of quartz traversed, until it emerges at G, with the direction of the vibration now lying in the plane A′B′. Now that the light has left the "optically active" quartz, the plane of vibration of the farther course of the beam will be that of A′B′; and the plane of polarisation will be rotated, by passage through the quartz, by an angle equal to that between AB and A′B′.

Arago [1] observed in 1811 that the effect produced when a plate of quartz cut perpendicularly to its axis is placed between a polariser and analyser differs from that caused by a plate of mica in the same position.

Biot [2] was the first, however, to point out, in 1812, that a rotation of some kind was involved; he showed [3] also, in 1915, that this property was exhibited by turpentine and a number of other substances. The rotation depends on the thickness of active medium traversed and on the wave-length of the light being inversely proportional (approximately) to the square of the wave-length. The name Rotatory Dispersion has been given to this property.

Biot's polarimeter [4] had as polariser a plate of black glass, set at the polarising angle, viz. the angle at which polarisation was most complete. This was connected with a fixed divided circle by means of a V-shaped trough in which tubes containing liquids could be placed. The "analyser" consisted of a double-image prism, a prism, that is, giving two images, one formed by the "ordinary" and one by the "extraordinary" beams, these being polarised in planes perpendicular to each other. This prism was mounted in a tube carrying an index arm by which the angular rotation of the analyser could be read on the divided circle. The analyser was rotated until the image of the light source formed by the extraordinary beam was most near to extinction. When the optically active substance was placed in the trough, the image (from the extraordinary beam) would again appear, and the analyser rotated until extinction was obtained once more. It was with this very simple apparatus that Biot made the elementary observations that are of fundamental importance in polarimetry.

Ventzke [5] shortly afterwards employed Nicol prisms as polariser and analyser, thus securing *complete* polarisation at the polarising end, and the elimination of the double image at the analyser.

[5] Ventzke, *Erdman's Journ. für praktische Chemie*, 1842, xxv. 65.

Mitscherlich[1] was the first to appreciate the importance of monochromatic light in polarimetry; he also improved the illumination by placing a convex lens at the polariser end. Landolt, in using the Mitscherlich instrument, determined the point of extinction by setting the dark band of complete polarisation central in the field, and this was the forerunner of the accurate method used by Landolt in the construction of his polarimeter (cf. *infra*). The mean error in the readings with the Mitscherlich instrument was about 0·1°.

The Soleil[2] double quartz plate, or "biquartz," was added to the polariser by Robiquet,[3] and the polarimeter was thereby made much more sensitive.

§ (2) THE BIQUARTZ.—Biot had observed that the yellow rays of white light were rotated through an angle of 90° by a plate of quartz 3·75 mm. thick. Soleil's biplate, which utilised this effect, consisted of two semicircular discs of quartz of that thickness, the one half being right-handed quartz (*i.e.* quartz that orientated the plane polarised beam in a clockwise direction as viewed by the observer) and the other left-handed quartz. The principle underlying its action can be seen from *Fig.* 2. Let AA′ be the

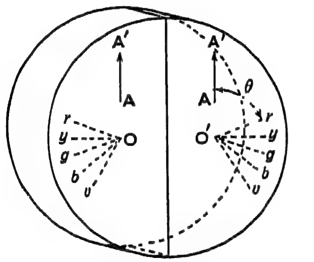

FIG. 2.

plane of polarisation of the white light entering the biplate. On emerging from the biplate the planes of polarisation of the red, yellow, green, etc., rays are indicated by dotted lines drawn from O and O′, the points of emergence of the rays. Owing to the structural difference in the two kinds of quartz, the planes of polarisation are rotated in opposite directions, the one phenomenon being a mirror image of the other. When the analysing nicol is parallel to the polariser, the yellow rays (which have been rotated an angle of 90° to AA′) will be cut out entirely. A portion of the light intensity of the red, green, and other rays will, however, be transmitted, the intensity transmitted being proportional to $\cos^2 \theta$, where θ is the angle that the plane of polarisation (of any particular wave-length), after emerging from the quartz, makes with that of the analyser. The resulting colour of both halves of the field is rose-lilac or amethyst.

In this position θ is, for the red rays, a little less than 90°, and for the green and green-blue a little more than 90°, while for all these rays $90 - \theta$ is not more than 45°.

Thus in the right half of the field a slight rotation of the analyser in a clockwise direction will cause the intensity of the red rays rapidly to increase, and that of the green and green-blue to diminish appreciably, the result being a very rapid change to a distinctly red hue. For a like reason the rotation causes the left half of the field to change as rapidly to a distinct blue.

Thus in the sensitive region where measurements are made the two halves of the field will have the same colour or tint only when the analyser is parallel to the polariser. If now an optically active substance be interposed, equality of tint can only be obtained by a rotation of the analyser to compensate for the rotation of the active substance. When the thickness of quartz is, as described above, so chosen that the yellow rays are extinguished by an analyser that is parallel to the polariser, the residual colour is exceedingly sensitive, turning either red or blue with a very slight rotation of the analyser. For this reason it has been called the sensitive tint, *teinte de passage*, or *Übergangsfarbe*. In order to have a complete explanation of why the 3·75 mm. quartz plate gives the most accurate results, the following factors must be considered: (1) Rotatory dispersion of quartz; (2) energy distribution of the white light spectrum; (3) relative sensibility of the average eye to radiation of different wavelengths. These together with the Malus $\cos^2 \theta$ law and the three primary sensation curves (red, green, and blue), such as given by Exner,[4] will give the change of tint with a given rotation of the analyser, by the method indicated by Ives.[5]

The disadvantages of this type are at once apparent: it must be used with white light, and the rotation obtained is approximately that for mean yellow light. Even if colourless substances are examined, there is no position of the analyser for which the tints in both halves of the field are the same, because of the rotatory dispersion of the substance itself, and thus systematic errors are introduced, of a kind extremely difficult to determine. This difficulty is considerably

increased when the substance is coloured. While it is almost impossible for a colour-blind person to use this method, there will be perceptible differences in the readings of normal persons, as the relative sensibility curves of individual eyes (to radiation of different wave-lengths) show considerable variation.

For these reasons the Soleil double plate is never employed in modern measurements.

§ (3) Jellett's Prism.—The next and probably the most important development in polarimetry is due to Jellett,[1] who utilised the photometric principle of matching two illuminated fields by varying their relative intensity. The eye is able, under favourable conditions, to detect very small differences of intensity (when no colour difference exists), and it is this principle that underlies the construction of all modern polarimeters and saccharimeters. A rhomb of Iceland spar is cut so as to form a right prism, as in *Fig.* 3. It is then cut in two in a plane B′BC parallel to the long edges of the prism and making a small angle a with the longer diagonal DD′ of the upper face. The one part is then

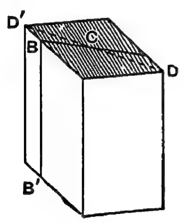

Fig. 3.

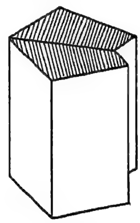

Fig. 4.

reversed, and cemented to the other as shown in *Fig.* 4. This composite prism is then mounted as the analysing prism, and the dividing line observed by means of a lens. This analyser receives a parallel circular beam from the polariser, and this beam is divided into four parts as in *Fig.* 5. The ordinary beams (one through each prism) remain central and symmetrical about the vertical interface; while the extraordinary images are refracted to the positions E and E′. These extraordinary images can be screened off by means of a suitable diaphragm at the eye side of the analyser.

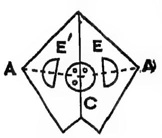

Fig. 5.

Let (in *Fig.* 6) CD represent the plane of polarisation of the polariser, and OA, OB the planes of polarisation in the two parts of the Jellett analyser. The two halves of the field will appear equally bright if the components of OA and OB on CD are equal, *i.e.* if OA is taken to equal OB, then they both make equal angles with CD. If now the analyser is rotated so that the polariser is in a position C′D′ with respect to OA and OB, the components of the latter (C′O, OD′ respectively) are no longer equal, the ratio of brightness being given, according to the law of Malus, as $(C'O)/(OD')^2$. It will be seen that under these conditions an equality of brightness in two halves of the field affords a sensitive means of determining optical rotation.

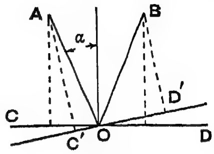

Fig. 6.

§ (4) Cornu's Prism.—Cornu[2] improved on Jellett's original prism, using a Nicol prism instead of the natural rhomb, the Nicol prism being divided in two in the same way as in Jellett's rhomb (*Fig.* 3). Instead of reversing the one half so as to have a resulting prism of the inconvenient and wasteful shape shown in *Fig.* 4, Cornu removed a thin wedge of spar, the apex of which was parallel to the long edges of the prism (see *Fig.* 7). The two parts were then cemented together without reversal, the planes of polarisation of the two parts making an angle with each other equal to the angle of the wedge of spar removed. This composite prism was placed at the polariser end, and a Nicol prism being used as analyser, the net result is much the same as that of the Jellett arrangement previously described, with the main differences that the double images of the Jellett prism are entirely eliminated, and that while Jellett used his prism as analyser, Cornu used his as polariser. This form of polariser is generally known as the Cornu-Jellett prism, and it remains in common use up to the present time for inexpensive polarimeters and saccharimeters.

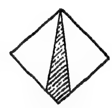

Fig. 7.

It is evident that the angle between the planes of polarisation of the Cornu-Jellett prism is fixed. This angle is called the "half shadow" angle, since to it is due that at the critical position of matching the field is neither dark nor yet completely illuminated. If this angle has been made comparatively small (say 2°-3°) in order to obtain greater sensitiveness, the prism may become no better than an ordinary nicol for examining the rotation of a light-absorbing substance, since the brightness of the field at the matching point, compared with the maximum brightness obtainable, is proportional to $\sin^2(a/2)$, where a is the half-

[1] Jellett, *Proc. Roy. Irish Acad.*, June 25, 1860; *ibid.* Jan. 22, 1863. The description of the use of this prism usually given seems to originate in an incorrect reading of *Rep. Brit. Assoc.*, 1860, ii. 13, and is incorrect.

[2] Cornu, *Bull. Soc. Chim. Paris*, 1870, xiv. 140.

shadow angle. Further, as will be seen later, it is not desirable to make this half-shadow angle too great, as the sensitiveness is reduced proportionately.

§ (5) THE LAURENT POLARIMETER.—In order to overcome this defect in the Cornu-Jellett polariser, Laurent [1] used a quartz plate covering half of a plane polarised beam from a Nicol prism. The principle can be understood from *Fig.* 8. The quartz plate A, whose optic axis lies in the plane of the paper, and has a direction OB, covers half of the circular aperture of the field of the Nicol prism in front of it. The thickness of the plate is chosen so that the difference between the paths of the ordinary and extraordinary rays, into which the incident plane polarised beam is divided, is some odd multiple of half the wave-length of the light that is used. If n_o and n_e are the refractive indices of the ordinary and extraordinary rays in the quartz for a given wave-length λ, then

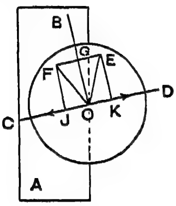

FIG. 8.

$$\delta = d(n_e - n_o) = (2m+1)\frac{\lambda}{2},$$

when d is the thickness of the plate, and δ the path difference introduced. For the sodium light D_1 and D_2 the minimum thickness is 0·0324 mm., but, as this plate would be too thin and fragile in practical use, some *odd* multiple of this thickness is chosen so that the plate is approximately ·5 mm. thick.

Let OE represent the plane of polarisation, and its length the amplitude of the linearly polarised homogeneous light coming from the polariser, whose plane of polarisation makes an angle $\theta/2$ with the optic axis OB of the quartz plate. The plane polarised beam, the direction and amplitude of which is given by OE, will, on entering the quartz plate, be divided into two parts, the one polarised in the plane of the optic axis OB and the other perpendicular to it in the plane CD. Thus OG and OK will represent the amplitudes and directions of the components at the moment that OE enters the plate. These components are in phase with each other.

Since the component of the beam represented by OK is accelerated in its passage through the quartz by an amount $(2m+1)\lambda/2$, m being an integer, as compared with the extraordinary ray OG, the position at emergence can be represented graphically by reversing the direction of OK, the components in phase on emergence being OG and OJ. Thus the resultant OF will represent the plane of polarisation after transmission of the beam through the quartz. If CD represents the plane of polarisation of the analyser, then a matching of the fields is obtained when the component OJ on CD is equal to the component OK from the unobstructed half of the field.

In order to vary the half-shadow angle, all that is required is to rotate the plane of polarisation of the polarising nicol; the angle that this plane makes with the optic axis of the plate is one-half the half-shadow angle.

This Laurent polariser, while allowing a variable half-shadow angle, is limited as to light source, the only permissible one being that for which the half-wave plate has been cut. The sensitiveness, as in all half-shadow polarisers, depends upon the magnitude of this angle, and on the intensity of the light source used. Heele [2] somewhat increased the sensitiveness by arranging the half-wave plate as a circular one mounted on a larger glass plate, as in *Fig.* 9 (i.), and Pellin has introduced the modification shown in *Fig.* 9 (ii.), when the retarding plate forms a ring around the centre of the field as shown.

FIG. 9.

When using a bright sodium light with a small half-shadow angle (about $1\frac{1}{2}°$) and taking the precaution suggested by Laurent of using a thin plate of potassium bichromate to cut off the other radiations of sodium, consistent settings can be made to within $\pm\frac{1}{2}'$.

Lippich [3] has, however, shown that the Laurent polariser cannot be relied on as an exact means of measurement. Since the relative importance of this type of polariser has become considerably smaller during the last twenty years, it will be sufficient to mention some of the main results of Lippich's analysis. The technical difficulties of making the plates perfectly parallel, with the optic axis lying exactly in the same plane, and of exactly the correct thickness for the particular wave-length chosen, are with modern methods perhaps not insuperable. But Lippich found that they certainly were not made with sufficient accuracy; and even had they been ideally perfect it would have been necessary, in order that different instruments might agree, that the thicknesses of all Laurent plates should be identical, and not merely *any* odd number of half-wave-length retardation. Again, even if agreement were thus secured, the precise significance of rotation measurements depended on a knowledge of the rotatory dispersion of the substance under test, which knowledge could not be obtained on instruments of the Laurent type.

Finally, one and the same instruments give different measurements of a rotation with different half-

[1] Laurent, *Journ. d. Phys.*, 1874 (I.), iii. 183; 1879, viii. 164; Dingler's *Poly. Journ.*, 1877, ccxxiii. 608.

[2] Heele, *Zeitsch. Instkde.*, 1896, xvi. 260.

[3] Lippich, *Sitz. Wien. Akad.*, 1890, abt. IIa, xcix. 695.

shadow angles. All these faults result from the imperfect homogeneity of all practical light sources.

Schulz[1] has recently examined the errors due to elliptic polarisation caused by the obliquity of the rays falling on the Laurent plate. He finds that if A is the diameter of the aperture or diaphragm at the polariser and B that of the analyser, and L is their distance apart, then if $A+B=\cdot023L$, the error caused by obliquity of the rays is not greater than $\cdot001°$. If A and B are to be the same, then for a polarimeter to take 200 mm. tubes (L=230 mm.) the value of $A=2\cdot6$ mm., for a 400 mm. instrument (L=430 mm.) A must not exceed 4·9 mm.

Notwithstanding the above criticisms, it cannot be doubted that the large discrepancies usually found in results with different Laurent polarimeters must be mainly due to defective manufacture and lack of purity of the quartz.

§ (6) Lippich's Polariser.—The polarising system of Lippich,[2] which is in general use in the best polarimeters at present, combines the advantages of a variable half-shadow angle, and freedom to use either a heterogeneous light source or homogeneous light of any desired wave-length.

In the Lippich system an ordinary nicol A (*Fig.* 10) is followed by a smaller nicol B covering half the field. The planes of polarisation of the prisms A and B make an angle θ with each other, and thus it is possible to employ the photometric principle of Jellett in measuring rotations, as has been previously described. In order to have a field of uniform brightness at the matching point, the nicol B must be so designed that all the rays followed back from any point within the diaphragm MN of the analyser must pass into A without any partial obstruction by the small prism B.'

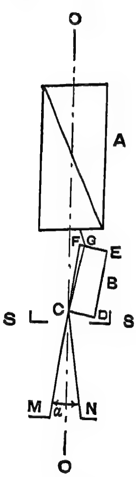

Fig. 10.

If $\alpha/2$ is the half-cone angle subtended by the analyser diaphragm at C, then in order that no light from A shall enter the analyser after external reflection at the surface CF the latter must make an angle with the axis OO′ slightly greater than $\alpha/2$ (say $(\alpha/2)+\beta$). If the ray NC traced back from the analyser is to pass through B, without internal reflection, then in order that the ray CG should make a small angle ϵ with the side CF the angle FCD must be suitably chosen. It is found that if ϵ and β are made about 10′, the angle FCD must be between 92° and 94°. This small prism is commonly called the "half Lippich prism."

Lippich improved on his original two-field system by having two half Lippich prisms B and C mounted as shown in *Fig.* 11. The resulting field (DEF) is divided into three parts.

The original intention of Lippich was that the planes of polarisation of the half prisms B and C should be slightly inclined to one another, so that if a match is made between D and E, the difference in brightness between E and F is just discernible. By this means the range of uncertainty in setting should theoretically be halved.

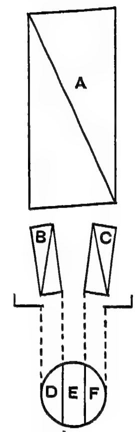

Fig. 11.

Perhaps the greatest advantage of the three-field system, however, lies in the fact that it enables the observer to correct any slight error in the alignment of the light source with the optical axis of the polarimeter. The distribution of the intensity of illumination over the field is liable to change rapidly with a slight displacement of the light source, and an error due to this cause would generally be far greater than that due to the lack of sensitiveness of the eye, especially if the observer has had some practice in making polarimetric measurements.

Lummer[3] has constructed a polariser with a field divided into four equal parts. This is done by adding to a double-field Lippich system two more very small half Lippich prisms each of which covers a field equal to a half of prism B in *Fig.* 10. These are placed at the outer edges so that the field is divided into four equal parts. In this polariser it is not a condition of uniform brightness that is aimed at, but the equally distinct appearance of two of the parts on a uniform background.

Whether this type of polariser shows any real gain of sensitiveness over the Lippich three-field polariser does not appear to have been adequately tested. The arrangement is too complicated ever to come into general use, unless its advantages were very real. In practice it is found difficult enough to adjust, and keep in adjustment, the Lippich three-field type.

§ (7) Variation of Sensitiveness with the Half-shadow Angle.—It has been mentioned that the sensitiveness or accuracy of setting with the photometric matching principle of Jellett depends on the half-shadow angle. It is generally assumed that the eye can recognise a difference of brightness of about 1 per cent when examining two adjacent fields.

[3] Lummer, *Zeitschr. Instkde.*, 1896, xvi. 209.

Let OA and OB (in *Fig.* 12) represent the planes of polarisation in each part, and their lengths represent their amplitudes which are assumed equal, and let AOA represent the plane of polarisation of the analyser when the two fields are equally bright. Then, if the analyser be rotated a very small angle δ into the position A′OA such that the beam originally polarised in the direction OA is, after passage through the analyser, just perceptibly brighter than that of the other half of the field, OA and OB will then make angles of $90-\theta-\delta$ and $90-\theta+\delta$ with the new plane of polarisation of the analyser. The ratio of the intensities in the two halves will be, according to the law of Malus:

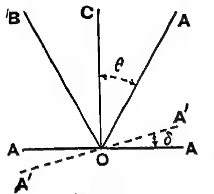

FIG. 12.

$$\frac{\sin^2(\theta-\delta)}{\sin^2(\theta+\delta)}=p,$$

which gives

$$\delta=\frac{(1-\sqrt{p})}{(1+\sqrt{p})}\tan\theta.$$

(In obtaining this expression, which gives δ in circular measure, δ is taken to be so small that $\cos\delta=1$ and $\sin\delta=\delta$.)

If p is taken to be ·99, which is equivalent to saying that 1 per cent change of intensity can be detected, then

$$\delta=\cdot 0025\tan\theta.$$

Remembering that θ in *Fig.* 12 is half of the half-shadow angle, the solid line in *Fig.* 13

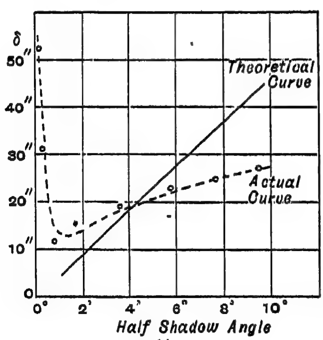

FIG. 13.

represents the kind of variation in sensitiveness with half-shadow angle that is to be expected on theoretical grounds. The actual curve of mean error (dotted line) given by Schulz and Gleichen [1] indicates that with a half-shadow angle of about 9°-10° the accuracy of setting is considerably greater than that shown by the theoretical curve. This shows that under favourable conditions the eye can detect a change of intensity of illumination of about ·75 per cent.

It is usually assumed that the cause of the rapid loss of sensitiveness as the half-shadow angle becomes less than 1° is that the general illumination then becomes too faint for accurate matching. The chief reason, however, is that with such half-shadow angles the effect of the elliptic polarisation becomes appreciable. The light incident on the analyser is assumed to be completely *plane* polarised, whilst in practice it is always to a slight extent *elliptically* polarised, to an extent depending on the total amount, and azimuth of the double refraction, present, between the oil or balsam film of the polariser and that of the analyser. There is also always a slight admixture of depolarised light. The effect as seen through the analyser can be regarded as merely adding an equal amount of general illumination to each field. This is not appreciably altered as the half-shadow angle is made to approach 0°, and as the intensity of illumination from the plane-polarised component becomes a smaller and smaller proportion of the total intensity of the field, the analyser has to be rotated a correspondingly greater amount before the eye can discern a change of intensity. This can be easily verified by observing the sensitiveness of a polarimeter with a half shadow of 2°-3° using a very poor light source, so that the field at the matching point is very dark. With such an arrangement a much higher accuracy will be attained than with a half-shadow angle of, say, ½°, even when in the latter case the light source is so improved that the intensity of illumination at the matching point is considerably brighter than with the larger half-shadow angle.

It can be shown that in consequence of the inequality of the intensity of illumination in the two halves of an ordinary Lippich polariser, a systematic error is made in the measurement of a rotation either if the substance under examination is slightly bi-refringent or if a small amount of accidental double refraction is otherwise introduced into the path after the zero reading of the polarimeter has been taken.

This has not yet been fully investigated, but it is found that with a half-shadow angle of about 3° and an ellipticity of 1/100 (ratio of minor to major axis) the error is of the order of 1′.

§ (8) WILDE'S POLARIMETER.—Other forms of polariser have been suggested from time to time, none of which, however, have come into general use.

In the form of polarimeter devised by

[1] Schulz und Gleichen, *Polarisationapparate und ihre Verwendung*, Stuttgart, 1919, p. 66.

Wilde,[1] both the polariser and analyser are ordinary Nicol prisms. In order to obtain an accurate setting, a Savart plate is mounted in front of the analysing nicol. As this consists of plates of Iceland spar or quartz, the optic axes of which make an angle of 45° with the direction of the light, and whose principal sections are at right angles, a system of interference fringes is seen in general. When the plane of polarisation of the beam from the polarising nicol coincides with the principal section of either of the plates, the fringes disappear at the centre of the field. By reducing the intensity of the light source, the breadth of the band showing no fringes can be considerably narrowed, and this can then be set symmetrically with respect to a pair of cross lines placed at the focal plane of two lenses that form a telescopic system interposed between the Savart plate and the analysing nicol.

The instrument can be used with a homogeneous light source of any wave-length, and has the great advantage that a strong light source is not required. Considerable practice is required before the observer can obtain an accuracy of setting comparable with that of a half-shadow polariser, as the termination of the fringe system is not sharply defined. For this reason the Wilde instrument is very rarely used.

§ (9) Landolt and Lippich.—Landolt[2] observed that when a very intense light source is examined by a pair of wide-angled Nicol prisms, the field, instead of being uniformly dark, is crossed by a narrow black band only. This was first explained by Lippich,[3] who showed that, due to the varying obliquity of the rays incident on the prism, the directions of vibration at different parts of the field were not strictly parallel. He showed further that in the case of Nicol prisms whose end faces were perpendicular to the axis of the prism the direction of the vibration was represented by a system of converging lines which met at a point P outside the prisms. The direction of the plane of polarisation will therefore be given by arcs of circle with P as centre. In *Fig.* 14 the solid arcs *abcd*, etc., will indicate the direction of the plane of polarisation at any point in the field.

A similar state of affairs holds in the case of the analyser, when the *dotted* arcs *a'b'*, etc., will represent the direction of the planes of polarisation of the analyser at various points in the field.

It will be noticed that these two sets of curves are only perpendicular to each other along the locus FG-J, and therefore complete

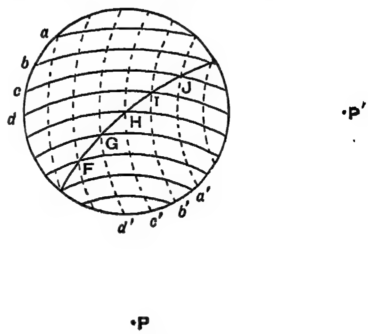

Fig. 14.

darkness will occur only along this line. A slight rotation of either the analyser or polariser will obviously change the position of this locus. Lippich made use of this fringe in the construction of a polarimeter, when the position of the fringe with reference to a pair of cross-hairs served as the criterion instead of the matching of fields as in a half-shadow polariser. By this means Lippich states that it is possible to set the analysing nicol to within two or three seconds of arc,[4] an accuracy considerably greater than that obtained by any type of half-shadow polariser. In order to see the fringe, the light source must be very intense (*e.g.* sunlight or the electric arc), and so the method cannot be conveniently applied for polarimetric work, since it is difficult to obtain the necessarily homogeneous light source of the required intensity.

§ (10) Lummer's Polarimeter.—In the polariser evolved by Lummer,[5] plane polarised light falls on a 45° prism the hypotenuse face of which has silvered strips S (*Fig.* 15). The light enters the prism normal to the face ABCD. The portion falling on the unsilvered part of the hypotenuse face ABEF is totally reflected, while the light falling on the silvered surface suffers metallic reflection. If the plane of polarisation of the incident beam is parallel or perpendicular to the plane of reflection, the planes of polarisation of the reflected beams (total reflection and metallic reflection) will be coincident. If the polarising nicol is rotated through an angle θ, the portions of the beam suffering total reflection will be rotated an angle $\theta°$ from its original azimuth,

while that reflected from the silver strips will be rotated through an equal angle in the opposite direction. A half-shadow arrange-

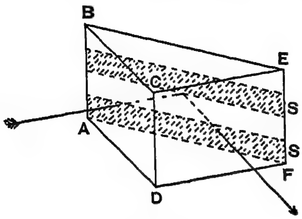

FIG. 15.

ment is thus obtained, as in the case of the Lippich system, with a half-shadow angle of 2θ, which can be varied as required.

Owing to the comparatively large amount of glass in the path, the effect of small amounts of double refraction, which is negligible in thin plates, now becomes appreciable and the field at the matching point is not uniform, having brighter or darker patches in the field of view. With a large half-shadow angle, the linearly polarised light becomes elliptically polarised, and, as can be shown from the electromagnetic theory, the ellipticity will be different in the two cases. For half-shadow angles as used in practical work, the ellipticity introduced at reflection is negligible, the only drawback being the double refraction due to lack of homogeneity and annealing of the glass.

It is possible that, as the technique of optical glass manufacture is improved, this type of polariser may come into common use. A detailed investigation of its properties has been made by Volke.[1]

§ (11) GENERAL CONSIDERATIONS.—A large number of polarisers have been devised which depend on the double refraction or rotatory power of quartz for their half-shadow effect, and a typical example, the Laurent plate, has been described in detail.

A most serious objection to this class of polariser is the great scarcity of optically good quartz, the purity of which immediately sets the limit to the accuracy and sensitiveness of the particular polariser. From this cause alone a considerable variation is to be expected between the performances of individual polarisers of any one type.

(i.) *Poynting's Polariser.*—The polariser of Poynting[2] is made by dividing a circular plate of quartz, cut perpendicular to the optic axis, along the diameter. One half is slightly reduced in thickness and the two halves reunited. The half-shadow effect is obtained by the difference of the rotation produced in each half of the plate. The half-shadow angle is therefore a fixed one, and furthermore it is necessary to employ a homogeneous light source to avoid the effects of rotatory dispersion.

(ii.) *Nakamura's Polariser.*—Nakamura[3] has shown that maximum sensitiveness of a Soleil double quartz plate is obtained when the plate is approximately ·4 mm. thick, instead of 3·5 mm. or 7 mm. as originally used. Wright[4] independently arrived at the same conclusion, and as this polariser admits of only one fixed half-shadow angle, the latter[5] has evolved an ingenious application, which not only affords a variable half-shadow angle, but also gives this variation without a change of the zero position of the analyser—a most important consideration in the case of saccharimeters. It consists of two wedges of quartz of equal angle but of opposite rotation, the one mounted above the other as shown in *Fig.* 16, and immediately behind each half

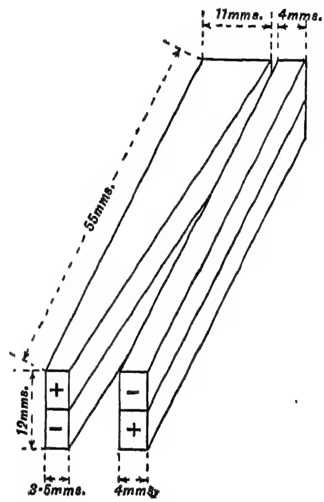

FIG. 16.

wedge is a parallel plate of quartz of opposite rotation. The dimensions suggested by Wright for polarimetric work are given in the figure. It will be seen that at a point 3·3 mm. from the thinner end of the wedge the total rotation is zero in both parts, since the thickness of the double wedge is then the same as that of the double plate of opposite rotation. The field of view when the nicols are crossed will therefore be comparatively bright, except for a narrow dark band at this point, which will run vertically across the field. If either nicol is given a slight rotation the part of the dark

[5] *Ibid.* pp. 391-398.

band in the upper wedge will move rapidly in one direction, whilst the dark band in the lower wedge will move a corresponding distance in the opposite direction. In using this device an approximate setting is first made, and biquartz wedge is then placed in the path, the accurate reading being obtained by rotating the analysing nicol until the black bands are brought in alignment.

As the thicker end of the double wedge is moved into the field, the coincidence of the two parts of the black band remains unaltered, the field itself becoming generally brighter while the band itself is not so sharply defined. With wedges of the dimensions given in *Fig.* 16, illumination, equivalent to that given by a Lippich polariser of 15° half-shadow angle, is obtained when the thicker end of the wedge is in the field of view. As only one magnifying lens is needed, the usual light-absorbing observing telescope can be dispensed with. This form of polariser has not yet been employed in any commercial polarimeter or saccharimeter.

(iii.) *Brace's Polariser.*—Probably the most sensitive and accurate form of half-shadow polariser is that of Brace.[1] Essentially it consists of two plates of mica mounted between crossed nicols. The first consists of a strip (about ·00017 mm. thick or $\frac{1}{100}\lambda$ retardation) covering part of the field, and is fixed; the second "compensator" plate covers the whole field and has a retardation of $\frac{1}{4}\lambda$. Two positions of the compensator plate can be found at which the intensity of the light is uniform over the whole field. By varying the angle which the principal section of the strip makes with the azimuth of the polariser (or analyser) a variable half-shadow effect is obtained. For a complete account of the principles underlying its use, reference must be made to the original papers. The main advantages of this polariser are that the separating line is vanishingly fine, and that the double refraction due to strain between the polariser and analyser is reduced to a minimum, so that it can be successfully used with what is equivalent to a very small half-shadow angle. It is mostly used for determination of ellipticities; with a very thin sensitive strip a change of phase of $6{\cdot}2\times10^{-7}$ can be detected under favourable conditions. Bates[2] has applied this type of polariser to a spectra polarimeter and found the extreme differences of readings less than ·007°. The Brace system is, however, rather fragile, and its use is not recommended except in work requiring the highest obtainable precision.[3]

§ (12) CONSTRUCTION AND MECHANICAL DESIGN OF POLARIMETERS. *Simple Types.*—Since the requirements in polarimetry are so varied, it is only to be expected that the various types available should be numerous. For many purposes, such as urine analysis, an accuracy of measurement of ·1° is sufficient, and a simple instrument such as is shown in *Fig.* 17 is all that is required. The polarising system P is connected to a divided circle C

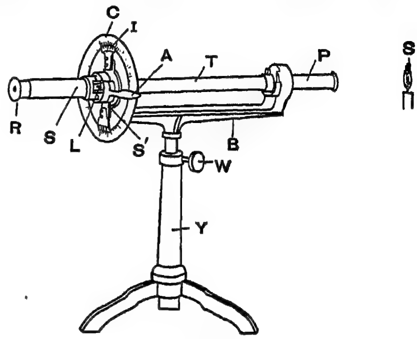

FIG. 17.

by means of the bracket B. The analysing system can be rotated by means of the lever A, and its azimuth is given by the index arm I. The observation tube T rests on suitable supports at each end, and the whole instrument is supported by a tripod stand Y.

In making an observation, the sodium light source S is either focussed on the polariser end P or brought as near to it as is possible without unduly warming the polariser, the tube T is filled with water and placed in position, the eyepiece R of the observing telescope is either pushed in or drawn out, until a sharp image of the separating line of the polariser is seen. The arm A is rotated until a position is reached when the two fields are *equally dark*. If the index arm I does not then read exactly 0° or 180°, the procedure is as follows. The analysing nicol is mounted in a tube with a short arm L fastened to it. This tube again in turn fits in the outer tube to which A is fixed, and the analyser can be rotated a small amount with respect to it by means of thumb-screws which bear on L in the manner shown. The arm A is moved, therefore, until the index arm reads 0, and the thumb-screws turned until a match is obtained. The tube T is now filled with the liquid to be examined, and in general both parts of the field will appear bright. The arm A is again rotated until a position of equal darkness is obtained. The new reading of the index arm will give the rotation of the substance.

In some forms the whole instrument can be inclined, and clamped in any position by means of a swivel joint and bolt. This obviates the necessity of raising or lowering the light source to suit the instrument. The circle C is

[1] Brace, *Phil. Mag.*, 1903, v. 161; *Phys. Rev.*, 1904, xviii. 70; *Phys. Rev.*, 1904, xix. 218.
[2] Bates, *Ann. d. Physik*, 1903 (4), xii. 1096.
[3] *Circl. Bur. Sta.*, 1918, No. 44, p. 12.

generally about 3 in. in diameter and divided into degrees; the possible error in measurement is therefore ·1° or ·2°. When slightly greater accuracy is required, a vernier reading to 0·1° is engraved on the arm I instead of the single fiduciary line, and it is often the practice to mount a magnifying lens on this movable index arm, with a small mirror attached to it that projects outside the circle and reflects on to the scale and vernier enough light from the source *s* to make a reading possible in an otherwise darkened room.

The optical arrangement is shown in *Fig.* 18. The source *s* being either focussed on or close to the aperture A, the latter can be considered as the virtual light source. The position and focal length of the condenser C are chosen so that the image of the stop A falls on the objective M of the observing telescope. The polarising system immediately follows the condenser. In the figure the Laurent polariser is shown, D being the polarising nicol, and E the half-wave plate covering a part of the field. In this type of instrument having a fixed half-shadow angle, the Cornu-Jellett polariser is often employed instead of the Laurent. A second diaphragm F limits the beam and prevents stray illumination by reflection from the sides of the observation tube GH. The calcite prisms are difficult to clean without scratching; a thin protecting window K′ is therefore mounted in the aperture F, and a similar one K at J. A low-power telescope MN immediately follows the analyser L, and this is adjusted to give a clear image of the separating line of E in the field of view.

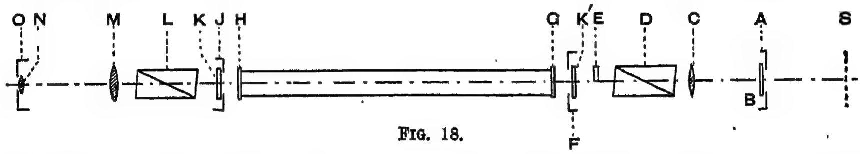

FIG. 18.

Since the radiation from a sodium burner consists of lines in blue and other parts of the spectrum as well as the strong yellow radiation, a filter B (*Fig.* 18) of potassium bichromate is placed close to the aperture A. This usually consists of either a thin plate (about 1 mm.) of potassium bichromate crystal balsamed in between two glass cover plates, or a glass cell containing a solution of the bichromate in water.

The instrument described above is as manufactured by Pellin; in a corresponding simple polarimeter of Schmidt and Haensch, a Lippich polariser with a fixed half-shadow angle is employed.

In the corresponding polarimeter of Bellingham and Stanley, which reads by vernier to ·05°, the polariser consists either of a Laurent plate or a modified Jellett prism. In the latter case, instead of reversing the one half prism as described by Jellett (see § (3)), two small natural rhombs are taken, and a section *abcd* (*Fig.* 19) is cut with the long sides *ad* and *bc* parallel to the cleavage edges of the rhomb, but with *ab* and *cd* making an angle $90° - \theta$ with the principal section EF which contains the optic axis of the crystal; while in the second rhomb *ab* is made to give an angle $90 + \theta$ with EF. When these are joined or cemented together with their corresponding faces *abcd* in contact, the principal section of the one half makes an angle of 2θ with that of the other. In order to have a sharp separating line, the one rhomb is placed a few millimetres behind the other so that the single edge *ab* of the one rhomb forms the separating line. The corner G of each rhomb is ground into a flat surface parallel to the line *cd*, but making a small angle with the plane *abcd*. This allows greater latitude in adjustment without the extraordinary ray from G coming into the field of view. This polariser forms a single detachable unit that can be quickly interchanged.

The circle is bevelled at 45° to its own plane, and the vernier is engraved on another fixed circle similarly bevelled.

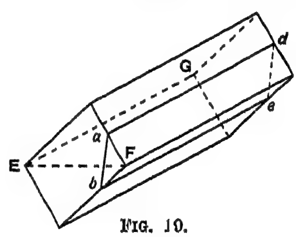

FIG. 19.

The graduated scale and vernier therefore lie in the same surface, and no parallax error can be introduced. Since this vernier is engraved on a second complete circle instead of on a narrow index arm, the danger of widening the space between the scale and vernier, caused by accidental knocks, is considerably lessened. In this instrument the vernier is fixed while the circle rotates with the analyser. In order to avoid the accidental tilting of the instrument, which is liable to occur in the type shown in *Fig.* 17 when the thumb-screw of the swivel *w* has not been sufficiently tightened, the girder connecting the polariser and analyser is furnished with two bored holes into either of which the upright of the tripod can be placed. The one

supports the instrument in a rigid horizontal position, and the other inclines the polariser end downwards, at an angle of about 15°. This instrument has a movable trough, consisting of two close-fitting circular tubes. Except for a narrow portion at each end, nearly a half of each tube is cut away, so that the tube holding the liquid to be examined can be inserted. When the inner tube is now rotated by a suitable knob through an angle of approximately 180°, the observation tube is completely enclosed. The chief advantage of this kind of trough is that no hinges are required; these often corrode after coming in contact with some of the liquids used in polarimetric analysis.

The vernier is engraved to read directly to ·05°.

§ (13) HIGH ACCURACY POLARIMETERS.—When an accuracy of ·01° is required, several changes are necessary, the most important being that of eliminating the eccentric error in the circle graduation. After the circle has been turned, it is usually mounted on the spindle of another machine for dividing, consequently the common centre of the radial graduation lines will not coincide with the true centre of the circle when a small particle of matter is lodged between the spindle and the sleeve of the circle. Unless exceptional care is exercised, the error in measuring an angle of about 90° may amount to ·02°. If two verniers are used, mounted approximately at 180° to each other, this error is eliminated if the *mean* value of a rotation (as given by each vernier) is taken as the true rotation. This will hold good for eccentricities up to any likely to occur in practice. When the use of the polarimeter is not confined to a special purpose, a variable half-shadow angle becomes almost a necessity. Furthermore, it is desirable to make the instrument as rigid as possible, and since a small change from alignment with the light source may cause an appreciable error in the measurement, the instrument should stand firmly on the table or bench. For these reasons it is usual to design the more accurate instruments to have trestle mounts with a substantial base. In addition, the space surrounding the optical axis of the instrument, between the polariser and analyser, should be as free as possible, to allow for the interposition of electromagnets, thermostats, or electric furnaces, as may be required.

In order to show the mechanical construction of a modern accurate polarimeter, the construction and setting of one instrument will be described in detail and the more important differences in the design of other manufacturers will be noted.

(i.) *Adam Hilger, Ltd.*—In the polarimeter illustrated in *Fig.* 20 (made by Adam Hilger, Ltd., London) the half-shadow angle of the polariser is varied by means of the small lever arm A which moves behind a small fixed scale giving directly the half-shadow angle; by means of the small thumbscrew shown, it can be clamped in any position. The verniers GG at the analyser end are fixed while the circle can be rotated with the analysing nicol. The verniers are observed by means of the low-power eyepieces MM.

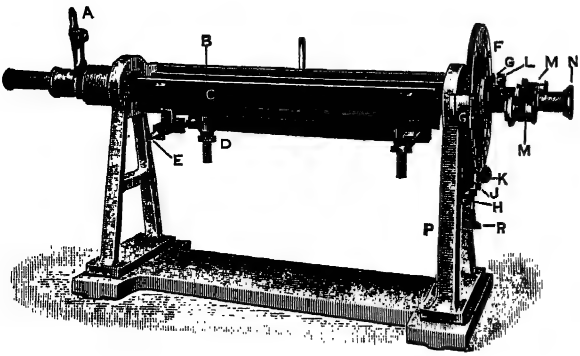

FIG. 20.

A monochromatic light source is placed in alignment with the optical axis of the instrument, and in such a position that a real image of it is formed approximately at the analyser. The eyepiece N of the low-power observing telescope is moved in or out until the edges of the half Lippich prisms at the polariser are sharply in focus. The circle F is set at the zero position. If the three parts of the field are not of equal intensity, the analyser is slightly rotated by means of the thumb-screws at L while the circle remains stationary.

The trough C can be raised or lowered or slightly tilted by means of knurled nuts on the screws DD. If a large observation tube is to be used the trough must be correspondingly lowered so that the centre of the tube corresponds with the optical axis of the instrument.

The observation tube being placed in position, the circle F will have to be rotated to a new position before a match of the fields is obtained. When this position has been found approximately the screw head R is tightened. A ring with a projecting arm J fits smoothly on a collar that forms an integral part of the circle. When R is tightened, this ring, and consequently the arm J, is clamped to the circle.

The latter can therefore be slowly rotated by turning the screw K which bears against the arm J. When the end of the screw K is moving away from J, the latter is kept in contact with the screw by pressure of the spring and plunger H on the other side. A slow motion arrangement such as the one explained above is practically a necessity when settings have to be made to within ·01°.

The trough C slides on the pins E for centring, and can be quickly removed when required. If necessary, the bar B connecting the polariser and analyser can also be unscrewed and removed, as the trestle mounts PP are sufficiently rigidly attached to the massive iron base S.

(ii.) *Bellingham and Stanley.*—In the corresponding Bellingham and Stanley (London) polarimeter special attention has been devoted to the illumination of the circle, as shown diagrammatically in *Fig.* 21. The scale and

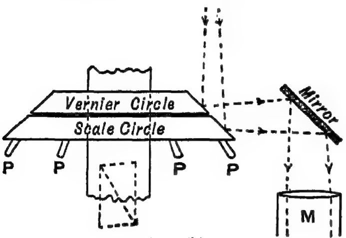

FIG. 21.

verniers are turned conically away from the observer, and are illuminated by light from the source. A plane mirror set approximately parallel to the face of the vernier and scale, as shown, serves to reflect the light into the low-power eyepiece M. A similar arrangement (not shown in the diagram) is mounted on the opposite side so that the eccentric error can be eliminated. The scale circle can be rotated and set approximately by means of the capstan heads PP, the final adjustment being made with a slow motion similar in principle to that already described.

For very accurate work it is necessary to have the room in complete darkness, so that the condition generally known as the "dark adapted eye" may be obtained. All the light from the source other than that entering the polariser must then be screened off, and the scale and verniers have to be illuminated independently as in other instruments. But it is an appreciable advantage of this arrangement that the graduations do not become clouded with moisture from the breath of the observer, as the scale is turned away from him. When a variable half-shadow polariser is required with this instrument, a modified Lippich system is supplied instead of the Jellett arrangement previously described. Here the long rhombs of spar (that form the components of the Jellett prism) are placed in the usual positions of the half Lippich prisms, and the large nicol is rotated to vary the half-shadow angle as usual. A circular trough is used instead of the V-shaped trough of the Hilger instrument; this can be quickly removed, and two adjustable V-shaped supports can be used to hold an observation tube that is either too large or too small for the trough.

(iii.) *Schmidt and Haensch.*—Corresponding polarimeters of Goerz and Schmidt and Haensch (Berlin) are generally similar in design to the Hilger instrument described above, except that the circles in these instruments are completely encased so as to keep the scales from tarnishing in a chemical laboratory. In the Goerz instrument the parts PP and S of *Fig.* 20 are one casting, PP being massive iron pillars.

It is also customary to fit a small circular table on the base S, which can be raised or lowered as required.

The large polarimeter made by Schmidt and Haensch at the instance of Landolt has some interesting features. The trestle holding the analyser circle is about two inches thick, so as to ensure a smooth-running circle; the bush in which the rotating tube from the circle turns is long enough to ensure that there will be no sagging of the circle due to the projecting weight. The optical axis of the instrument is only about 6″ above the upper face of the base, compared with 9″ as is usual, thus making the instrument exceptionally rigid. Instead of a single trough, a series of four are mounted side by side on a common axis, so that any one trough can be quickly brought into the optical axis of the instruments. This serves for the rapid intercomparison of the rotations in two or more observation tubes without the necessity of handling them and the consequent temporary rise in temperature.

§ (14) SPECTRO-POLARIMETERS.—It is often necessary to determine the rotation of substances for various wave-lengths that cannot be obtained singly with the same ease as the yellow doublet of sodium. In the method devised by Fizeau and Foucault,[1] a slit is placed at the polariser of a simple polarimeter (consisting of two Nicol prisms and a graduated circle) with a prism and telescope. Sunlight is used as the light source. The nicols are crossed in the absence of the optically active material; when the latter is placed in the path a spectrum is seen at the telescope. On rotating the analyser, a dark band will be seen to move across the spectrum, and the rotation of the substance for a given wave-length is given by the amount that the analyser has to be rotated until the black band is at the position of that wave-length in the spectrum.

[1] Fizeau et Foucault, *Compt. Rend.*, 1845, xxi. 1155.

The method has been improved by Lippich[1] and others, but it only gives good results when the rotatory dispersion is large.

A convenient method of accurately determining the rotatory power of substances for different wave-lengths is shown in *Fig.* 22, the arrangement being similar to that used by Lowry[2] in his investigation on the rotatory dispersion of quartz. The light source S is placed at the focal plane of the short focussed

plane of polarisation is parallel to that of the analyser, there is no appreciable reduction of intensity on transmission through the analyser.

It follows, therefore, that in order that these radiations may not influence the sensitiveness or the position of matching for the particular wave-length that is desired, the proportion passing through the slit must at most be of the order of ·1 per cent. Owing to slight scattering at the refracting surfaces of the

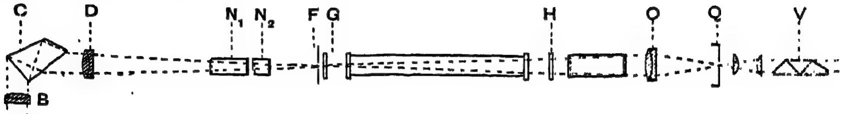

FIG. 22.

condenser W, which is close to the slit A, so that the latter is uniformly illuminated. To secure brightness of the final image the focal length of the condenser is so chosen that the light from S (which has a definite magnitude) fills the objective B of the collimator, or so much of it as is operative in forming the final image. The parallel beam emerging from B enters a constant deviation prism C, and the resulting spectrum is focussed at the slit F of the polariser by means of the long focussed objective D. The Lippich

deviating prism, lenses, etc., this spectral purity can never be attained in practice. It is therefore desirable to use a second spectroscope in the form of a direct vision prism V at the analyser. If, for example, a quartz mercury lamp be used as the source, and it is desired to observe the rotation of a substance for the green line (5461), this line is set on the slit F of the polariser. When the analyser is rotated to the matching position, and the slits F being narrow, the green band as seen through N will be accompanied by slightly fainter bands of yellow and violet. When a rotatory dispersive medium is placed between

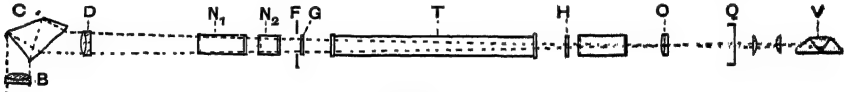

FIG. 23.

polariser N_1N_2, which is usually of the three-field type, is arranged so that the separating lines are horizontal. G and H are glass protecting covers for the polariser and analyser nicols.

When the fields are matched with a half-shadow angle of $1\frac{1}{2}°$, the intensity of illumination is only about ·1 per cent of the intensity when the polariser and analyser are parallel (theoretically it is ·06 per cent, but a slightly higher percentage is transmitted owing to the almost inevitable elliptic polarisation in the light when it reaches the analyser). When an active substance is placed in the tube, the planes of polarisation of other wave-lengths may lie in azimuths considerably different from that of the analyser, so that the latter only reduces their intensities slightly. In the extreme case of a particular wave-length whose

the polariser and analyser, these may become so important as to prevent an accurate reading of the rotation of the green ray, as described in general terms above.

One of the writers has found that somewhat better results are obtained with an arrangement as shown in *Fig.* 23. Here the light source S is *focussed on* the slit A by means of the condenser W, and the light of a particular wave-length emerging from the prism C is focussed by means of the lens D on the objective O of the observing telescope (the usual condition of illumination in polarimetry). The whole of the field at F is uniformly illuminated, and the slit can be opened until the yellow and green bands (supposing a mercury light source is used) as seen with the direct vision prism nearly overlap.

The diaphragm Q in *Figs.* 22 and 23 serves to eliminate the effects of internal reflection in the observation tube.

The mechanical construction of the spectropolarimeter, made by Adam Hilger, Ltd., can be seen from *Fig.* 24. The monochromator,

[1] Lippich, *Wien. Sitzungsber.*, 1882 (II.), lxxxv. 307.
[2] Lowry, *Phil. Trans.*, 1912, ccxii. 261.

polariser, and analyser form separate units that can be clamped in any position along the girder bed. In the illustration they are arranged for a trough to take observation tubes up to 100 cm. long. The drum of the monochromator has a long rod attached to it so that various wave-lengths can be set from the analyser end. While it is not absolutely necessary, it is best to use a direct vision prism that does not greatly deviate the par-

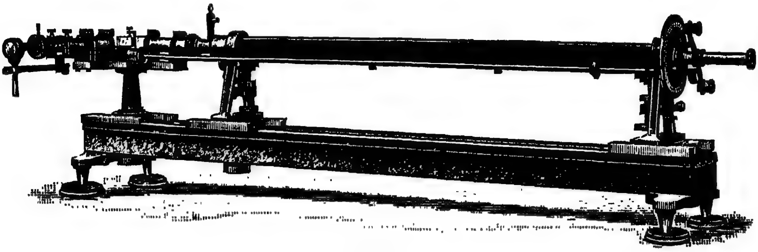

FIG. 24.

ticular wave-length that is employed; thus a set of three interchangeable prisms giving direct vision for the red, green, and violet respectively are required for a complete examination of the rotation of a substance over the whole visible spectrum.

In a spectro-polarimeter of Bellingham and Stanley, the light source is placed directly above the prism (no collimator and slit being used), whilst in the Schmidt and Haensch instrument a direct vision spectroscope is mounted with a second slit, at the focal plane of the condenser in the polariser head.

§ (15) POLARIMETERS FOR SPECIAL PURPOSES. (i.) *Micro-polarimeter.*—When it is necessary to find the rotation of substances that can only be obtained in small quantities, diaphragms are mounted at both F and J (*Fig.* 18) so as to limit the beam. The tube into which the substance is placed has often to be a capillary tube of about 1 mm. diameter. In the instrument made by Schmidt and Haensch the diaphragms at F and J have, therefore, apertures slightly less than this, in order to avoid possible reflections from the walls of the tube. As the field of view is so small (it is not practicable greatly to increase the magnification of the observing telescope without making the field too faint for accurate setting) it is best to use a two-field Lippich polariser, the separating line of the half Lippich prism always bisecting the field whatever size diaphragms are used. This instrument is fitted with a direct vision spectroscope (as described above), with a Nernst lamp attached as the light source. The small aperture diaphragms are removable so that the instrument can also be used for ordinary polarimetry, where the supply of a substance is sufficient for the usual observation tubes.

(ii.) *Diabetometer.*—When the total rotation of the substance is small it is possible to dispense with the circle and yet be able to measure a rotation accurately. In the diabetometer of Yvon, as made by Ph. Pellin (Paris), the analysing nicol is mounted in the tube A (*Fig.* 25). When the screw D is turned by means of the divided drum E, the part B, being engaged to the screw, is rotated about the centre of A. The block C is merely to prevent E from turning too easily, as the screw will have to move this backwards and forwards against the frictional pressure of the spring.

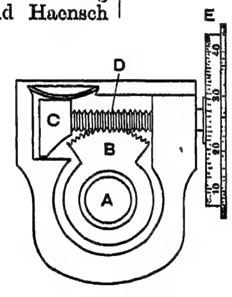

FIG. 25.

The scale on the drum is graduated so as to give directly the number of grammes per litre of sugar or glucose in diabetic urine, allowance being made for the addition of 10 per cent (by volume) of subacetate of lead needed for clarification.

§ (16) LIGHT SOURCES FOR POLARIMETRIC WORK.—As sources of sodium light a very large number of lamps have been designed. For most purposes it is sufficient to use a piece of fused borax on the grid of a Meker-Bunsen burner; in many commercial lamps, the salt is contained in a platinum boat, and especially when a coal gas-oxygen flame is used, the intensity is considerably greater. The Bureau of Standards found[1] that for an intense sodium light source it is best to feed some form of fused Na_2CO_3 into an oxy-hydrogen flame. The borax must not be allowed to melt too quickly, otherwise a reversal of the lines is obtained. For precision work, the Na lines must be regarded as an inferior source, since, although the separation of the lines (6 Å.) is too great to consider the doublet as a homo-

[1] *Circl. Bur. Standards*, 1918 (2nd ed.), No. 44, p. 15.

geneous source, yet the lines are too close for convenient spectroscopic separation.

The green line of mercury (5461 Å.) forms a very suitable light source for spectro-polarimetric work. Although this line has a complex structure when analysed by means of an echelon grating or other high resolving apparatus, the difference in wave-length between its extreme satellites is less than ·4 Å., fifteen times less than the separation of the two sodium lines, and it is found that it can be regarded as homogeneous for rotations as great as 250°. If a quartz mercury-vapour lamp of the type manufactured by the Westinghouse Cooper-Hewitt Co. is used, this source is of great intensity, and can be used indefinitely with little or no attention; although its radiations are, owing to the higher pressure, not so homogeneous as those of the glass tube lamps of the same company. The violet line of mercury, though not so prominent, can be successfully employed; the yellow lines cannot be so readily used, since here we are confronted with the same difficulty as in the case of the sodium doublet, a separation of only 21 Å. The most useful lines are therefore 5461 (green) and 4359 blue (the blue-green 4916 is only about half the intensity of the other lines and does not prove very satisfactory).

Lowry [1] has suggested that, in addition to the sources and lines mentioned above, the following lines are useful for spectro-polarimetry: the lithium red 6708 and the cadmium lines 6438 (red) and 5086 (green). The lithium line is obtained as in the case of the sodium, a small oxy-hydrogen flame being used if great brightness is required, while the cadmium lines are given by a rotating arc. The electrodes are made of 28 per cent cadmium and 72 per cent silver, and are rotated in opposite directions at a speed sufficiently high to prevent flickering. A more convenient cadmium source is the cadmium vapour lamp of Sand,[2] a modification of which has been suggested by Bates,[3] but unfortunately no reliable cadmium vapour lamp has yet been put on the market.

§ (17) Observation Tubes.—The simplest form of polarimeter tube is shown in the left-hand part of *Fig.* 26. It consists of a straight tube of glass of an internal diameter of about 10 mm. and with walls about 2 mm. thick. The ends are ground to the correct length, and should be parallel to within a minute of arc. The ring C, the outside of which is threaded, is cemented on the glass tube, so that the latter projects slightly. The end cap D screws on the ring C, and this carries the end plate or cover glass G. In order that the plate should be held evenly against the end of the glass tube, a soft rubber washer R is placed between the plate and the face of the end cap.

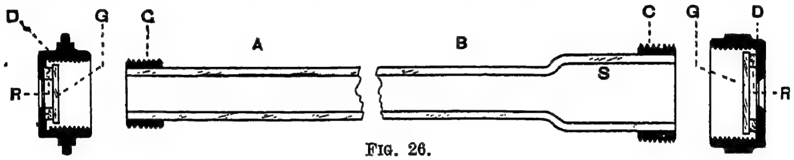

Fig. 26.

Unless the tube is very carefully filled a small bubble of air is left in the tube, which often materially obstructs the path of the beam. This difficulty was overcome by Schmidt and Haensch (Berlin) by enlarging one end of the tube as shown on the right-hand side of *Fig.* 26. The bubble rises to the top of the enlargement S, which is outside the direct path of the beam. The same purpose is effected in the tubes of Bellingham and Stanley (London) by blowing a small bubble or enlargement at the centre of a straight tube.

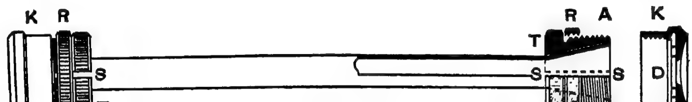

Fig. 27.

The cement with which C is fastened to the tube often becomes loose in time, and the screwing of the end cap tends to draw the ring over the end of the tube, virtually lengthening the column of liquid and so introducing an error in the rotation per unit length. In order to avoid this Neumann [4] has designed the tube shown in *Fig.* 27. Both ends of the tube are ground conically. The ring T is ground to fit the cones of the tube exactly, and is placed in position by splitting the rings along SS. Another ring R is screwed up as shown and serves to keep the split ring tightly clamped to the cone of the tube. The ends A are then ground to the correct length and parallel, the end cap K and the cover glass

[4] Neumann, *Chem. Zeitung*, 1913, No. 51.

D being the same as in the ordinary tube. The great advantage of this type of tube is that it can be used with ether, alcohol, chloroform, benzol, zylol, etc., which attack the cement in many of the ordinary tubes. The tube can be made of fused silica or porcelain and used for high temperature work in an electric furnace, when the cement of the ordinary tube would melt. It is made by Schmidt & Haensch (Berlin).

In very accurate work, it is necessary that the temperature of the substance should be uniform and that it should be accurately known, since rotatory power is a function of the temperature. The most convenient way of doing this is to surround the tube with another metal tube having small side tubes in it that can be connected to a thermostat. The better made water-jacketed tubes, as they are called, have baffles mounted between the outer and inner tube, so that the flow of the water should be helical and envelop the inner tube. An opening in the middle of the inner tube (see *Fig.* 28) provides for the insertion of a sensitive thermometer, the rotation not being measured until the temperature has become steady.

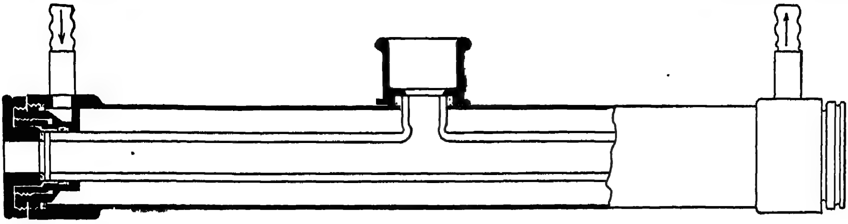

FIG. 28.

When rotations have to be determined for temperatures below the dewpoint of the atmosphere, the end plates must be protected against the condensation of moisture. Wiley [1] employed a second cap made of some non-conducting material such as hard rubber; the air-space in between the two cover glasses contain some desiccating substance.

The jacketed tube is not very satisfactory for use at comparatively high temperatures owing to the fall of temperature along the tube due to conduction, etc. It is then preferable to have the tube in a thermostat mounted between the polariser and analyser.[2]

The measurement of rotation in fermenting liquids (for biochemical work) has to be carried out at 37° C. Abderhalden,[3] in conjunction with Schmidt and Haensch, has evolved an ingenious arrangement whereby six small tubes are mounted on a horizontal wheel in a circular box, any one of which can be brought in line with the optical axis of the polarimeter. The tubes are electrically heated and the temperature can be kept constant at 37° C. by means of a rheostat.

§ (18) APPLICATIONS OF POLARIMETRY.—The property of optical rotation is of prime importance in organic chemistry. The work of Pasteur (1848) showed that substances otherwise identical can exist in a right-rotating, left-rotating, and inactive form. Later he introduced the conception of molecular assymetry, which led van't Hoff and Le Bel (both in 1874) to the discovery that optical activity always indicated assymetric distribution of the carbon valencies in the molecule. The further developments of this theory are fully dealt with in text-books on stereochemistry. Wilhelmy in 1850 used the polarimeter to measure the rate of inversion of cane sugar, and employed the results as a basis for the first correct mathematical treatment of the velocity of a chemical reaction.

The polarimeter is extensively used in analytical chemistry for quantitative determinations. In this connection, the term *specific rotation*, introduced by Biot, is employed. By this term is meant the angle of rotation caused by a length of 10 cm. of a solution containing 1 grm. of active substance per c.c. This will vary with the wave-length used and with the temperature, and is designated by the abbreviation $[\alpha]_D^{20°}$, which indicates the specific rotation of a substance at 20° C. using the yellow (D) lines of sodium as a light source.

It then follows that $[\alpha]_D = a/l \times c$, where a is the observed rotation and c the number of grammes of the substance per c.c. of solution. $[\alpha]$ varies not only with the wave-length and temperature, but also with the concentration, the relationship being somewhat complex; fortunately the variation is usually small, and need only be taken into consideration in accurate work such as the determination of sugars. Knowing the specific rotation, the polarimeter can be used for a large number of analytical determinations, such as the estimation of the alkaloids, camphors, and essential oils. Rosin

or castor oil may be detected in mineral oils by their optical activity.

The use of the instrument is not necessarily confined to the determination of optically active substances; a large number of inert substances exert a powerful influence on the rotatory power of active solutions. Thus acetone or boric acid can be determined in solutions of tartaric acid of known strength. The solvent used to dissolve an optically active substance has considerable influence on the rotatory power of the latter, and this property will very likely be capable of many new analytical applications in the near future.

The instrument forms a useful tool for the study of fermentation and other problems in biochemistry.

Polarisation Spectrophotometers: instruments in which the brightness match is obtained by the rotation of a polarisation device. See "Spectrophotometry," § (12).

Polariscope, Tourmaline. See "Polarised Light and its Applications," § (9).

POLARISED LIGHT AND ITS APPLICATIONS

§ (1) Introduction.—Fresnel's original conception of the disturbance producing the sensation of light was, briefly, a train of waves propagated by vibrations of ether particles taking place in all directions perpendicular to the direction of propagation of the disturbance. Later, he modified this conception to obviate the mechanical objection to two adjacent particles moving in totally different directions, and he postulated a vibration at any given moment of all particles along parallel lines, but with so rapid a change in the common direction of motion that a period of vibration in any one direction cannot be isolated in the analysis of a beam of ordinary light. Under special conditions, however, the vibrations may be restricted in such a way that any one particle continues to describe the same path, whether it be linear, circular, or elliptical, and all the particles affected by the disturbance describe exactly similar paths. It is this restriction of vibration that is known as the polarisation of light.

§ (2) Discovery of Fundamental Phenomena.—Two and a half centuries ago Erasmus Bartolinus discovered the power of a crystal of Iceland spar to resolve a beam of ordinary light into two separate rays; twenty years later Huygens repeated his work, and found that two rays were produced unless the light was travelling parallel to the crystallographic axis of the crystal, and, moreover, that each ray could again be subdivided by its passage through a second crystal unless the latter was orientated in one of four definite directions relative to the first crystal. In that case the two rays were transmitted without further division. A few years later Newton confirmed these observations, but still no explanation was forthcoming, although both these pioneers recognised the fundamental property of polarised light, namely, its asymmetry about its direction of propagation. "Have not," wrote Newton, "the rays of light several sides endued with several original properties?"

Early in the nineteenth century Malus made the chance discovery that light reflected from glass possessed in part the characteristics of rays emerging from a calcite crystal, and that these characteristics became most marked for a definite angle of reflection. Experimenting later with light reflected from other surfaces, he found that this held good for all reflecting surfaces other than metals, but that the angle producing the maximum result varied with each individual substance. Endeavouring to find an explanation for these facts, he rejected the wave theory of light as offering no possible solution: at that time Young's longitudinal vibration theory had not yet been superseded by Fresnel's more far-reaching transverse vibration theory, and obviously the former could give an even less satisfactory explanation than could the older corpuscular theory of Newton. Malus concluded that the phenomena must be due to some induced property of the corpuscles transmitting light rays, comparable with a magnetic or electric charge, and producing in the light a definite bias or "polarity," and this gave birth to the title of "polarisation," which has survived the destruction of the theory to which it owes its origin. The group of workers responsible for leading the explanation along new theoretical lines included Young, Fresnel, Arago and Brewster, who suggested and elaborated a theory of polarisation based on a wave theory of light. Nevertheless,

although his efforts at explanation did not stand the test of time, Malus accumulated a mass of results from minute and accurate observation on the behaviour of polarised light which furnished conclusive evidence for the law which bears his name.

The asymmetry of a ray polarised by reflection becomes very evident when the ray suffers reflection from a second surface, and Malus found that the intensity of the final ray was dependent upon the plane of incidence at the second surface. He attributed to each ray a plane passing through its path which bore a definite relation to its asymmetric properties; this he called the *Plane of Polarisation* of the ray, and defined it as the plane of incidence of a polarised ray upon a surface when the reflected ray was of maximum intensity. The angle of reflection from a surface for which the polarisation of the light was most complete he termed the *Angle of Polarisation.* His *Law of Polarisation* could then be stated as follows:

When a ray of light polarised by reflection at one surface falls upon a second surface at the angle of polarisation, the intensity of the twice-reflected ray varies as the square of the cosine of the angle between the two planes of reflection.

The foundations of the theory of polarisation which holds to the present time were laid by Young and Fresnel in their conception of light transmission by transverse wave motion. Fresnel saw the immediate application of the conception to the case of polarised light, and suggested the restriction of the vibrations to a definite unchanging path at right angles to the direction of propagation. Accepting his hypothesis, we shall for the moment consider only light whose vibrations are linear and take place in one definite direction. To this has been given the name of *Plane Polarised Light.*

A crucial test of Fresnel's theory lay in the investigation of the behaviour of two plane polarised rays under conditions which might be expected to produce interference. Fresnel and Arago carried out this work, and their results added evidence in favour of the wave motion hypothesis, and led to the establishment of the following five laws governing the interference of polarised rays, known as the *Fresnel-Arago Laws*:

1. Two rays polarised in the same plane interfere with each other under the same conditions as for ordinary light.
2. Two rays polarised at right angles to one another do not interfere under these conditions.
3. Two rays polarised at right angles, if obtained from unpolarised light, may subsequently be brought into the same plane of polarisation without acquiring the power of interference.
4. Two such rays derived from plane polarised light will, under the same conditions, show interference.
5. In the latter case a phase difference of π, equivalent to half a wave-length, must be added to the estimation of the path difference.

At about the same time Brewster deduced from experimental data another law governing the size of the angle of polarisation. *Brewster's Law* may be expressed simply in the statement that the tangent of the angle of polarisation is equal to the index of refraction of the reflecting substance. From this it follows that at the polarising angle the sum of the angles of incidence and refraction is 90°, or that the reflected ray is perpendicular to the refracted ray, and that when light travelling in a medium is polarised by reflection from the bounding air-surface of the medium the refractive index is the cotangent of the polarising angle. Evidently, therefore, the polarising angle will vary with the wave-length of the light used. With most substances the dispersion is too low to show the effects of this law, but with substances of very high dispersive power, such as nitroso-dimethyl-aniline, the effect is visible in the distinct coloration of the image of a white source of light, and in the variation of the colour with the angle of incidence.

By the examination of light polarised by refraction through a crystal or by reflection at a glass surface various definite facts were deduced. The two rays emerging from a crystal of calcite were found to be polarised with their planes of polarisation parallel and perpendicular respectively to the plane containing the incident ray and the crystallographic axis. The ray reflected from a polished non-metallic surface was polarised in the plane of incidence and the refracted portion was partially polarised in a perpendicular plane. After a second refraction at the polarising angle the percentage of polarised light in the refracted ray was increased, while again the reflected ray was wholly polarised in a perpendicular plane, and this process could be repeated at any number of surfaces until the final refracted beam contained no appreciable amount of unpolarised light. These facts are capable of simple explanation on the wave theory of light propagation.

§ (3) Explanation on Wave Theory.—A transverse vibration in any direction may be resolved into two component vibrations at right angles in the same plane; moreover, it can be shown that an elliptical or circular vibration can be resolved into two simultaneous linear vibrations at right angles to each other differing in phase. It may be supposed that a crystal such as calcite has an inherent power of resolving light vibrations in this way; a separation of the two rays would be effected if we suppose that the one set of vibrations possesses a different rate of propagation through the crystal from that of the perpendicular set. This subject will be investigated more fully a little later in the general discussion of the behaviour of crystals in transmitting light. Turning now to the question

of polarisation by reflection, the wave theory supplies an equally simple explanation. When a beam of light meets a flat surface of a transparent medium, part of the light is reflected, but the greater part is transmitted. If in a ray of light incident on a surface at the polarising angle the vibrations are resolved into directions parallel and perpendicular to the plane of incidence, the polarised reflected ray can be regarded as derived from the reflection of part of the component whose vibrations are perpendicular to this plane. No part of the component in the plane appears in the reflected ray. The refracted light then consists of the remainder of the perpendicular component together with all the light vibrating in the plane of incidence, and the preponderance of vibrations in the latter direction causes the refracted beam to appear partially polarised in the corresponding sense. On a second reflection the degree of polarisation of the refracted ray is increased by a repetition of the same process, while the reflected light again consists of vibrations perpendicular to the plane of incidence, and reinforces the beam reflected at the first surface. Each additional surface augments this double process of reflection and refraction until the final refracted ray is deprived of all vibrations perpendicular to the plane of incidence, and consists wholly of vibrations taking place in this plane.

§ (4) Relation between Plane of Polarisation and Direction of Vibration.—So far no definite relationship has been established as existing between the plane of polarisation, as defined by Malus, and the plane in which the vibrations take place. Various investigators have assumed the alternate possibilities of the parallelism or perpendicularity of these planes. Fresnel, to whom we owe so much of our knowledge in this branch of Optics, assumed as a basis for his mathematical investigations that the vibrations were perpendicular to the plane of polarisation: M'Cullagh, on the other hand, deduced as a consequence of his theory that the vibrations were in Malus's plane of polarisation. At the present time the electromagnetic theory indicates the existence of vibratory motion in both planes; the electric force is perpendicular to the plane of polarisation, the magnetic force is in that plane, and both these are concerned in the transmission of the light.

Stokes, working on the elastic solid theory, produced his Dynamical Theory of Diffraction,[1] wherein he arrived at a result which could be employed as a criterion of the actual vibration direction in plane polarised light. He showed theoretically that, if plane polarised light is diffracted, each diffracted ray is also plane polarised, and further, that if the plane of polarisation of the incident ray is inclined successively at regularly increasing angles to the plane of diffraction, the planes of polarisation of the corresponding diffracted rays are crowded together towards the plane of diffraction or towards a perpendicular plane according as the vibrations are parallel or perpendicular to the plane of polarisation. Experiment with finely ruled gratings showed that the latter effect is produced, which indicates the correctness of Fresnel's hypothesis.

Another suggestive experiment was carried out by Tyndall. A ray of polarised light was passed longitudinally through a tube containing very fine particles in suspension. If the vibrations of the beam were confined to one plane, say the vertical plane, the beam would possess no energy capable of producing horizontal vibrations. It has been shown that the intensity of plane polarised light scattered by fine particles is zero in the direction parallel to the vibrations of the light; consequently, there would in this case be no scattered light visible in the vertical direction; the vertical vibrations would, however, render scattered light visible in the horizontal direction perpendicular to the axis of the tube. Using light polarised in the horizontal plane, Tyndall found that scattered light was visible only in a horizontal direction, which may be taken as an indication that the vibrations in a plane polarised ray are perpendicular to its plane of polarisation.

§ (5) Double Refraction.—It will be convenient at this point to consider the general behaviour of crystals in transmitting light, as upon this we are dependent to a great extent for the production, analysis, and technical applications of polarised light.

A substance in the crystalline state differs from an ordinary isotropic medium in that many of its properties may vary in different directions. All crystals can be referred to definite systems of crystallographic axes,[2] and are divided into classes according to the relative length and inclination of these axes. In its natural form the shape of a crystal is governed by the character of the axes, which determine the size of the angles contained by all possible crystal faces, and just as the morphology of a crystal varies along the different axial directions, so there is a corresponding variation in other physical properties, mechanical, thermal, electrical, magnetic, and optical. In short, a crystal is possessed of a definite molecular structure on which depend the physical properties along any definite direction. In the most regular system, the cubic, the three axes are all equal and perpendicular, and the optical properties are constant in all directions, but in other systems, as the relation between the crystallographic axes becomes more complex and less regular, corresponding variations appear in all physical properties.

It has already been noted that the property of double refraction in Iceland spar was discovered as early as 1670, and later Huygens and others established definite facts connected

[1] *Mathematical and Physical Papers*, 1901, ii.

[2] See "Crystallography," § (4), etc.

with this phenomenon. A ray of light in passing through a calcite crystal is in general divided into two perpendicularly polarised rays, only one of which obeys the laws of ordinary refraction. They are termed respectively the *ordinary* and *extraordinary rays*, and they travel along slightly different paths, the separation between them varying with their inclination to the crystallographic axes, and becoming zero when the light travels along a definite direction in the crystal known as the *Optic Axis*. All doubly refracting crystals may be classified as *uniaxial* or *biaxial* according to the presence in the crystal of one or of two directions along which there is no separation of a refracted ray. Since the case of uniaxial crystals is very much simpler, we shall deal first with that alone; moreover, this class is of the greater importance in optical work, as it includes the two crystalline media most commonly used, namely, quartz and calcite.

§ (6) Uniaxial Crystals.—The separation of the rays produced by refraction indicates the existence of two values of the refractive index of the crystal for rays polarised in two perpendicular planes. If the direction of the incident ray is varied it is found that the refractive index corresponding to the ordinary ray is constant for all directions through the crystal, while that for the extraordinary ray varies, reaching extreme values parallel to the optic axis, when the index is that of the ordinary ray, and perpendicular to the axis. It can be shown, too, that the ordinary ray is always polarised in the principal plane, that is to say, in the plane containing the refracted ray and the optic axis, so that its vibrations are always perpendicular to the optic axis, while the extraordinary ray is polarised in the plane at right angles to the principal plane.

(i.) *Huygens' Construction for Path of Rays.*—Although with his conception of the nature of light transmission Huygens could not explain the polarisation of doubly refracted rays, he was able to represent the formation and paths of the two rays by a graphic method,[1] attacking the problem by a consideration of the wave-fronts of light disturbances travelling in a crystalline medium. Supposing a disturbance to emanate in all directions from an isolated point in the crystal, two separate wave-surfaces will be formed, that of the ordinary rays travelling at the same speed in all directions, and spreading out in the form of a sphere with ever-increasing radius. The rate of propagation of the extraordinary ray will vary along different directions, and consequently the wave-surface will no longer be spherical. Huygens assumed that it would take the form of a spheroid generated by the revolution of an ellipse, the axis of revolution coinciding with the diameter of the spherical wave-surface that is parallel to the optic axis. This assumption satisfied the necessary condition that the refractive index for the extraordinary ray should have an extreme value in the direction of the optic axis, and a second extreme value in all directions perpendicular to the axis.

Huygens' graphical method of determining the position of a refracted plane wave-surface by considering each point on the refracting surface as an origin of secondary disturbance is well known. Suppose AB (*Fig.* 1) represents

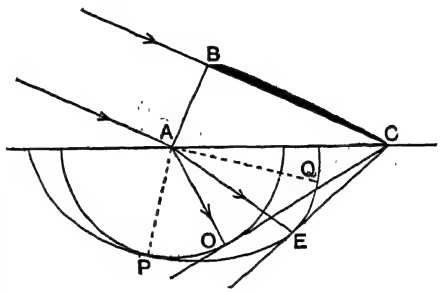

Fig. 1.

a section of the plane wave-front impinging on the plane surface AC of a doubly refracting medium, both planes being perpendicular to that of the paper. The point A may be taken as an origin for the two disturbances propagated in the crystal, one of which will spread in a spherical form, and the other in a spheroidal form. Let the plane ABC contain the optic axis, which lies in the direction AP; then these wave-surfaces may be represented by the circle through P and O with its centre at A, and the ellipse through P and E with AP and AQ as its axes, where AP/BC and AQ/BC represent the extreme values of the refractive index, the former for both rays travelling along the optic axis, and the latter for the extraordinary ray travelling perpendicular to it. The refracted wave-fronts of the whole beam will consequently be represented by the tangent planes[2] respectively to the ordinary and extraordinary wave-fronts. These will be perpendicular to the paper and cut it in lines CO and CE respectively. It is clear that in the case of the latter ray the sines of the angles of incidence and refraction bear no constant relation to each other, and, moreover, the wave-front CE is not perpendicular to the direction of the ray AE unless the latter is travelling parallel or perpendicular to the optic axis.

If the optic axis is not co-planar with AB and AC, the plane through C and the intersec-

[1] See "Light, Double Refraction of."

[2] See "Light, Propagation of."

tion of the incident wave and the refractory surface tangential to the spheroid described round A will not touch the spheroid in the plane of incidence ABC; in this case, therefore, the extraordinary ray does not obey either of the laws governing ordinary single refraction. Various special cases can be examined by applying the necessary modification to the graphical representation of the simple case considered here.

Much work has been done by later investigators, proving that Huygens was justified in his assumption as to the shape of the wave-surface of the extraordinary ray. There are two possible cases to be considered: the refractive index for the extraordinary ray perpendicular to the optic axis may be either less or greater than that for the ordinary ray. In the former case the wave-surfaces within the crystal will take the form of a spheroid enclosing a sphere, having a common diameter parallel to the optic axis; calcite belongs to this class of crystals, which are said to possess *negative birefringence*, or, more shortly, to be negative crystals. In the other case the spherical wave-surface encloses the spheroid, and the crystals are said to be *positive*. Quartz may be instanced as an example of a positive crystal, although it will appear later that owing to its rotatory power the two wave-surfaces in a quartz crystal do not touch at any point, that is to say, the difference in refractive index for the two rays reaches a minimum along the optic axis, but never disappears entirely.

§ (7) Biaxial Crystals. (i.) *Wave Surface.*—Huygens did not extend his theory to explain the phenomena exhibited by biaxial crystals, and his construction is not applicable to this case. It is to Fresnel that we owe the earliest complete theory of double refraction, dealing with both biaxial and uniaxal crystals. Some account of this will be found in the article "Light, Double Refraction of." Meanwhile, it is sufficient to say that the wave-surface is of a somewhat complicated form, having two sheets; as shown in *Fig.* 2 the section of the surface by each of the principal planes is a circle and an ellipse.

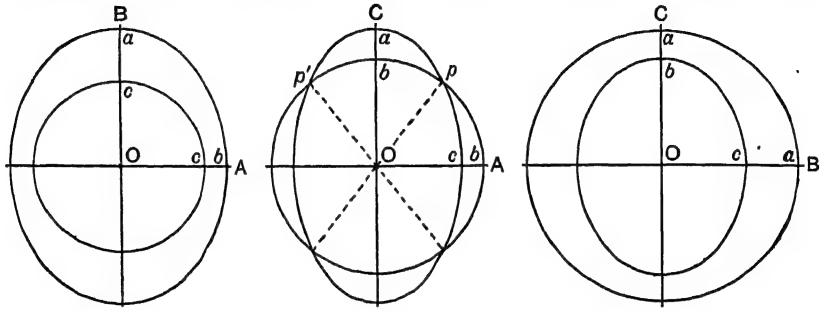

Fig. 2.

Fletcher's Indicatrix.—Another widely used representation of the optical properties of a crystal is *Fletcher's Indicatrix*. It is identical with the older "Index-ellipsoid" of M'Cullagh, the ellipsoid being constructed on semi-axes proportional to the three refractive indices referred to before (article "Light, Double Refraction of"). Space does not permit of a full explanation of the properties of the Indicatrix, which may be found in the larger treatises on Crystallography, or in the original paper by its inventor;[1] it must suffice to state that in any section of the ellipsoid the axes are proportional to the refractive indices of the two polarised rays whose wave-fronts move along the normal to that section, and indicate the vibration directions in the rays, while their difference in length gives a measure of the double refraction along the normal to the section.

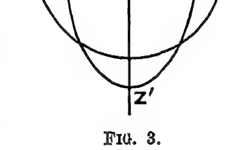

Fig. 3.

(ii.) *Primary and Secondary Optic Axes.*—The position of a plane wave for which there is only single refraction through the crystal will, as we have seen (article "Light, Double Refraction of"), be the plane tangential to the two wave-surfaces. Taking a section in that plane through two axes of the ellipsoid in which two sheets of the wave-surface intersect in N (*Fig.* 3), MM' represents the common tangent which touches the circular section in M and the elliptical section in M'. OM, the normal to the tangent plane through M, represents the direction in which a single wave-front is propagated, and, therefore, is the optic axis. ON, joining the centre to the point of intersection of the circle and ellipse, and representing the direction in which a single ray is propagated, is sometimes described as the *Secondary Optic Axis*; or it is described more completely by the name *Axis of Single Ray Velocity*.

[1] *Min. Mag.*, 1891, ix. 278.

(iii.) *Conical Refraction.*—Now if the complete wave-surfaces are considered and not merely the sections in the ZX plane, it can be proved mathematically that the common tangent plane through MM′ touches the surfaces in a circle and not merely in two points, as Fresnel originally assumed.

If, then, a plane wave is incident on the crystal parallel to the tangent plane MM′, any line joining points on this circle of intersection to the centre O will be possible directions for rays entering the crystal. The direction will be determined by the plane of polarisation of the incident light; if the latter is unpolarised, that is to say, if it contains vibrations in all possible directions, the refracted rays will take the form of a hollow cone of rays, each element of the cone being polarised in a separate plane. This phenomenon, known as *internal conical refraction,* was predicted by Sir William Hamilton,[1] and verified practically by Dr. Lloyd.[2] An analogous effect, known as *external conical refraction,* is produced by the refraction out of a crystal of a ray travelling along ON, or the axis of single ray velocity. The direction of the wave normal in the crystal will be normal to the plane touching the wave-surface at the point where it is intersected by the ray inside the crystal. Since the ray ON meets the wave-surfaces at the apex of a cone, there are an infinite number of tangential planes to the wave-surfaces at this point, and the normals from N to these planes will form a hollow cone. The ray ON when refracted out of the crystal will therefore form a hollow cone of light. The practical demonstration of both these phenomena, which are consequent on the theory of birefringence in crystals, helps to establish the correctness of that theory.

(iv.) *Relation between Morphological and Optical Properties.*—It is essential from the point of view of practical work with actual crystals to have a clear idea of the relation between their morphology and their optical properties.[3] It has already been stated that crystals exhibiting the highest possible symmetry, and therefore belonging to the cubic system, possess identical optical properties in all directions, and from an optical point of view behave in all respects as an isomorphous medium. Crystals of the tetragonal, hexagonal, and trigonal systems are uniaxial, their optic axis coinciding with the main crystallographic axis. Crystals of other systems, the rhombic, monoclinic, and triclinic systems, are biaxial. In a rhombic crystal the axes of Fresnel's or of Fletcher's ellipsoid coincide with the crystallographic axes in direction, although not necessarily in length. A monoclinic crystal possesses one crystallographic axis perpendicular to the plane containing the other two, which may be inclined to each other at any angle, and this axis, about which the crystal is symmetrical, coincides with one axis of the ellipsoid. The other two axes of the ellipsoid lie in the perpendicular plane of symmetry, but neither of necessity coincides with a crystallographic axis, and their position may show changes with a change of temperature or wave-length. In a triclinic crystal, which possesses no symmetry about any crystallographic axis, there is no definite relationship between the positions of the morphological and optical axes.

[3] See "Crystallography," §§ (7) and (21).

Dispersion of Axes and Bisectrices.—In dealing with the position of the optic axes and the bisectrices of the optic axial angle it was assumed that the wave-length of light remained constant. If white light is used in the examination of a crystal there may be different directions in the crystal for different wave-lengths along which there is no double refraction, and this will cause a *dispersion of the optic axes. Dispersion of the bisectrices* also may take place, the effects varying in different classes of crystals. In all cases in which an optic axis or a bisectrix coincides with a crystallographic axis there can be no dispersion; hence in uniaxial crystals the position of the axis is independent of wave-length. In rhombic crystals the bisectrices coincide with crystallographic axes, so that dispersion is limited to the optic axes. In some crystals it is almost too small for measurement, but in extreme cases the optic axial angle for red light is large, decreasing with decrease of wave-length until the crystal becomes uniaxial for light of a definite wave-length; for still shorter wave-lengths the optic axial angle opens out again but in the perpendicular direction. This phenomenon is known as *crossed axial dispersion.*

In monoclinic crystals dispersion of the bisectrices may also occur, since of the ellipsoidal axes only one coincides with a crystallographic axis. The effect produced varies according as this crystallographic axis coincides with the acute bisectrix or the obtuse bisectrix, or is perpendicular to the optic axial plane. Dispersion of the optic axis may also appear simultaneously and in certain cases may be unequal for the two axes. For fuller information on this subject the reader is referred to the standard text-books on Crystallography and Petrographic Methods by Tutton, Miers, Johannsen, Rosenbusch, Weinschenk and Clark, and other writers.

§ (8) Methods of Production of Polarised Light.—The various methods of producing a ray of plane polarised light from an ordinary unpolarised beam all depend fundamentally upon the resolution of the light into two components with vibrations in perpendicular directions, combined with the isolation of one component.

(i.) *By Reflection.*—We have seen that this can be effected very simply by repeated refractions of a ray incident at the polarising angle. A pile of thin glass plates may be

used for the purpose; while an increase in their number tends to increase the degree of polarisation of the transmitted light, it decreases the intensity simultaneously, and to minimise this disadvantage the plates used should be as thin as possible consistent with a fair degree of rigidity. Seven or eight plates of the thickness used for cover-glasses are sufficient to produce satisfactorily complete polarisation of both the reflected and the refracted light, while not reducing too greatly the intensity of the latter.

It is frequently desired to study the behaviour of various substances in polarised light, and generally, as well as a means of polarising the incident light, we require a means of analysing the final transmitted or reflected rays. The same instrument is usually capable of fulfilling both purposes, for if it transmits light vibrating in one direction only, thereby acting as a polariser, it can also be used as an indicator of the vibration direction of a polarised beam, and fulfils the function of an analyser. For some purposes the vibration direction of the analyser is arranged parallel to that of the polariser, but more usually their vibration directions are perpendicular; in the latter case the polariser and analyser are said to be "crossed."

(ii.) *By Refraction.*—For some purposes for which a small readily handled contrivance is preferable to a more perfect instrument requiring careful manipulation, a plate cut from a large tourmaline crystal parallel to the long hexagonal axis is found of use. Tourmaline is strongly birefringent, and also possesses a different coefficient of absorption for the two rays, with the result that the ordinary ray is completely absorbed, while the extraordinary ray is transmitted. Selective absorption lends the transmitted light a deep green colour, however, which greatly reduces its intensity and renders this method of production unsuitable for many purposes.

§ (9) Tourmaline Polariscope.—A simple polariscope can be constructed of two tourmaline plates mounted one above the other, and held in a pair of wire tongs in such a way that either plate can be rotated relatively to the other. The contrivance is well adapted for a rough examination of the behaviour in polarised light of a crystal specimen placed between the two plates. The lower plate acts as a polariser of light passing upwards through it, while the upper plate is used to analyse the light emerging from the specimen. If the plates are so orientated that the vibration direction of the extraordinary ray in the upper is at right angles to that for the lower plate, no light can pass through both plates, unless the presence of a crystal slice between them causes a rotation of the vibration direction of light transmitted by the lower plate. Any such effect can be examined by a rotation of the upper tourmaline.

§ (10) Nicol Prism.—The heavy loss of intensity due to the strong selective absorption of tourmaline is obviated if calcite is used, and this is employed in the construction of the *Nicol Prism,* which is the most generally used instrument for the production and examination of polarised light. With a rhomb of calcite special means have to be adopted to eliminate one of the two polarised rays. Early in the nineteenth century William Nicol [1] devised a means of attaining this result by slicing a rhomb of calcite diagonally and symmetrically through its blunt corners, polishing the cut surfaces and cementing them together with a thin layer of Canada balsam. The success of the device depends upon the fact that the refractive index for Canada balsam lies between that for the ordinary ray in calcite and the maximum refractive index for the extraordinary ray. Thus the dimensions of the prism must be so designed that the ordinary ray falls on the balsam film at an angle greater than the critical angle, and is totally reflected, while the extraordinary ray is transmitted. The ratio of the long edge of the crystal to the short end-face should be between 1 : 3·0 and 1 : 3·7; the sides of the prism are blackened to absorb the reflected light and the end-faces are polished. This represents the Nicol prism in its simplest form; modifications will be treated of later.

On looking through a Nicol prism and varying the angle of obliquity the observer sees that the polarised field is limited on one side by a blue haze which gradually obscures the light, and on the other by a narrow band of interference fringes beyond which the intensity is increased but all images are doubled.[2] A consideration of the actual passage of rays through the Nicol will show that these limits mark on the one hand the beginning of the region of total reflection of both rays, and on the other the end of the region of total reflection of the ordinary ray, the fringes being produced by the interference of the two rays within the balsam film; in the region beyond the fringes the increase in their path separation causes the formation of double images.

Fig. 4 represents a section of the prism perpendicular to the cut section. In the natural crystal the three faces bounding the obtuse solid angle A (*Fig.* 5) make equal angles with one another and with the crystallographic axis, which coincides with the optic axis AO. This latter lies in the plane ABCD, and makes an angle of about 45° with the end-face AD, the whole angle DAB being about 109°. The

[1] *Edinburgh New Phil. Journ.*, 1833, vi. 182, and 1839, xxvii. 332.
[2] Thompson, *Phys. Soc. Proc.*, 1877, ii. 185.

plane of section AC is inclined at very nearly 90° to the end-face AD. If the transparent film is of Canada balsam, the critical angle

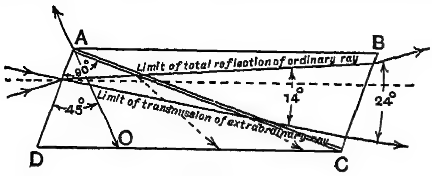

FIG. 4.

for the ordinary ray passing from calcite to balsam is 67° 53′; this limits the polarised field to an angle of 3° from the longitudinal axis in the direction of AB. Now although the maximum refractive index for the extra-

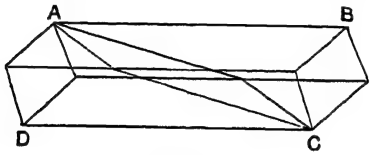

FIG. 5.

ordinary ray is greater than that of the balsam, as the angle of incidence with AC increases, the ray is travelling more nearly parallel to the optic axis, and its index decreases to a smaller value than that of the balsam, so that at a certain angle of incidence the extraordinary ray strikes the balsam at the critical angle. The value of this angle will vary with the wave-length, for the refraction at the end-face AD will cause the red rays to fall on the balsam film at a more oblique angle than the violet rays; hence the red rays are the first to suffer total reflection, and a blue fringe shows the limit to the useful field on the side nearest DC. The fringe appears at an angle of obliquity of about 11° inside the prism; the useful field within the prism is therefore limited to 14°, which corresponds to an external angular field of about 24° in air. The middle line of the field is inclined to the longitudinal axis at about 10°, and this gave rise to the custom often used of grinding the end-faces to make an angle of 68° with the sides before sectioning the prism On the other hand, Ahrens has adopted the practice in late years of trimming the end-faces by about 3° in the other direction, and then cutting the section plane perpendicular to them; this has the effect of increasing the field of view at the cost of making it less symmetrical with regard to the long axis of the prism. Square-ended prisms are also cut, and this not only decreases the percentage of light lost by reflection at the end-surfaces, but obviates any displacement of the image as the prism is rotated about its axis.

Since the extraordinary ray is polarised in a plane perpendicular to the principal plane, that is, perpendicular to the plane ADCB, its vibrations will take place in this plane. The trace of the vibration direction of transmitted light on the end-face of the prism will therefore be along AD, the shorter diagonal of the rhombic face.

§ (11) OTHER POLARISING PRISMS.—Various devices have been adopted to give improvements in the directions of widening the field of view, lessening the percentage of light lost by reflection, increasing the working aperture relative to the length of the crystal, and of giving uniform polarisation over the whole field. To these ends modifications have been made in the inclinations of the section plane and end-faces to the long sides, and in the substance used for the transparent film. A full account of the detailed construction of the Nicol prism, together with a description of other cognate forms of polarising prisms, is given by Silvanus P. Thompson.[1] The chief modifications are due to:

Hartnack,[2] who widened the field of view by cutting the section perpendicular to the optic axis, at a great cost of material.

Foucault,[3] who dispensed with the difficulties attached to cementing the interface by using an air-film. This gave a very narrow field of view and introduced the disadvantage of multiple reflections caused by the air-film.

Glan,[4] who designed a square-ended Foucault prism with the plane of section containing the optic axis.

Jamin,[5] who reversed the construction of the Nicol, and used the ordinary ray transmitted by a thin plate of spar placed between rectangular prisms of carbon bisulphide contained in a metal tube with glass ends. This was further modified by Zenker,[6] who used prisms of dense flint, and by Feussner.[7]

Leiss,[8] who proposed the substitution, for economical reasons, of a prism of glass of similar index for the second half of a Nicol prism.

Thompson (*loc. cit.*) also describes many different forms of prism devised by himself, with references to several other investigators, including Dove,[9] Glazebrook,[10] and Bertrand,[11] who have sought to find the ideal mean

between a prism of greatest utility and one involving small waste of material, an almost equally important consideration owing to the small supply of large flawless crystals of Iceland spar.

Ahrens[1] devised a triple prism (*Fig.* 6), consisting of two calcite prisms cut with their refracting edges parallel to the optic axis, cemented on either side of a calcite prism cut with its edge perpendicular to the axis. A

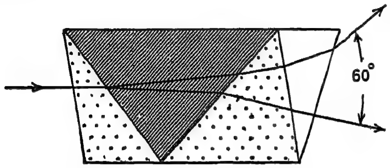

FIG. 6.

rectangular prism of flint glass cemented to the third prism serves to deflect the unused ray 60° from the normal. This prism has a comparatively large angular field. A later form consisted of a triple prism cut from a rectangular block of spar (*Fig.* 7), the three wedges being cemented together with balsam. The ordinary ray is deflected partly to the right and partly to the left, and the extraordinary ray passes through normally, perpendicular to the optic axis. The prism possesses a large aperture relative to its length.

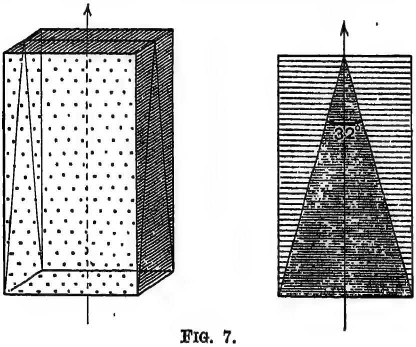

FIG. 7.

Other polarising prisms have been designed by several authors.

Abbe's[2] design consisted of two 30° crown glass prisms cemented with a substance of the same refractive index to the sides of a 60° prism of calcite cut with its refracting edge parallel to the optic axis. The refractive index for the glass must be that for the extraordinary ray in calcite, so that this ray passes undeflected through the block, while the ordinary ray is deviated. The prism has a field of view of about 23°.

Stolze[3] designed a polarising prism constructed entirely of glass. A ray entering normally is twice internally reflected, first at a silvered surface, the polarisation taking place at the second surface by total reflection at the polarising angle, after which the ray emerges normally from the end-face. The lateral displacement of the emergent ray and its incomplete polarisation, due to almost unavoidable strains present in the glass, detract from the utility of this prism.

Schulz's[4] design obviates both these disadvantages, but the prism is not so simply constructed (*Fig.* 8). The surfaces AE and BD are silvered, and a ray entering AB normally leaves EF normally and is reflected at the polarising angle from CE, the emergent beam being in line with the incident beam;

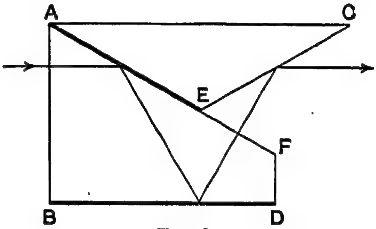

FIG. 8.

the polarisation is unaffected by strain in the glass since it takes place outside the prism. Ten per cent of the incident light is transmitted as compared with 25 per cent to 40 per cent by the Nicol prism, but since no calcite is used there is not the same objection to using a larger prism if a greater amount of light is required.[5]

§ (12) DOUBLE-IMAGE PRISMS.—Various prisms have also been designed to produce two widely separate images of a single object. *Wollaston's Prism* consists of two rectangular prisms of calcite ABC and DAC (*Fig.* 9) cemented together to form a rectangular block. The prism ABC is so cut that the optic axis of the crystal is parallel to the surface AB at which the light enters, while in the other prism the axis is still parallel to the surfaces AB and CD but turned through 90°. A ray of light entering AB normally

[1] *Journ. Roy. Micros. Soc.*, 1884 (2), iv. 533, and 1886, vi. 476; *Phil. Mag.*, 1884 (5), xix. 69, and 1886, xxi. 476.

[3] *Atelier der Photographen*, 1895, p. 140.

[4] *Zeits. Instrumentenk.*, 1911, xxxi. 180.

[5] A device used before the invention of the Nicol prism was the truncation of the blunt corners of a calcite rhomb, each cut limiting the field of view laterally so as to prevent the clear passage of the ordinary ray through the prism. A somewhat similar device has recently been reintroduced for use in polarimetry and other purposes where a wide field of view is not essential; the prisms give good polarisation and are free from the disadvantages attached to a cemented prism.

will travel perpendicularly to the axis and will be divided into two coincident polarised rays vibrating parallel and perpendicular to

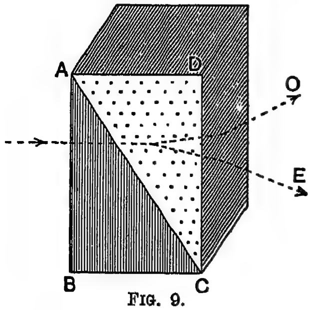

FIG. 9.

the plane of the paper. On crossing the plane of section the ordinary ray of the first prism becomes the extraordinary ray of the second, and *vice versa*; the refractive index therefore increases for one ray and decreases by the same amount for the other ray, so that both are deflected in opposite directions from the normal to AB. The divergence of the rays is further increased on their refraction at the surface CD, and they form two widely separated images polarised in perpendicular planes. On rotating the prism about the normal to AB the two images rotate simultaneously, each retaining the same position relative to the prism. If the prism is tilted so that the rays are incident obliquely the images are seen to separate or approach according to the direction of tilt, always supposing the tilt to be in the plane containing the two images. A modification is sometimes made by using one calcite prism and one glass prism. In this case the change of refractive index for each ray at the interface is less, though still in opposite directions, so that such a prism, although cheaper in construction, does not give as great total deviation.

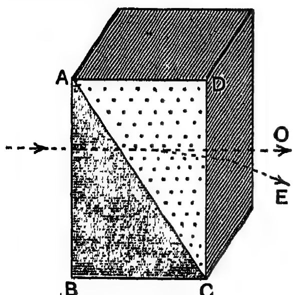

FIG. 10.

Rochon's Prism (*Fig.* 10) is similar in general design, except that the optic axis in the first prism is perpendicular to the entrance face. No separation of normal light occurs in the first prism, therefore, and on passing into the second half the ordinary ray travels on unchanged in direction while the extraordinary ray is deviated further from the normal to the plane of section. On emergence, therefore, the rays form two images of which only one is deflected from the normal, and on rotating the prism only the latter image rotates while the ordinary image remains stationary.

§ (13) GENERAL EQUATIONS REPRESENTING VIBRATIONS OF POLARISED LIGHT.—So far we have dealt only with polarised light in which the vibrations are restricted to rectilinear motion, and it was merely noted in passing that light may also be polarised in such a fashion that the particles describe circular or elliptical orbits. The relation of such vibrations to those of plane polarised light is best shown by an examination of the mathematical equations representing them.

The simple equation representing the displacement at any moment of a particle moving in simple harmonic motion in a straight line is

$$y=a \sin 2\pi\frac{t}{T},$$

where a is the amplitude, T the period of the vibration, and t the time that has elapsed since the particle was in its zero position. We may equally well look upon y as a periodic electrical force.

Now suppose this equation to represent the vibration of a plane polarised ray striking a doubly refracting plate. Let OX, OY (*Fig.* 11) represent the directions of vibration in the plate, and let OK, the direction of vibration of the incident ray, make an angle i with the direction OY. On entering the plate the vibration OK is decomposed into components along OX and OY, represented by

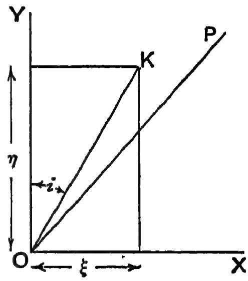

FIG. 11.

$$\xi=a \sin 2\pi\frac{t}{T} \sin i, \quad \eta=a \sin 2\pi\frac{t}{T} \cos i.$$

These two vibrations in general travel through the crystal plate with different velocities, so that if O and E represent the distances travelled in air in the times taken by the ordinary and extraordinary waves respectively to traverse the plate, the displacements will be

$$\left.\begin{aligned}\xi&=a \sin i \sin 2\pi\left(\frac{t}{T}-\frac{O}{\lambda}\right)\\ \eta&=a \cos i \sin 2\pi\left(\frac{t}{T}-\frac{E}{\lambda}\right)\\ &=a \cos i \sin 2\pi\left(\frac{t}{T}-\frac{O}{\lambda}+\frac{O-E}{\lambda}\right)\end{aligned}\right\}, \quad . \quad (1)$$

where λ is the wave-length of the light in air.

The two waves emerge parallel and the light refracted from the plate will be resultant of two superposed vibrations of the same period and amplitude but differing in phase by an amount $(O-E)/\lambda$, which varies with the thickness of the plate.

Combining equations (1) by the elimination of t we shall obtain an expression for the resultant vibration.

Let $2\pi\left(\frac{t}{T}-\frac{O}{\lambda}\right)=\theta$ and $2\pi\left(\frac{O-E}{\lambda}\right)=\phi$.

Then equations (1) may be written

$$\frac{\xi}{a\sin i}=\sin\theta,$$

$$\frac{\eta}{a\cos i}-\sin\theta\cos\phi=\cos\theta\sin\phi.$$

Squaring both sides of the second equation and substituting for $\sin^2\theta$ and $\cos^2\theta$ from the first, we obtain

$$\frac{\eta^2}{a^2\cos^2 i}+\frac{\xi^2}{a^2\sin^2 i}\cos^2\phi-2\frac{\xi\eta}{a^2\sin i\cos i}\cos\phi$$

$$=\left(1-\frac{\xi^2}{a^2\sin^2 i}\right)\sin^2\phi.$$

Hence $\frac{\xi^2}{a^2\sin^2 i}+\frac{\eta^2}{a^2\cos^2 i}-\frac{2\xi\eta\cos\phi}{a^2\sin i\cos i}=\sin^2\phi,$

or

$$\xi^2\cos^2 i+\eta^2\sin^2 i-2\xi\eta\sin i\cos i\cos 2\pi\frac{O-E}{\lambda}$$

$$=a^2\sin^2 i\cos^2 i\sin^2 2\pi\frac{O-E}{\lambda}. \quad (2)$$

This indicates that the general form of the resultant vibration is an ellipse one of whose axes is inclined to the vibration direction in the plate at an angle i.

Special cases may be considered.

(i.) *Plane Polarised Light.*—If the difference in optical path $O-E=n\lambda/2$, so that $2\pi(O-E)/\lambda=n\pi$, equation (2) reduces to

$$\xi^2\cos^2 i+\eta^2\sin^2 i\pm2\xi\eta\sin i\cos i=0,$$

or $$\xi\cos i=\pm\eta\sin i. \quad (3)$$

Hence if the plate is of such a thickness that the phase difference on emergence is equal to any whole number of half wave-lengths, the resultant vibrations are plane polarised. If n is even, $\xi/\eta=+\tan i$, and the vibrations are parallel to those of the incident light. If n is odd, $\xi/\eta=-\tan i$, and the vibrations are in a direction equally inclined to the Y axis but on the side of it remote from the incident vibration direction.

Moreover, this is the only condition which reduces equation (2) to the rectilinear form.

(ii.) *Circularly Polarised Light.*—If, however, $O-E=(2n+1)\lambda/4$, and $i=45°$, we have

$$\sin i=\cos i=1/\sqrt{2},$$

and $$2\pi(O-E)/\lambda=(2n+1)\pi/2.$$

Equation (2) then becomes

$$\xi^2+\eta^2=a^2/2, \quad (4)$$

representing uniform motion in a circle of radius equal to the amplitude of the original vibration. When, therefore, the phase difference between the two rays is equal to an odd number of quarter wave-lengths, and when the plane of polarisation of the incident ray is equally inclined to those of the rays traversing the crystal plate, the emergent ray will be circularly polarised. A crystal plate which fulfils this condition of phase difference between its emergent vibrations is known as a *quarter-wave plate* ($\lambda/4$ plate), and provides a ready method of producing circularly polarised light.

(iii.) *Elliptically Polarised Light.* — If $O-E=(2n+1)\lambda/4$, but i is not equal to 45°, equation (2) becomes

$$\frac{\xi^2}{\sin^2 i}+\frac{\eta^2}{\cos^2 i}=a^2. \quad (5)$$

That is to say, if a quarter-wave plate is so orientated that its vibration directions OX and OY are not equally inclined to the vibration direction, OK, of the incident light, the emergent ray is elliptically polarised, the axes of the ellipse being parallel to OX and OY. It is obvious that in the limiting cases when $i=0°$ or 90°, the ellipse becomes a straight line parallel to OY or OX, that is to say, the crystal transmits one ray only.

§ (14) Circularly Polarised Light. (i.) *Production by Refraction.*—Circularly polarised light can be produced, as mentioned above, by the use of a quarter-wave plate. Such a plate is most easily prepared by splitting mica along its cleavage planes into very thin sheets; by trial a sheet can then be chosen such that it produces between the transmitted rays a phase difference of $\lambda/4$ for any fixed value of λ. For use with sodium light the thickness of a quarter-wave plate of mica is 0·032 mm. It is useful not only to know the vibration directions in the plate, but also to be able to distinguish between the directions of slower and faster transmissions.

The vibration directions are easily found by holding the plate between crossed Nicols. When it is in such a position that the field remains dark its vibration directions must be parallel to those of the Nicol prisms. A method of distinguishing definitely between the directions of the fast and slow transmissions is given by R. W. Wood.[1] If the mirrors of a Michelson interferometer are adjusted to give a system of fringes in white light plane polarised in a horizontal plane, the introduction into the path of one ray of a quarter-wave plate with its vibration directions

[1] *Physical Optics*, 1914, p. 320.

horizontal and vertical will produce a retardation in that ray relative to the other, and a shift of the fringes will ensue. Now if the plate is turned through 90°, there will be a further shift in the fringes. If it is in the same direction as before, it is clear that a further retardation of that ray has taken place; that is to say, the direction which was at first horizontal is the direction of vibration of the faster moving component.

(ii.) *Production by Reflection.*—We have seen that when a plane polarised ray strikes the dividing surface between two media at the polarising angle the reflected ray and the refracted ray are polarised in perpendicular planes. Now if the conditions be those required for total reflection, both rays will be reflected along the same path, but there will be a phase difference of $\lambda/8$ between their vibrations. Two total reflections of the rays will therefore produce the phase difference of $\lambda/4$ necessary for the production of circularly polarised light, and the only other necessary condition is that the original plane of polarisation should be at 45° to the plane of incidence. Fresnel constructed a glass rhomb through which a plane polarised ray could pass (*Fig.* 12), suffering two total internal reflections

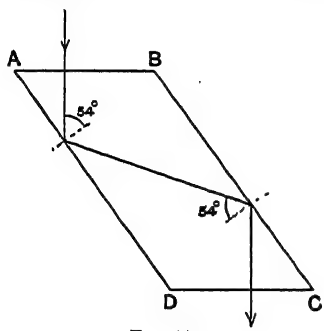

FIG. 12.

at the polarising angle of 54°, and thus attaining a phase difference of $\lambda/4$ between the two emerging components. Since the polarising angle for a glass-air surface varies very little with change of wave-length, the phase difference of the emergent rays is nearly independent of the colour of the light, and in this respect this method of production of circularly polarised light is preferable to the use of a quarter-wave plate.

(iii.) *Methods of Detection.*—It is obvious that circularly polarised light differs from both plane and elliptically polarised light by possessing no unique pair of perpendicular planes about which the path of a vibrating particle is symmetrical. Consequently when examined by an analysing prism a circularly polarised beam shows no change on rotation of the prism. In this respect it resembles unpolarised light, but can be distinguished from the latter by its behaviour in conjunction with a quarter-wave plate, for if the plate be so orientated that it neutralises the phase difference existing between the two components of the circularly polarised light the emergent light will be converted to plane polarised light, which can then be extinguished by a suitable orientation of the analysing prism.

It is of use in some connections to determine the direction of rotation of circular vibrations, which, if produced by a crystal plate, will vary according to the character of the crystal and the plane of polarisation of the incident light. This will be clear on reference to *Fig.* 11. Suppose OP represents the vibration direction of the incident light. The force moving a particle from O towards P will be resolved in the plate into two perpendicular forces tending to move the particle from O towards X and Y, where OX and OY are the vibration directions of the ordinary and extraordinary rays respectively. In a positive crystal the ordinary ray travels the faster, so that the vibration along OX, say, is executed more quickly than that along OY. After a certain interval of time there is a phase difference between the rays of $\lambda/4$, that is to say, while the particle is about to move from X towards O there is an equal force propelling it in a perpendicular direction upwards. Hence it will move by a circular path in a counter-clockwise direction from X to Y. If at this moment the rays emerge from the plate there will be no further change in the phase difference, and the vibration will continue to be circular and counter-clockwise. In a negative crystal it is obvious that under the same conditions the path of a vibrating particle would be clockwise. These deductions, together with a consideration of the case when the vibration direction of the incident ray is perpendicular to OP, leads to the rule that if the vibration direction of the incident light is turned in a clockwise direction through 45° from the direction of fastest vibration in the crystal plate, the circular path of the emerging vibrations will be described in a clockwise direction also.

The direction of vibration can be found experimentally by means of a quarter-wave plate for which the direction of the faster vibration is known. By a suitable orientation of the plate the phase difference of the light under examination can be neutralised or doubled, with the production of light plane polarised parallel or perpendicular to the incident light, and the directions of fast and slow vibrations in the unknown plate can be deduced. An application of the construction given above then determines the rotational direction.

§ (15) Elliptically Polarised Light. (i.) *Production.*—From what has already been said it is evident that the conditions under which circularly polarised light is produced are special cases of the conditions necessary to produce elliptically polarised light. The production of the latter, therefore, generally requires the fulfilment of one condition less than the number necessary for the production of circular polarisation. For example, dealing first with methods of production by refraction, if a quarter-wave plate is used, elliptically polarised light is produced if the plane of polarisation makes any angle with the vibrations in the plate between 0° and 90°; at an angle of 45° the elliptical vibration becomes circular. The condition regulating the thickness of the plate for the production of circular polarisation may be relaxed for elliptical polarisation, which will result from the passage of plane polarised light through a thin plate producing any phase difference that is not a multiple of $\lambda/4$, but in this case the axes of the ellipse will be inclined to the original direction of vibration.

For production by a reflection method, it is obvious that the necessary conditions are fulfilled by a single internal total reflection in a glass prism of plane polarised ray at the polarising angle, for this produces a phase difference of $\lambda/8$ between two coincident perpendicularly polarised rays. When the plane of polarisation of the incident light is inclined to the plane of incidence at an angle of 45° the light reflected from any medium is to some extent elliptically polarised. With transparent media the eccentricity of the ellipse is so great that the vibrations are very nearly linear, but if the reflection takes place from a metallic surface the ellipticity of the polarisation is pronounced, and when the incident light is polarised at an angle of 45° with the angle of incidence the polarisation of the reflected light is nearly circular.

Drude[1] explains this production of elliptical polarisation by postulating a gradual, in place of an abrupt, change of refractive index at the surface of the medium. Further work by Lummer and Sorge[2] on solid media and by Lord Rayleigh[3] on liquid surfaces shows that a higher surface refractive index, due in the former case to the action of polishing materials and in the latter to the presence of a thin film of grease, tends to produce elliptical polarisation of reflection, but the two former authors have also shown that in some cases the phenomenon is probably due to the presence of surface strains in the medium, and is affected by subjecting the medium to pressure.

(ii.) *Methods of Detection and Analysis.*—When examined with an analysing prism elliptically polarised light shows a waxing and waning of intensity on rotation of the prism, the maximum and minimum points occurring when the vibration direction of the Nicol is parallel to the longer and shorter axes of the ellipse respectively, but no orientation of the analyser wholly extinguishes the light. In this respect elliptically polarised light behaves like a mixture of plane polarised and unpolarised light, but it can be distinguished from the latter, as in the similar case of circularly polarised light, by its reduction to plane polarised light by means of a quarter-wave plate suitably orientated. The direction of the axes of ellipse can be deduced at the same time, for they must of necessity be parallel to the principal planes of the quarter-wave plate when it is in position to render the emergent light plane polarised. The ratio of the axes can be calculated by determining, by means of a Nicol prism, the angle between the vibration direction of the emergent plane polarised light and the directions of the axes of the ellipse.

(iii.) *Babinet's Compensator.*—A more accurate method of determining the constants of an elliptical vibration is by the use of *Babinet's Compensator.* This consists of two rectangular prisms of quartz (*Fig.* 13) placed with their hypotenuses in contact so that together they form a plane parallel plate, the thickness of which can be varied by sliding the prisms along their interface. The optic axes are parallel and perpendicular to the plane of the paper in the two halves as represented by the shading of each prism. Plane polarised monochromatic light entering the plate normally is resolved into two rays whose separation is further increased on entering the second prism. The relative retardation produced between the rays by their passage through the whole plate is proportional to $(e_1 - e_2)(\mu_e - \mu_o)$, where e_1 and e_2 are the distances traversed in the two prisms, and μ_e and μ_o are the two extreme refractive indices. Along certain lines parallel to the prismatic edges the phase difference between the emergent rays will be equal to a whole number of wave-lengths; there will therefore be equidistant lines of plane polarised light occurring in the emergent light, which can be made to appear as dark bands by the use of an analysing prism crossed with reference to the polariser. Between the bands the light will be elliptically polarised in general; half-way between each band the light will be plane polarised in a direction oblique to the plane of polarisation of the first set, being perpendicular to it. If the plane of polarisation of the incident light

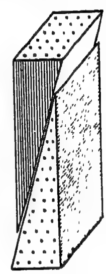

Fig. 13.

[1] *Lehrbuch der Optik*, 1900, p. 266, Engl. trans., 1920, p. 287.
[2] *Ann. d. Physik*, 1910, xxi. 325.
[3] *Phil. Mag.*, 1908, xvi. 444; *Scientific Papers*, iii. 496.

is at 45° to the vibration directions of the prisms, this condition gives the best definition to the bands when examined with an analyser.

The compensator can be used as a measure of phase difference, since the space between each dark band or graduation corresponds to a difference in retardation of $\lambda/2$. If now one prism is slid over the other through a certain distance, the system of dark bands moves unchanged through half that distance. If a is the linear distance between two adjacent bands, a shift of the prisms by an amount x will produce a change in the retardation at any point of $\frac{1}{2}\lambda x/a$. Any change taking place in the state of polarisation of the transmitted light will be accompanied by a change in the retardation produced, and this can be measured by the relative alteration in position of a dark band. The original form of compensator was provided with a cross-wire controlled by a micrometer screw, the prisms being fixed in position; Jamin adapted the instrument to the special study of light vibrations, and replaced the movable cross-wire by a fixed wire, at the same time connecting one prism to the micrometer screw.

To determine the phase difference of the two components forming an elliptically polarised ray the cross-wire of the instrument is set on the central dark band, corresponding to zero phase difference. Elliptically polarised light is then substituted for the incident plane polarised light, and the quartz wedge is moved by the micrometer screw to bring the central band and cross-wire into coincidence again. This gives a measure of the phase difference producing the elliptical vibrations; if the compensator is rotated until the phase difference is $\lambda/4$, the axes of the elliptical vibration will be parallel to the vibration directions in the quartz prisms, while their ratio is given by the tangent of the angle between one of these directions and the vibration direction of the analysing Nicol.

(iv.) *Savart's Polariscope.*—*Savart's polariscope*, which is used for the detection of small quantities of plane polarised light in a partially polarised beam, is constructed to give similar parallel dark bands. A plane parallel plate is cut from a quartz crystal at an angle of 45° to the optic axis. The plate is then sectioned parallel to the plane surfaces, one half is rotated through 90° relative to the other, and the two are cemented together. The greatest sensitivity is attained when the direction of the polarised vibration is perpendicular to the dark bands produced between crossed Nicols; in this position as little as 1 per cent of polarised light can be detected.

§ (16) Behaviour of Crystal Sections in Polarised Light.—One of the chief applications of polarised light is to the examination of thin crystal sections, for the variation in their behaviour towards transmitted light is one of the most valuable criteria for the identification of crystals.[1] In general the crystal to be examined is obtained in the form of a plane-parallel plate, too thin to cause the total separation of the ordinary and extraordinary rays when both are produced, but thick enough to give clear indications of the isotropic or birefringent nature of the crystal and its general optical character.

The most essential instrument for the examination of crystal sections is some form of petrographical microscope, fitted with removable polarising and analysing Nicols which can be rotated together relative to the specimen or separately relative to one another. The microscope should also possess fittings to hold a quarter-wave plate, quartz wedge or gypsum plate, the use of which will appear later. The whole subject of crystal examination is vast and intricate; it is proposed to give here only a brief indication of the main characteristics of crystal sections and the general methods employed. It must be borne in mind that, although it is mainly the characteristics of principal sections of crystals that are dealt with, an examination of a microscopic slide will in general show crystal sections cut in all directions, in which case their properties will be modifications of those described.

There are two main classes of phenomena displayed by crystal sections: firstly, those displayed in parallel plane-polarised light, and, secondly, those occurring when the polarised rays are convergent. The former class, as being the simpler, will be considered first.

§ (17) Crystal Sections in Parallel Light.—It has been shown that in many respects the character of a crystal may vary in different directions. This may be applicable also to its powers of absorbing light.

(i.) *Pleochroism.*—Some crystals show different powers of selective absorption for the ordinary and extraordinary rays, with the result that a section parallel to the axis may appear of one colour when the ordinary ray only is transmitted and a different shade of the same colour, or an entirely different colour, when it is seen by extraordinary rays only. The coloured mica known as biotite is a good example of a *pleochroic crystal*, as it is termed; the extreme case of tourmaline has already been mentioned, and in sections not sufficiently thick to absorb the ordinary ray completely there is a variation in colour from a pale bluish-green to an almost opaque brown as the plane of polarisation of the incident light is rotated.

(ii.) *Interference Tints.*—The appearance of crystal plates between a pair of Nicols depends

[1] See "Crystallography," § (21).

on the nature of the rays emerging from the crystal. In general the two rays produced by a birefringent crystal emerge with a definite phase difference depending upon the nature of the crystal, its thickness, and the wave-length of light used. Assuming that the section is of a standard thickness, so that the effects produced by different sections can be correlated easily,[1] the polarisation of the emergent light will depend upon the wave-length of the light; if white light is used, the difference in retardation for different wave-lengths will lead to the plane polarisation of light of some colours and elliptical or circular polarisation of light of other colours. If the Nicols are crossed, the observer will lose light of all wave-lengths for which the phase difference in the plate is any multiple of λ (remembering that the resolution of the two perpendicularly polarised rays to the vibration direction of the analyser causes a further retardation of $\lambda/2$), and the resultant light will possess the colour complementary to that absorbed. The colours corresponding to retardations of varying amounts are given in the well-known Newton Scale of Interference Colours. A crystal of low birefringence will produce a small phase difference equivalent only to one wave-length for some particular shade. That colour alone will be eliminated, and a tint of the first order appears, clear grey, yellow, or red; higher birefringence entails the loss of more than one colour, and is indicated by the brilliant second order tints, while very powerful double refraction gives the soft impure tints of still higher orders.

(iii.) *Extinction.*—If the vibration direction of the analyser is parallel to one of the vibration directions in the section, the polarised light will pass through the crystal unresolved, and will be cut off completely by the analyser. Thus if a crystal section is revolved in its own plane between crossed Nicols, in four perpendicular positions the field appears dark; these are known as the *positions of extinction*, and the line in the section then parallel to the vibration direction of the polariser is known as the *direction of extinction*. The angle between the direction of extinction and a crystallographic axis indicates the nature of the crystal; uniaxial crystals have "straight extinction," that is to say, their extinction angle is zero. Accurate measurement of this angle, either with the microscope or by other methods, is of great importance in the systematic investigation of a crystal. Sections of birefringent crystals perpendicular to an optic axis and all sections of a cubic crystal will, of course, appear dark in all positions between crossed Nicols.

(iv.) *Sign of Birefringence.*—The sign of the birefringence may be deduced by the use of a *gypsum plate*. Such a plate is a thin cleavage section of the monoclinic crystal gypsum (selenite), the cleavage being parallel to the plane of symmetry, which contains the optic axes. A section of suitable thickness shows a uniform interference tint of first order red between crossed Nicols, and a slight change in the phase difference is enough to change the tint sharply to the lower first order blue-grey or the higher second order yellow. Now, if a crystal section whose extinction directions are known is superposed on the gypsum plate between crossed Nicols, so that one extinction direction, that is to say, the vibration direction of one ray, is parallel to one vibration direction in the plate, a raising of the colour tint to yellow will indicate that the directions of fast vibration in the two crystals coincide. It is only necessary to have the directions of fast and slow vibrations marked on the gypsum plate to be able to deduce at once the corresponding directions in the crystal, and thence by reference to the position of its optic axis, or axes, to determine the sign of its birefringence.

§ (18) Crystal Sections in Convergent Light.—The second class of phenomena shown in the examination of crystal plates is produced when the section is viewed in convergent or divergent polarised light, and takes the form of the well-known "rings and brushes" produced by interference. For this purpose the microscope has practically to be converted into a telescope; details of the necessary arrangement may be found in Spitta's *Microscopy*, p. 203 (1907), or in F. E. Wright's *Methods of Petrographic Microscopic Research*, p. 39 (1911). (To the latter work the reader is also referred for a very detailed account of the apparatus and methods used in the exact microscopic measurement of the optical constants of a crystal.) With this arrangement any point on the field of view corresponds not to any special point on the section, but gives the total effect of all rays travelling through the section at a certain angle, the centre of the field corresponding, of course, to the effect produced by light parallel to the axis of the system and normal to the section.

(i.) *Uniaxial Crystals.*—Let us consider first the behaviour of a plate cut from a uniaxial crystal perpendicular to the axis. Suppose the light to be diverging from S, and polarised to vibrate vertically (*Fig.* 14A), and let P represent the crystal section whose optic axis is in the direction of OS. Any oblique ray will emerge from the plate with a definite phase difference between its two perpendicularly polarised components. The phase difference will vary with the angle of obliquity, assuming that the thickness of the plate and the wave-length are constant. Hence

[1] The thickness of a rock section or crystal section cut for general examination is usually between 0·01 mm. and 0·02 mm., producing in quartz the clear grey and yellow of the first order interference tints.

for a certain ray Sp the phase difference produced by the plate will have a value λ, and when examined through an analyser the corresponding point in the field of view will appear dark. The locus of all points corresponding to rays passing through the plate with the same obliquity but varying azimuth, must by symmetry be a circle round O; consequently there will be a dark circular

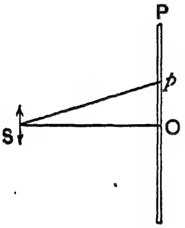

FIG. 14A.

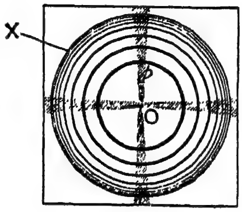

FIG. 14B.

fringe visible marking a phase difference of λ. Similarly, there will be other concentric circles marking the locus of points where the retardation is 2λ, 3λ, . . . $n\lambda$, their separation decreasing towards the edges of the field. Moreover, any ray lying in the planes parallel or perpendicular to the vibration direction of the polariser will not undergo resolution in passing through the plane, and will be cut out

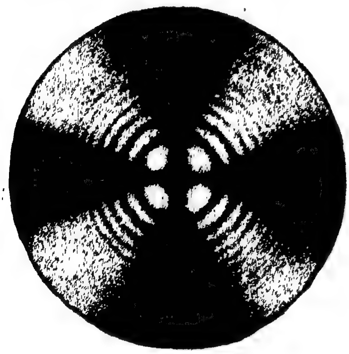

FIG. 16.

FIG. 17.

entirely by the analyser. This will result in the field of view being crossed by dark rectangular diagonals parallel to the vibration directions of the polariser and analyser, and the appearance of the field will be similar to that shown in *Fig.* 14B. With monochromatic light the fringes will be black; white light will give coloured fringes. The black fringes, known as *isochromatic lines*, represent the intersection with the crystal plate of the *isochromatic surfaces*, which are the loci in space of all points at which the phase difference is the same. For uniaxial crystals each isochromatic surface is formed by the revolution of a hyperbolic curve about the optic axis. This surface is shown in *Fig.* 15, together with the more complicated form for biaxial crystals. Sections of a uniaxial crystal perpendicular to the optic axis show circular fringes, as we have already

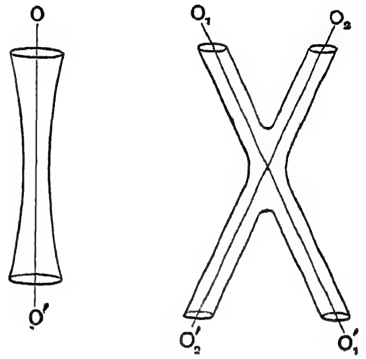

FIG. 15.

seen; in sections parallel to the optic axis the intersection with the isochromatic surfaces will be hyperbolae. Photographs of the interference figures for uniaxial crystals are shown in *Figs.* 16 and 17. The case of quartz and other optically active crystals is worthy of comment. The interference figure for quartz cut perpendicular to the axis is shown in *Fig.* 18. It will be noted that it resembles that of other uniaxial crystals except in that part representing rays travelling along or close to the optic axis. As will be shown later, the rotatory power of quartz leads to the deduction that a ray parallel to the axis is resolved into two circularly polarised rays which combine on emergence to form light polarised in a direction dependent on the thickness of the crystal. Except for certain thicknesses of quartz, therefore, the centre

of the interference pattern produced will show bright between crossed Nicols.

(ii.) *Biaxial Crystals.*—In the case of biaxial crystals a section perpendicular to the acute bisectrix will show the isochromatic lines as a family of lemniscates enclosing the points corresponding to light travelling along the optic axes. These will be crossed by dark brushes, the position of which varies with the

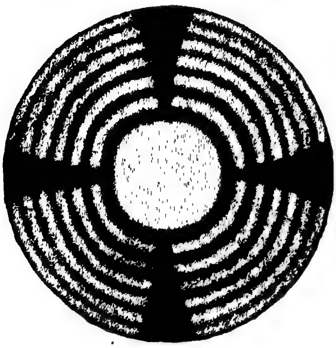

FIG. 18.

position of the optic axial plane in the section relative to the vibration directions of the Nicols. *Fig.* 19 shows the appearance of the fringes when these directions are parallel;

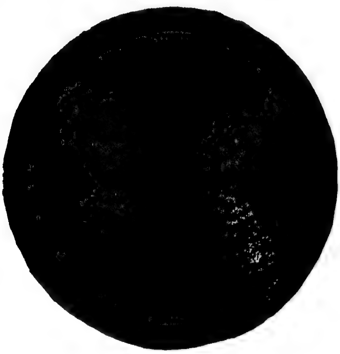

FIG. 19.

if the section is rotated through 45° the brushes become hyperbolae, whose vertices are at the points corresponding to the directions of the optic axes (*Fig.* 20). If white light is used the effect is complicated by dispersion of the optic axes and bisectrices.

(iii.) *Measurement of Optic Axial Angle.*—It is this latter 45° position that is used for measuring the optic axial angle. By tilting the section about an axis in its plane perpendicular to the line joining the optic axial points, the position of the hyperbolic fringes is changed, and the tilt can be adjusted until one vertex lies on the cross wires of the microscope. Then rays parallel to the axis of the microscope must travel along an optic axis. If both vertices

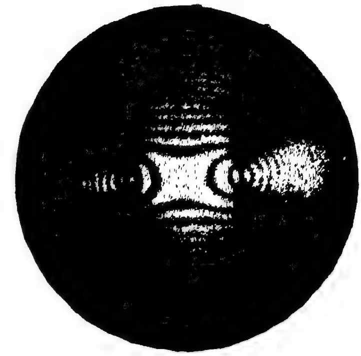

FIG. 20.

are brought in turn on to the cross wires the angle of tilt between the two positions gives the angle between the optic axes in air. It may be necessary, if the optic axial angle is very large or very small, to use a liquid of high refractive index between the objective and the section, so that both axial rays can be brought normal to the field in turn; by obtaining measurements in sections cut perpendicularly to the acute and obtuse bisectrices the actual optic axial angle in the crystal can be obtained.[1]

(iv.) *Sign of Birefringence.*—Mention must be also made of the use of a quarter-wave plate and a quartz wedge in determining from the interference figure the sign of birefringence of a crystal. Suppose a quarter-wave plate of mica is inserted between the analyser

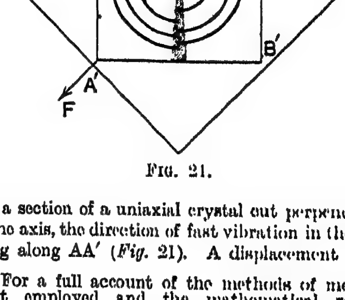

FIG. 21.

and a section of a uniaxial crystal cut perpendicular to the axis, the direction of fast vibration in the mica being along AA′ (*Fig.* 21). A displacement of the

[1] For a full account of the methods of measurement employed and the mathematical relation between the apparent and true optic axial angles see F. E. Wright (*loc. cit.*), and *Manual of Petrographic Methods*, Johannsen, p. 102.

ring system will occur, adjacent quadrants expanding and contracting. If the crystal is positive the rings in quadrants A and A′ will expand and those in B and B′ will contract; with a negative crystal the result will be reversed. This follows very simply from a consideration of the retardation at a point P, say, in the quadrant B. If P lies on BB′ the retardation in the crystal will take place between rays vibrating parallel to OB and OA, and if the crystal is positive, OA will be the direction of faster vibration, which therefore coincides with the faster vibration direction of the mica plate. The retardations of the crystal and the mica will therefore be additive, and the total phase difference increased; this will apply to all points in the quadrants B and B′. Hence a smaller thickness of the crystal will, together with the mica plate, produce a retardation of λ, and consequently in these quadrants the fringes will close in towards the centre. In the alternate quadrants A and A′ a corresponding decrease in the total phase difference will produce a movement of the rings away from the centre.

With a biaxial crystal a similar effect is observed, and the closing of the curves in the quadrants joined by the direction of slow vibration in the mica plate again denotes a positive birefringence. The movement is not always easy to trace, however, and a better indication is obtained by the use of an elongated *quartz wedge* cut with its line of greatest slope and its edges parallel to the optic axis. The section is placed with the trace of its optic axial plane at 45° to the vibration direction of the incident light, and the thin end of the wedge is inserted along the line of the optic axes. The faster vibration in the quartz is perpendicular to the long axis; if the crystal is positive its direction of faster vibration is perpendicular to the axial plane; hence the quartz and the crystal will have a subtractive effect, and the fringes will open as the wedge is pushed further in and a greater thickness of quartz is brought into operation. With a positive crystal there is a corresponding contraction of the fringes as the wedge is inserted parallel to the line joining the optic axes.

§ (19) Detection and Measurement of Strain in Isotropic Materials.—An important application of polarised light is its use in testing glass for strain. Brewster called attention to the production of birefringence in isotropic media by mechanical stresses, and later Clerk Maxwell [1] attacked the problem of a strained plate mathematically. A full description of the methods used will be found elsewhere and will not be treated of further here.

An analogous method is also employed to obtain quantitative measurements of stresses present in mechanical constructions, although at present the whole subject has hardly passed beyond the experimental stage. A comprehensive summary is given by Low in the *Aeronautical Journal*, 1918, xxii., together with a full bibliography of other researches and publications.[2] The general method may be outlined here.

A model of a mechanical construction is cut out of an isotropic medium; glass has been used, but xylonite, although not so transparent, serves the purpose better, inasmuch as it is easier to work and can be obtained in thick sheets showing no strain, and resembles in its mechanical properties the actual metals used in the full-scale construction. The presence of stresses in the model causes the stressed portion to act as a birefringent medium, and transmitted light is resolved into two rays polarised parallel and perpendicular to the direction of stress. The rays travel with different speeds, and as in the case of a thin crystal plate, the emergent light is coloured owing to the elimination of certain wave-lengths by interference. The tint produced varies with the retardation between the rays, which in turn is dependent on the amount of stress present. It is possible, therefore, by means of a block subjected to known stresses, to tabulate for any given thickness of the medium the stresses corresponding to the various tints produced, and from this table to deduce the stress present in any model giving a certain interference tint. A more accurate method of quantitative measurement depends upon the fact that while two superposed similar stresses have a simple additive effect if parallel, the total effect of two similar perpendicular stresses is proportional to their difference. Thus an unknown stress coloration may be balanced by superposing a plate subjected to a stress of known amount and direction to produce between crossed Nicols a uniformly dark field.

It is of importance to note that the birefringence is dependent upon the stress present and not upon the strain; a plate strained beyond its elastic limit may show no optical effect if the actual stress is removed.

§ (20) Rotatory Polarisation (i.) *Crystals.*—When discussing the behaviour of crystals in the transmission of polarised light, the optic axis was defined as a direction in the crystal along which light travels without division of path. While in many crystals this is equivalent to a statement that polarised light travelling along an optic axis emerges from the crystal unchanged, some crystals, most notably quartz, have the power in the direction of the axis of rotating the plane of polarisation. All such crystals, known as *optically active substances*, belong to those classes of their respective crystallographic systems which possess no plane of symmetry; they are all enantiomorphous, all but one class possessing only symmetry of rotation about an axis, the other class possessing no degree of symmetry at all. With these crystals two forms are possible, each being the mirror image of the other, but not capable of complete identification with the other by any change of orienta-

[1] *Roy. Soc. Edin. Trans.* xx. Part I.; *Scientific Papers*, i. 30.
[2] See also *Roy. Inst. Proc.*, 1916, xiv., Lowry.

tion. In all cases in which the two forms have been obtained it is found that similar plates of the two cut perpendicular to the optic axis rotate the plane of polarisation of transmitted light by equal amounts but in opposite directions. The two crystal forms of quartz are well known, and can be distinguished morphologically by the position relative to the fundamental prismatic and pyramidal faces of six pairs of small faces occurring three at each end of the crystal and known in the Millerian system of notation as $\{41\bar{2}\}$ and $\{4\bar{1}\bar{2}\}$. The second of the pair is often absent, but the presence on the $\{41\bar{2}\}$ face of striae parallel to its line of intersection with the $\{4\bar{1}\bar{2}\}$ face indicates what would be the position of the latter if developed, and shows the right- or left-handed nature of the crystal.

There is considerable confusion[1] in the definitions given by various authors of "right-handed" and "left-handed" rotation of the vibration plane; this, no doubt, is due partly to the fact that the convention adopted is based on the aspect of the phenomenon as it appears to an observer, and is not descriptive of the motion taking place along the path of the ray itself. An optically active substance is said to produce *right-handed rotation*, or to be *dextro-rotatory*, when to an observer looking along the path of the light towards its source the vibration direction is rotated in a clockwise direction; if the rotation is counter-clockwise the substance is said to be *laevo-rotatory*.

Examples of crystals possessing rotatory power are found in the various crystal systems; sodium chlorate and sodium bromate, crystallising in the cubic system, and therefore possessing no unique axis, show optical activity to the same extent in all directions; sulphate of strychnia, a tetragonal crystal, and the double sulphate of potassium and lithium which belongs to the hexagonal system are other examples, while cinnabar, a trigonal crystal, shows a rotatory power nearly twenty times as strong as that of quartz.

(ii.). *Liquids and Gases.*—Many optically active crystals lose their power when in solution, or when in a non-crystalline state; quartz in solution in potash or in a fused amorphous state is inactive, but sulphate of strychnia is an exception to this rule, and shows activity both when crystalline and when dissolved. This power is shared by many organic liquids and solutions of organic compounds; in the process of other investigations Biot accidentally discovered the laevo-activity of oil of turpentine, and on inquiring further into the matter found that a similar activity was displayed by many other liquids. The rotatory power of sugar solutions is well known, and forms the basis of the universal method of testing and examining sugars. [A separate article dealing with polarimetry and saccharimetry will be found elsewhere, to which reference may be made for full information on the subject.] Substances which are optically active in solution were found by Biot to retain their power in the solid state if they did not crystallise; since all these on solidification formed biaxial crystals, the signs of rotatory power were completely masked by birefringent effects. Later work by Pocklington[2] and Dufet[3] on cane-sugar and various salts crystallising in the rhombic and monoclinic systems has demonstrated the presence of optical activity in the crystals and the possibility of measuring its value along an optic axis. Biot further showed that the transformation of a substance to a gaseous state does not destroy its optical activity, and later Gernez[4] proved by experiment that the rotatory power of a certain tube-length of vapour is equal to that of the column of equal cross-section of liquid into which it condenses.

§ (21) Optically Active Substances. (i.) *Rotatory Power.*—Apparently, then, there are two classes of optically active substances; some substances, like quartz, depend for their power on their crystalline state, that is, presumably, on the grouping of the molecules forming their crystals, while in others the rotatory power appears to be an inherent property of each molecule, since their separation by solution or vaporisation does not affect the power. This conception led to the introduction of the term "*molecular rotatory power*"; if a solution of density d containing p grams of an optically active substance in q grams of solvent is contained in a tube l decimetres long, and if R is the angular rotation produced by the tube,

$$\mathrm{R}=(\rho)\frac{pd}{p+q}\cdot l,$$

$pd/(p+q)$ being the amount by weight of the substance in unit volume of the liquid. (ρ) was taken to be a constant for the substance for any specified temperature and wave-length, and was denoted by the *molecular rotatory power* or *specific rotation* of the substance. Putting $q=0$ and $l=1$, $(\rho)=\mathrm{R}/d$; hence the molecular rotatory power may be more specifically defined as the angular rotation of 1 decimetre of the substance in the pure solid state divided by its density. This is the definition which should be adopted, for Biot showed that the angular rotation produced is not strictly proportional to the amount of substance

present. Landolt,[1] after careful investigation, deduced the formula

$$R = A + Bq + Cq^2,$$

where R is the rotation produced by 10 cm. of a solution containing q parts by weight of the solvent in 100 parts by weight of the solution, A is the molecular rotatory power of the pure substance, and B and C are constants to be determined for each substance and solvent by observations on solutions of different strengths. It should be possible, if B or C is negative, for the same solution to exhibit positive and negative rotation at different concentrations, and this has been shown to occur in the case of malic acid, which is dextro-rotatory in concentrated solutions, and laevo-rotatory when dilute, a solution containing 65·7 per cent of water being inactive.

The effect of temperature on the angle of rotation is considerable, and is of importance, especially in connection with polarimetric work; it will be treated under that head, therefore, and not further described here.

(ii.) *Variation with Wave-length of Light.*—The variation of the rotation with wave-length is, however, of more far-reaching importance. Biot's observations led to the result that the angle of rotation is approximately inversely proportional to the square of the wave-length. From Biot's figures for quartz Stephan proposed the empirical formula

$$R = -1{\cdot}581 + \frac{0{\cdot}80403}{\lambda^2},$$

which gives results in fair accordance with the observed values, the first term representing the amount of departure from the inverse square law. Boltzmann[2] suggested the addition of a fourth order term to Biot's simple proportion formula, putting

$$R = \frac{k_1}{\lambda^2} + \frac{k_2}{\lambda^4} + \ldots,$$

which yielded more accurate results and was applicable to substances other than quartz.

More modern investigations of the problem have led to the development of equations of the form

$$R = k + \frac{k_1}{\lambda^2 - \lambda_1^2} + \frac{k_2}{\lambda^2 - \lambda_2^2} + \ldots,$$

where k, k_1, k_2, . . . λ_1, λ_2, . . . are constants on which the properties of the medium depend. This expression with the five constants indicated has been verified to a high degree of accuracy by Lowry.[3]

§ (22) Applications. (i.) *General.*—This variation of rotation with wave-length affords a simple means of distinguishing between right- and left-handed rotatory power. If plane polarised white light is transmitted through an optically active substance, any orientation of the analyser can only eliminate light of one wave-length, so that the final beam may show any tint contained in the Newton scale of interference tints. Since violet light suffers greater rotation than the rays of longer wave-length, the colour produced by a dextro-rotatory substance will change from the shade complementary to red to the shade complementary to violet as the analyser is given a clockwise rotation. The sequence will be reversed if the substance is laevo-rotatory, and a clockwise rotation of the analyser will produce a change from a reddish tint through the so-called "transition violet" to bluish green. The transition violet marks the point at which the most intense part of the spectrum, the yellow region, is eliminated; a very slight rotation of the analyser is sufficient to cause a marked change of colour at this point, to red on the one side and to blue on the other.

(ii.) *Biquartz.*—This sudden change has been utilised in the *Biquartz plate*, which is of great use in setting the planes of analyser and polariser accurately perpendicular, or in detecting very small amounts of rotation of the vibration plane. The biquartz consists of two equal plane-parallel semicircular plates cut perpendicular to the axis from right- and left-handed quartz crystals, and cemented together to form a circular plate. The thickness of the plate is designed to produce the transition violet tint when placed between two Nicols; if the thickness is 3·75 mm. the tint is produced between parallel Nicols, while a plate of double this thickness gives the same effect with crossed Nicols. A rotation of the vibration plane of the analyser, or of the incident light, tends to produce a change in the colour of one half of the plate towards red of the first order of Newton's scale, and in the other half to a blue or green of the second order, and the juxtaposition of the two halves makes it possible to detect a very small alteration of the vibration direction. If the biquartz is used with sodium light there will be a corresponding difference of intensity produced between the two halves, which affords an almost equally sensitive test.

A single quartz plate cut from either a right- or a left-handed crystal, and producing between crossed Nicols a uniform transition violet colour, sometimes known as a *Biot quartz plate*, may be employed instead of a gypsum plate, the use of which has been described in dealing with the microscopic

examination of double refraction in crystal sections.

(iii.) *Theoretical Considerations.*—It has been suggested that optically active crystals owe their power to the arrangement of molecules in the crystal. Further support was lent to this theory by Reusch, who successfully imitated a plate of quartz cut perpendicular to the axis by a pile of thin mica plates so arranged that their maximum velocity axes formed a spiral. The thinner the plates and the greater their number, the more complete was the imitation. Later Ewell [1] showed that a similar effect is obtained by passing light along the axis of a twisted cylinder of gelatine.

In the case of liquids, solutions, and gases, where no definite arrangement of the molecules can be postulated, it is of importance to note that in all cases the optically active substance contains the tetravalent carbon atom, and it is an obvious inference that just as similar molecules may be grouped together to form crystals related to each other as object and mirror image, so the four atoms or univalent groups of atoms linked to the central carbon atom may be arranged in two distinct ways to produce molecules similarly related. Le Bel and Van't Hoff [2] explained the occurrence of dextro- and laevo-rotatory liquids along these lines.

It is impossible here to enter into a full theoretical discussion of the phenomenon of optical rotation; a complete explanation has been advanced from the standpoint of the electromagnetic theory, and is to be found in various advanced text-books, more especially that of Drude,[3] whose treatment is followed in outline by R. W. Wood [4] (see "Quartz, Optical Rotatory Power of").

An explanation must necessarily involve a more precise knowledge of the nature of the vibrations that are transmitted along the optic axis of a rotatory crystal. The earliest information on this point, due to Fresnel, was based on the fact that circularly polarised light passes unchanged along the optic axis of a quartz crystal. A linear vibration may be regarded as the equivalent of two superposed and oppositely described circular vibrations of equal period and amplitude. Fresnel assumed that plane polarised vibrations, on entering a crystal along the optic axis, are resolved into two such circular vibrations, one of which travels with a greater velocity than the other. It is easily shown that in such a case, if the vibrations emerge from the crystal at the moment when one is retarded by half a wave-length relatively to the other, they will compound to form a linear vibration whose direction is at 90° with that of the incident light, that is to say, the crystal has caused a rotation of the plane of polarisation by 90° in the direction of rotation of the faster moving vibration.

(iv.) *Fresnel's Compound Prism.*—This simple theory explains the dependence of the angle of rotation upon the thickness of the medium traversed and upon the wave-length of light; moreover, Fresnel was able to demonstrate the real existence of two circularly polarised rays within a crystal by showing that they were capable of complete separation and could each be analysed after leaving the crystal. This he accomplished by building up a compound rectangular block of alternate prisms of right- and left-handed quartz (*Fig.* 22). At each interface the refractive indices

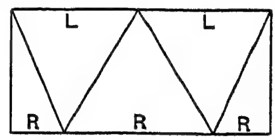

FIG. 22.

for the rays are interchanged, since the slower travelling ray in right-handed quartz becomes the faster moving ray in left-handed quartz, and the obliquity of the interfaces is so arranged as to increase the consequent separation of the rays at each refraction, until the emergent rays are completely separated. On analysis by means of a quarter-wave plate the rays are found to be circularly polarised in opposite directions.

It may be noted in passing that precautions have to be taken in the construction of quartz prisms for spectroscopic work to eliminate this separation of the rays. Cornu showed that a 60° prism will produce a separation of 27″ between the rays of sodium light travelling along the optic axis, but by using a prism composed of two similar halves of right- and left-handed quartz the separation produced in the first half is exactly neutralised by that produced in the second half, and this is the common type of prism in use at the present.

(v.) *Form of Wave-surfaces in Quartz.*—This phenomenon of double refraction along the optic axis of quartz necessitates a modification in our conception of the wave-surfaces within the crystal. The sphere and spheroid which in inactive uniaxial crystals touch at the extremities of the axis are not in similar contact in the case of quartz. Moreover, it has been shown that in addition to an increase in velocity, or a decrease in refractive index, for the extraordinary ray as its inclination to the optic axis decreases, there is a very slight increase in the velocity of the ordinary ray, only noticeable when its inclination to the

[4] *Physical Optics*, R. W. Wood. 1914.

axis is very small, so that it appears that in the case of quartz the extraordinary wave-front is slightly depressed, and the ordinary wave-front elongated, in the direction of the optic axis.

(vi.) *M'Cullagh's Theory.*—A mathematical investigation of the double refraction of quartz in all directions was published by Airy in 1831.[1] As his hypothesis he assumed that for the general case both rays were elliptically polarised, with their major axes perpendicular and parallel to the principal plane of the crystal, that the rotatory vibrations were in opposite directions, and the ratio of their axes was equal, becoming unity when the rays were parallel to the optic axis and infinity when perpendicular to the axis. Five years later M'Cullagh attacked the problem again, and, starting with the ordinary differential equations representing wave-motion, introduced arbitrary modifications which made them inclusive of the effects of rotatory power.

The ordinary equations are:

$$\frac{\delta^2\xi}{\delta t^2}=b^2\frac{\delta^2\xi}{\delta z^2},\quad \frac{\delta^2\eta}{\delta t^2}=b^2\frac{\delta^2\eta}{\delta z^2},$$

where ξ, η are the displacements in a plane perpendicular to the optic axis of a particle whose ordinates are x, y, and z relative to the same axes, the optic axis coinciding with the z axis; b is the velocity of propagation of the wave-front along the axis. To these M'Cullagh added an arbitrary term, giving the equations the form

$$\frac{\delta^2\xi^2}{\delta t^2}=b^2\frac{\delta^2\xi}{\delta z^2}+c\frac{\delta^3\eta}{\delta z^3},\quad \frac{\delta^2\eta}{\delta t^2}=b^2\frac{\delta^2\eta}{\delta z^2}-c\frac{\delta^3\xi}{\delta z^3}.$$

This addition was justified by his obtaining equations for the motion of the two rays representing right- and left-handed circular vibrations, and his resulting expression for the rotation,

$$R=\frac{2\pi^2cV^2}{b^4\lambda^2},$$

shows it to be inversely proportional to square of the wave-length λ, if V, the velocity of the ray within the medium, is constant, that is to say, if dispersion is neglected. The constant c, which is shown to be very small, is positive in a dextro-rotatory, and negative in a laevo-rotatory crystal. The full investigation is to be found in Verdet's *Leçons d'optique physique*, vol. ii., together with a bibliography of other writings on the subject published prior to 1866. A more modern treatment by Drude, based on the electromagnetic theory, is contained in the latter's text-book on Optics which has already been mentioned.

POSITION-FINDER, THE MIRROR

§ (1) General Principles.—In the development of the theory and practice of anti-aircraft gunnery it became necessary to employ some rapid and accurate means of determining the path, or the position at any moment, or the velocity, of an object in the air. To meet this need the mirror position-finder was designed early in 1916. This instrument, however, gave satisfactory results only at high angles of elevation, above (say) 35°, and at the end of that year the window position-finder was designed to deal with the lower angles. The principle of either instrument is the same, and together they make it possible to record the positions or movements of aerial objects, from the vertical to the horizontal. The principle is illustrated most simply by *Fig.* 1, in which GK, G'K' represent two rectangular sheets of glass lying in the same plane, but at a considerable distance apart. At A_1, A_1', are two small apertures through which observers can look at a distant object, P, on the further side of the glass. Each aperture is at the same distance, h, from the glass, and the distance, B, between A_1 and A_1' is known accurately. Perpendiculars from A_1 and A_1' meet the glass at O and O'. The observer at A_1 marks on the glass at m the apparent position of the object, P; the observer at A_1' does the same at m'. If the positions of m and m' relative to O and O' are determined, the two lines A_1m and $A_1'm'$ are fixed and a simple calculation gives the position of P.

If the glass sheets are horizontal and the eye apertures are placed as shown at A_1 and A_1', it is necessary for the observers to look upwards. This is inconvenient, and the difficulty is avoided in the mirror position-finder by the use of horizontal mirrors. The apertures, A and A', are placed above the mirrors, each at a height h, and in such a way that A_1 is the image of A and A_1' that of A'. The observers look downwards at the images of P in the mirrors. In the window position-finder the glass sheets are vertical

and the observers look through them in the manner described above.

§ (2) Description.—The mirror position-finder consists of two horizontal plane mirrors, etched on the silvered side in centimetre squares, mounted—if possible at the same level—at the ends of a base of measured length B, aligned accurately on one another and carefully levelled. The stations (which we will call O and O′) are connected by telephone; the observer at each station wears a receiver on his head and holds a microphone in his left hand. Each mirror is provided with a movable stand, carrying an aperture

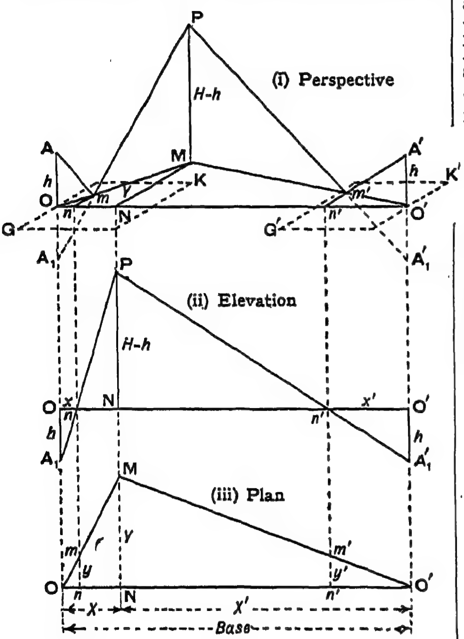

Fig. 1.

at height h above the mirror: it is best to employ a skeleton aperture so as to impede the view as little as possible. The observer looks through the aperture at the reflection in the mirror of the object which he desires to observe, and notes with a pen on the surface of the glass the position of the image at any desired moment or series of moments, care being taken to put the real point of the pen, and not its image, on the image of the object. Simultaneous observations are made at both stations, and from these observations the position of the object can be simply calculated. The ink used should be of the non-drying variety (made with glycerine), both to ensure that the pen marks when required and to enable a permanent record to be made of the observations. For the latter purposes, after the observations are completed, a pair of suitable axes is inked in on the glass, and a piece of absorbent ("Roneo") paper laid over it. The results can then be measured up and the appropriate calculations made subsequently.

The aperture is placed vertically above the intersection of two suitable rulings on the glass, by looking through it and placing its image on that intersection. The positions of the dots recording the position (or rather the direction) of the object are expressed in Cartesian co-ordinates, measuring from the point on the mirror vertically below the aperture, x being the distance in centimetres parallel to the base, and y the distance perpendicular thereto, x' and y' being corresponding co-ordinates of the dot made at the other station O′. The position of the object in space is expressed similarly in Cartesian co-ordinates and referred to the same two axes, being $\{X, Y, H\}$ as measured from O, and $\{X', Y', H\}$ as measured from O′. It is assumed that X, X', x, x', are all measured *towards* the other station, that the co-ordinates of the object in space are very large compared with those of its image in the mirror, and that the stations are at the same level. It is obvious then from considerations of similarity (see *Fig.* 1) that the following relations hold:

$$\frac{X}{x}=\frac{Y}{y}=\frac{H}{h}=\frac{X'}{x'}=\frac{Y'}{y'}=\frac{X+X'}{x+x'}=\frac{B}{x+x'},$$

since $\qquad X+X'=B.$

Hence $\qquad X=\dfrac{xB}{x+x'},$

$$Y=\frac{yB}{x+x'},$$

$$H=\frac{hB}{x+x'},$$

and $\qquad y=y'$, since clearly $Y=Y'$.

The formulae for X, Y, and H enable the position of the object in space to be calculated by simple arithmetic and without the use of trigonometry. The relation $y=y'$, on the other hand, is a valuable check on the observations, and may be employed also to determine simultaneous points on two continuous records (one at each station) of the path of an object in space. Indeed the "equality of the y's" enables the complete track of an aeroplane or other aerial object to be calculated without any means of ensuring simultaneity of observation, the two complete records being co-ordinated with one another merely by taking points with equal y's. The method, of course, breaks down when the path of the object is parallel, or nearly parallel, to the base. The "equality of the y's" has a third value in

enabling the observer at one end of the base to point out objects to the distant observer, so enabling him, for example, to discriminate between different aeroplanes, or different shell-bursts, or different parts of a cloud.

§ (3) THE OBSERVATIONS.—The method of observation is not difficult: it involves one of the most refined and highly developed of human faculties—the accurate adjustment of hand and eye—and so enables the record to be made with quickness and precision. The rulings on the glass are a great assistance in accurate observation, by enabling the eye and brain to "fix" the direction of the object at any desired moment, and so to note it with the hand without undue hurry. With every precaution taken, good glass for the mirrors, telescopes for alignment, sensitive spirit-levels for levelling, fair visibility, and trained observers, experience at Portsmouth during the war in recording the positions of shell-bursts in the air showed that the probable error of one observation was not more than 0·1 or 0·2 mm. in x or y, an error corresponding usually only to a few feet in the calculated position of the object. The most serious error indeed, unless special precautions be taken, is caused by unevenness in the glass, which should be chosen (or better, manufactured) as flat and as parallel-sided as possible.

§ (4) GEOMETRICAL PROPERTIES. — The mirror position-finder possesses several useful geometrical properties in addition to the "equality of the y's." For example, if, as is common, an aeroplane be flying at a constant height the track on either mirror is exactly similar to the track in space, reduced in the ratio h/H. Or again, the height is given by the simple formula $\mathrm{B}h/(x+x')$, thus it is inversely proportional to the sum of the x's. Or again, the velocity of a horizontally moving object (such as a puff of smoke in the wind) is exactly the same as that of its image, recorded at measured intervals on the glass, multiplied up in the ratio of H/h. If, therefore, H be known, as, for example, in the case of a shell fired to burst at a known height, the speed and direction of the wind at that height can be determined at once merely by recording the motion of the image in one mirror of the smoke from the shell.

§ (5) THE WINDOW POSITION-FINDER. — This is similar to the mirror instrument in principle, the whole system of glass and aperture being revolved through 90° about the base line, the mirror in this case being replaced by ruled transparent glass, and the observer noting the direction of the object in ink on a vertical window instead of on a horizontal mirror. The practical working details of the instrument are different, and observation is not quite so easy or accurate, but the theory and the calculations remain the same. The geometrical peculiarities of the record of an object flying at a constant height of course no longer obtain. The instrument may be used for the accurate observation of objects or events in the sea or on the ground, as well as for aerial observation.

§ (6) USES OF THE POSITION-FINDER. — The instruments described have been employed for a variety of purposes:

(1) For determining the height, position, path, or speed of an aeroplane flying horizontally or in any manner required.

(2) For determining the position in space of a shell bursting in the air.

(3) For determining the point of impact of a shell striking the sea.

(4) For determining the velocity and direction of the wind at any height desired, by firing a shell to burst at that height and making timed observations on the path of the smoke; in this way observations of the wind have been made at heights up to 35,000 ft., and of speeds up to 115 miles per hour.

(5) For determining the height, direction of motion, and speed of a cloud.

The mirror and window position-finders have been and are employed by the British military, naval, and flying services for gun trials of various kinds, for recording anti-aircraft practices, for determining the height, speed, or position of aircraft, and for measuring the velocity and direction of the wind at various heights. The U.S. Army also have erected a number of stations at their Aberdeen Proving Ground in the Chesapeake Bay.

PROJECTION APPARATUS

§ (1) GENERAL.—Projection apparatus may be broadly defined as apparatus in which a source of light is associated with an optical device to produce localised distant illumination. Most light sources send out light more or less equally in all directions, and it is evident that if an optical device can be employed to bend the rays all into one direction, it should be possible to increase the volume of light passing in that direction enormously, and so ensure a degree of illumination at a great distance in that direction only, which would be equivalent to the illumination produced by the naked source alone at points comparatively near to it.

If the theory of projection apparatus is to be understood, it is necessary to investigate, first, the general theory of illumination, and secondly the theory of optical devices for bending the ray paths. Now the broad principles underlying both these are quite simple, and yet there is the profoundest ignorance as to the limitations of projection apparatus amongst otherwise well-informed people; such ignorance, for instance, as caused numberless inventors in all seriousness to propose that airships could be set on fire by concentrating the rays of a searchlight upon them. The object of this article is to explain the broad principles underlying the theory and practice of projection apparatus in the simplest possible way.

To begin with the theory of illumination; this obviously involves the measurement of brightness, and though accurate measurements in the laboratory are made with the aid of an instrument called a photometer, yet this is only a mechanical device to assist the eye. Ultimately the eye is the instrument that is used to compare one brightness with another, and the essential theory of illumination can best be discussed from the point of view of *what the eye sees* at any given point.

To be exact, no human eye can verify the illumination produced by a source of light *at any given point* of space; it can only form an estimate of the total amount of light energy from that source passing through the iris aperture, which has very definite though variable size.

For results to be strictly comparable, therefore, a "hypothetical eye" must be assumed with a small fixed iris-opening, capable of examining and estimating the illumination produced by the brightest sources without fatigue or dazzle. It will also be convenient to assume that this "hypothetical eye" has an infinite capacity for seeing detail so that it would recognise the shape of even the most distant sources. In what follows the term "eye" will be used as signifying an organ with these extended powers.

§ (2) DEFINITION.—It is desirable at the outset to get rid of that meaningless abstraction a "point of light." There is no such thing as "a point of light." Light cannot be obtained except from an incandescent source of definite and measurable size, and the theory of illumination can never be understood until this elementary fact has been clearly grasped. Light is a form of energy which is emitted from incandescent surfaces. Any particular surface will only emit visible light when raised to a certain minimum temperature; and after that temperature has been passed, it will emit more and more light as the temperature is raised. Surfaces made of different materials, but otherwise identical, when raised to the same temperature will usually emit quite different amounts of light per second.

The term "intrinsic brightness" is usually applied to the measure of this light-emissive power per unit of area of surface, and it is generally quoted in candle-power per square inch.

The fundamental fact on which the whole theory of illumination depends is that each element of any surface raised to a uniform temperature, and emitting light in consequence, appears always of the same brightness at whatever angle or from whatever distance it is viewed. Thus a uniformly bright surface appears to the eye simply like a flat sheet of brightness having a certain definite "apparent size and shape." For the sake of clearness

the "apparent size and shape" for any "view point" may be defined as the actual size in square inches and shape of a flat sheet which, when placed one foot from the eye with its plane perpendicular to the line of sight, exactly obscures the incandescent source or appears to coincide with it in shape and size as seen from that "view point."

It follows that the illumination produced at any point is proportional to the "intrinsic brightness" of the incandescent surface and to its "apparent size," since 2 square inches of flat glowing surface at 12 inches distance must produce double the illumination of 1 square inch of surface glowing with equal brightness at the same distance.

The unit of illumination is known as a foot-candle and is the illumination produced by an incandescent sheet of unit "intrinsic brightness" at a point at which it has unit "apparent size."

Again, the same sheet raised to a higher temperature will appear brighter; in fact, the "intrinsic brightness" of any particular material is a measure of its temperature; but different substances raised to the same temperature will glow with different brightnesses. The illumination produced, however, at any given standard distance can be made the same by increasing the *size* of the less bright material so as to compensate for its smaller "intrinsic brightness."

While, however, the illumination produced by a large gently glowing sphere may be of exactly the same intensity as that produced by a tiny intensely bright sphere, yet the two sources act *very differently* when associated with an optical device for projecting a beam localised in a certain direction.

§ (3) Optics of Illumination.—It is the peculiar function of optical devices that they can entirely alter the apparent shapes and sizes of sources as seen from certain directions, but they can never make them look brighter. Owing to transmission losses—colour in glass, or imperfect reflective power—they may make the source look less bright, but the variation in intensity of illumination produced in certain directions by an optical projector is simply due to its capacity to make the source look larger or smaller in those directions. Thus, an incandescent sphere S (*Fig.* 1) placed behind a plano-convex condenser may appear when seen through the lens L as of apparent size E instead of *e*, which would be the apparent size of the source as seen through a thick plane plate of glass in place of the lens L. The brightness of the source as seen through the parallel plate is exactly the same as the brightness of the magnified source when seen through the lens instead of the parallel plate, and this brightness is necessarily slightly less than the brightness of the naked source, owing to absorption and transmission losses in passing through the glass.

From the foregoing it is evident that there is a very definite limit to the intensity of illumination that can be produced by any projector of given size using a source of given "intrinsic brightness." The very highest efficiency for such a projector is that the whole front window or aperture of the projector, as seen from a distant point, shall be filled (or flashed) with the "intrinsic brightness" of the source. This is termed a "complete flash."

When only certain parts of the front aperture are seen as of the same "intrinsic brightness" as the source (less ordinary transmission losses), then the projector is said to afford a "partial flash." This latter term, it should be noted, applies not only to systems leaving dark patches in the front aperture, but also to systems in which certain areas of the front aperture are seen filled with a *coloured flash*, due to the "partial flashing" of certain primary colours causing such constituents to be absent in those areas.

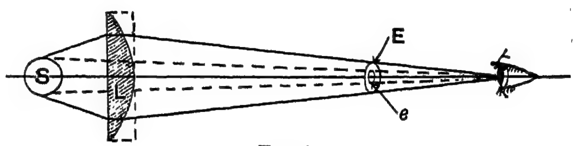

Fig. 1.

It will be noted that the condition for a "complete flash" will be satisfied if the ray directions traced from the eye through every point of the optical system are so bent and deflected that they all concentrate on to the source. Since a *distant* view point is assumed, such ray directions form a system of practically parallel lines at the projector. It will be seen, therefore, that for maximum efficiency with a source of minimum size the optical system must be designed to bend parallel ray directions, so that they all pass through, or at least *extremely* near to, a fixed point termed the "focus."

If then a small source be placed at that "focus" there will be one direction in which a relatively powerful beam will be projected. If, however, a source of the same candle-power but $\frac{1}{100}$th the apparent size, as seen, from the projector, be placed at the "focus" of the same projector, since its "intrinsic brightness" must be 100 times as great to make it the same candle-power, the beam projected will be 100 times as powerful, always provided the projector is efficient

enough to afford a "complete flash" in both cases. If, however, the second source be increased in size while remaining of the same "intrinsic brightness," no increase in the illumination produced in that particular direction will take place as a result of such increase in size, however great it may be, because the same-sized optical system affords a "complete flash" in either case.

It will naturally be asked, "Where then does all the increased light energy go to, if the intensity of the beam remains unaltered when a source of much greater candle-power is substituted?" The answer is that the beam projected fills a greater angle, so that if thrown on a distant white screen it will afford a "light patch" of bigger area. For all view points on the screen at which the optical system affords a "complete flash," the illumination produced will be the same, whether the source be large or small, always assuming the same "intrinsic brightness" for the source.

It is convenient to investigate projected beams by noting the shape and general intensity of the "light patch" projected on a distant white screen, and so it will make the argument clearer if the projected beams are considered in terms of the "light patch" received on a perfectly efficient white screen placed at some definite standard distance from the projector—a distance that shall be very large in comparison with the size of the projector. At whatever angle it is viewed, such a screen would make the brightness of the "light patch" at any point always strictly proportional to the illumination produced at that point by the projector. Each element of such a screen covered by the "light patch" would act like a self-luminous surface and send out light equally in all directions.

If, instead of the flat screen placed at standard distance from the source, a large hollow spherical screen of some definite standard size be imagined extending all round the source with the source at its centre, it will be seen that the optical projector, whatever it is, can only make use of the light energy represented by the complete spherical "light patch" cast by the original source on this spherical screen. Whatever light the optical system can intercept and bend in the required direction will be removed from the light falling on one part of the sphere and added where it is wanted. The most, therefore, that any optical system can do is to bend the rays of light in such a way that all the light energy spread over the whole sphere by the naked source is concentrated so as to fall only on one small portion of it.

Evidently, therefore, while optical projectors may be designed to produce relatively intense illumination from sources of small candle-power, yet the angular size of the beam projected under such circumstances can only be very small.

If the source were a glowing sphere the illumination produced by it in every direction would be the same, and if it were desired to produce from such a source by optical means a circular "light patch" one-thousandth of the area of the complete spherical surrounding screen (this would correspond to a beam having a semi-angle of about $3\frac{1}{2}°$ or a total angle of divergence of about 7°), then it would naturally follow that the most that could be expected would be that the intensity of the projected beam would everywhere be one thousand times as great as the intensity due to the naked source alone.

It would follow, therefore, from what has gone before that the front aperture of the projector must have at least one thousand times the "apparent size" of the spherical source as seen from the screen, since it is only by increasing the "apparent size" of the source by optical means to fill this aperture that the increase in illumination can be obtained.

It is always impossible to collect from all round the source, and it is generally only convenient to collect from a comparatively small fraction of the total area of the surrounding sphere. Twenty-five per cent of the complete sphere, or 50 per cent of the hemisphere, for instance, is quite good for a searchlight. If this percentage only be collected and it is desired to include just the same angle in the projected beam as before (viz. 7°), then it would only be possible to get one-fourth the light in the beam using the same imaginary spherical source and designed as before for "complete flashing." This projector, therefore, would have to have half the previous diameter; or if the *same* illumination were desired filling the same angle, then the source assumed to be of the same "intrinsic brightness" would have to have four times the area, *i.e.* have twice the diameter.

Where the optical system is symmetrical about an axis, the "angle of collection" is quoted as the angle of the right circular cone formed by the extreme rays collected by the projector.

To sum up, therefore, from the foregoing general considerations, it will be seen that if the *type* of source is given (*e.g.* acetylene flame, oxyhydrogen limelight, electric arc), in other words, if the "intrinsic brightness" is given, then the required intensity in the beam can be secured by having the projector big enough. On the other hand, a wide angle of divergence in the beam will be secured either by collecting the light from as large an angle as possible

or by employing a source of as large a size as possible. Neither of these two latter conditions, however, affects intensity, which is solely a question of making the front aperture as large as possible; it being always assumed that the optical system is equally efficient in every case as regards its ability to afford a "complete flash."

Again, if by any means the "intrinsic brightness" can be increased fourfold, then exactly the same beam having the same intensity and including the same angle can be projected by using a projector one-half the diameter in conjunction with a similarly shaped source only half as large (its total candle-power being the same, since it is assumed to have four times the "intrinsic brightness"): by increasing the "intrinsic brightness" sixteen times, the whole apparatus could be made one-quarter the diameter and yet give the same intensity within a beam of the same angle, and using a source of the same candle-power.

As these general considerations are very important, they will be again summed up in the following manner. The factors involved in the projection apparatus are:

A. The "intrinsic brightness" of the source.

B. The size of the source measured by *area*, or its apparent size, at standard distance.

C. The fraction of total energy of source collected by the projector.

D. The size of the projector, which must be measured by the *area* of its front aperture.

The resultant "light patch" projected has:

I. Size measured by its area.

II. Intensity measured by its brightness.

If one factor alone be varied, while the others are kept constant, it may be said:

Varying A causes II. only to vary proportionately.

Varying B causes I. only to vary proportionately.

Varying C causes I. only to vary proportionately.

Varying D causes II. to increase and I. to decrease proportionately to increase in D.

It should be noted that in the above the same efficiency for the projector is always assumed, that is to say, it need not afford "complete flashing" in every case, provided it always affords the same percentage of its front aperture flashed. It will be shown later that it is very difficult to increase the angle of collection of a projector without lowering its efficiency, so that when C is varied a fresh factor is introduced which modifies the above result.

§ (4) Projection Apparatus.—The study of projection apparatus is now seen to involve the study of the flashing of incandescent sources as viewed through optical devices.

The directions in which the eye sees things through an optical system can be ascertained mathematically by what is termed "ray tracing," since at every point of reflection or refraction in the optical system the change of direction follows known laws. If, therefore, a distant view point be taken and all possible ray directions emanating from it be traced through the optical system, then for well-designed projection apparatus they should, after being so traced through the optical system, come, if not to a true point focus, yet to a very high degree of concentration near the "focal point."

If the ray directions from a distant point on the axis of an optical system, traced through that optical system, all converge to a "point focus," then any source, however small, which includes that "point focus" within it, will be seen from that distant point as completely flashed. That is to say, an extremely diminutive source placed at the "focal point" would send a very powerful beam along the axis, though it would naturally have an extremely small angle of divergence. This "point focus," however, is impossible of attainment, though the ray directions do, as a matter of fact, come to a remarkably high degree of concentration at the focus of well-designed and well-made apparatus. If the smallest possible sphere be described surrounding what may be termed the "focal point" so as just, and only just, to include all the convergent rays, either intersecting it or just touching it, then this may be termed the "focal sphere."

When the source actually employed in projection apparatus is not larger than the "focal sphere," "partial flashing" alone is possible, and the theory is rather more difficult; also it is extremely difficult to get uniform brightness in the "light patch."

In the great majority of cases it is desired to project a beam which shall be symmetrical about an axis, and the optical system employed is also symmetrical about an axis. In fact, the difficulty of making optical devices which are not symmetrical about an axis is such that when unsymmetrical beams are wanted they are usually obtained by combining a symmetrical optical system with a suitably shaped source.

Optical systems symmetrical about an axis (in future termed "symmetrical projectors" for shortness), however complicated they may be and however often the rays passing through them may be bent or reflected, have the following very interesting properties which are of great value in elucidating the theory of their use for projection purposes.

If a ray PR (*Fig.* 2) drawn parallel to the axis SF of a symmetrical projector be traced through the optical system, it must always

on emergence intersect the axis at some point F. Again, if the finally emergent ray be produced backwards to meet the line of the

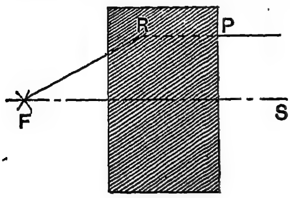

FIG. 2.

incident ray in R, then the "apparent width" of any small source (measured perpendicular to the axial plane PRF) as seen through the projector from P will always be the same as the "apparent width" of the naked source as seen directly from R (taking width again to refer to directions perpendicular to the axial plane PRF).

The "apparent height" of the source as seen from P may be either magnified or minified by the optical system as compared with the "apparent height" as seen from R; but all that can be said for certain is that the angular value of the width of any small source as seen from P through the optical system is exactly the same as the corresponding angular width of the naked source as seen from R; the whole "apparent shape" is similar, but possibly distorted, either drawn out or compressed in the direction of the axial plane containing the "view point."

If P be a point on the front aperture of the projector, then the "light patch" which would be projected if the whole front aperture were masked off except a tiny element at P would obviously have the same "apparent shape and size" as the "apparent shape and size" of the source as seen from P through the projector. But this is similar to, and of exactly the same angular width as, the "apparent shape and size" of the naked source as seen from R.

If the projector is to afford a "complete flash" throughout the whole of the projected beam, every such element of the front aperture must project a "light patch" which shall be coincident with that afforded by the complete projector.

Hence, there are two conditions to be satisfied for "complete flashing" throughout the entire projected beam: first, that the parallel ray directions such as PR must for all zones of the projector converge to one definite "point focus" F; secondly, the "apparent width" of the source as seen from every such point as R must be constant, *i.e.* the length RF must be constant for all zones of the projector.

The point R is conveniently termed the "equivalent bending point" for the ray PR, and all such points will lie on a surface coaxial with the optical system. This surface may be termed the "equivalent bending surface."

From the above it is evident that the two conditions to be satisfied by any projector designed to afford "complete flashing" throughout the whole of the projected beam are: first, that ray directions emanating from a "point focus" shall all be rendered accurately parallel to the axis; secondly, that the "equivalent bending surface" for such rays shall be a sphere having the "point focus" as centre.

§ (5) DETAILED CONSIDERATION OF USEFUL SOURCES.—It has already been made clear that the only way to increase the intensity of the beam projected from really efficient apparatus of given size is to increase the "intrinsic brightness" of the source; and hence, sources of the highest possible "intrinsic brightness" must be chosen for powerful projectors.

The subjoined table gives the "intrinsic brightness" of some well-known sources in candle-power per square inch:

Paraffin flame (enclosed in glass chimney)	10
Acetylene flame (burning in air) .	36
Incandescent oil (petroleum) with mantle	340
Ordinary tungsten filament (*in vacuo*)	960
Oxy-acetylene with pastille (in Messrs. Chance's projectors)	4,500 to 5,700
Tungsten filament in argon (·65 watt per candle)	7,500
Tungsten arc or "Pointolite" .	12,000 to 16,000
Tungsten filament in argon (·4 watt per candle)	17,000
The crater of ordinary carbon arc .	110,000
The sun at noon, summer, in British Isles	600,000
The sun at zenith	1,000,000

These figures indicate how hopeless it is to expect to do anything in the way of projecting beams which the eye can see at considerable distances in bright daylight except by using an arc lamp or a very highly overrun (so-called) half-watt electric lamp.

The obvious difficulty in the case of the latter source is the awkwardness of the shape of the filament. This can, however, be wound as an exceedingly close spiral coil, and so be made equivalent to a continuous incandescent cylinder.

The illustration (*Fig.* 3) is from photographs showing an actual incandescent filament eight times natural size, wound so as to form two such incandescent cylindrical shapes with axes parallel and very close together.

Both the "Pointolite" and the tungsten filament lamp are subject to the great disadvantage that the glass containing bulb has

to be very large in comparison with the dimensions of the source itself. This places a very definite limit to the possible proximity

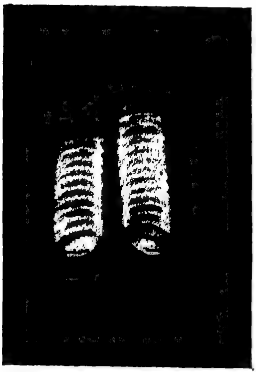

FIG. 3.

of any optical device used for projecting a beam from the source. Consequently such sources can only project beams of small divergence, unless "partial flashing" is resorted to and the projector made unnecessarily large. Another disadvantage is that when used with a reflector placed behind the source the glass containing bulb practically acts like an opaque body to the reflected beam, and so the only effective part of the reflector consists of the outer annulus, the beam from which just clears the bulb.

§ (6) THE PARABOLIC REFLECTOR.—The well-known property of the parabola, viz. that rays A*a*, B*b*, C*c*, D*d*, etc., drawn parallel to the axis FX (*Fig.* 4), are reflected at the curve so

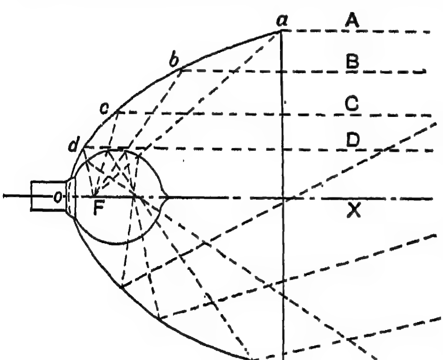

FIG. 4.

as to pass through the focus F, makes the parabolic reflector the most obvious optical element to employ for projecting powerful beams.

Inventors of special projection devices, however, have tended to overlook two important considerations, the first being that a parabolic reflector with a true point focus is a pure mathematical abstraction, and any commercially produced parabolic reflector has a "focal sphere" [1] of very definite and appreciable size.

The second is that the parabolic reflector only satisfies the first condition for affording a "complete flash" with an abruptly defined margin; the second condition, viz. that the "equivalent bending points" [2] shall all be equidistant from the focus, is obviously not satisfied by any parabolic reflector having any appreciable "angle of collection."

Thus, owing to the rapid increase in the focal distances to the points of reflection, as the vertex of the mirror is departed from, any parabolic reflector used in conjunction with a source larger than its "focal sphere" will project a beam in which the marginal zones will be weak.

§ (7) THE PARABOLIC REFLECTOR AND ELECTRIC HEADLIGHTS FOR MOTOR-CARS.—There is a particular type of projector, however, for which the parabolic reflector used in conjunction with an electric incandescent lamp is admirably adapted, viz. the motor-car electric headlight.

What is wanted here is a very wide angle beam, but of very much greater intensity within a central narrow angle as compared with the intensity of the marginal portion of the projected beam, and this kind of distribution is easily obtained from any parabolic reflector having a very large "angle of collection." For motor-car headlights the "angle of collection" is so large that, as shown in *Fig.* 4, the only light not collected from the source passes out from the front aperture of the lamp and forms part of the useful wide angle beam.

The "equivalent bending surface" [3] *is* the surface of the parabolic reflector, and the focal distances *a*F, *b*F, *c*F, *d*F vary enormously; in fact, with the angle *a*F*a′* equal to a right angle, the length *a*F is necessarily nearly seven times as long as the focal distance *o*F, and the whole front aperture *aa′* is necessarily more than 9½ times this same focal distance. But the glass containing bulb of the electric lamp used has got to go inside the reflector, and this sets a very definite limit to the smallness of F*o*, and hence to the possibility of keeping down the size of powerful headlights of this type.

To keep down the size, designers have arranged to place the source low down in the bulb, comparatively close to the cap, thereby increasing the percentage of light lost on the cap and also that lost due to

[1] For definition see § (4). [2] *Ibid.* [3] *Ibid.*

reflections from the bulb, the reflection on going slantwise through the walls of the bulb being much greater than the reflection when going perpendicularly through it. This reflected light, however, is not entirely lost to the beam; some of it goes to augment the wide angle beam, partly directly and partly indirectly, after undergoing a second reflection at the parabolic reflector, as shown in *Fig.* 4.

Starting from *o*, therefore, and going round the source, it will be seen that first there is a fairly large angle over which the light energy is absolutely lost on the cap; then there is a zone in which the light energy which gets through the bulb on to the reflector undergoes reflection at the parabolic mirror, followed by glancing reflection on the electric bulb. This ultimately gets added to the wide angle beam, but it contributes an entirely negligible quantity either to the central intense beam, or to the relatively fairly powerful beam that should closely surround it. It is only when the zones at *c* and *b* are considered that a relatively powerful beam results, since the angle within which the projected beam lies is so small in comparison with the angle around the source from which the "light energy" is collected.

It will, of course, be understood that with a source having an "intrinsic brightness" as high as 960 candles per square inch, anything approaching a "complete flash," even confined to the very centre of the beam, is entirely out of the question. A "complete flash" in a 10-inch headlight would mean a candle-power in the projected beam of more than 37,000, even if the efficiency of reflection be assumed as one-half. This would produce an illumination equal to full moonlight at a distance of well over a mile. No effort is made, therefore, to confine the filament close to one "focal point," nor is the reflector made very accurately so as to afford a very small "focal sphere."

As the bending of the rays in this case is done by pure reflection only, the "light patch" projected by each portion of the reflector is identical in "apparent shape and size" with that of the source as seen from the corresponding part of the reflector. The ray directions drawn in *Fig.* 4 correspond to the centre in each case of the "light patch," which will obviously be the sum total of a lot of thread-like twisted shapes corresponding to all the different views of the filament as seen from *a*, *b*, *c*, etc.

Obviously the zone at *a* is responsible for a narrow angle beam, that at *b* for a wider angle beam, and so on in the inverse proportion of the focal distances *a*F, *b*F, etc.

Commercially obtainable reflectors do not cause rays emanating from a "point focus" F to form a parallel beam after reflection. They have small errors of shape which cause the ray directions to vary within small limits, and provided these limits are kept well within the angular value of the central intense beam (about 6°) no real harm results. These irregularities simply further confuse the superimposed images and cause the reflectors to be less sensitive to displacements of the source from the theoretical focus.

Defective shape is not responsible for the poor performance of many electric headlights seen on the road, but imperfect focussing, or location of the source altogether outside the true "focal sphere." Displacement of the source in an axial direction may result in a hollow beam, there being no light from the reflector in the central part at all.

Displacement of the source perpendicular to the axis, causing an excentric position of the filament, affords an extremely unsymmetrical "light patch" with a very big halo all on one side.

To take a concrete instance: an ordinary candle-power for the bulb of a 10-inch electric headlight is 24. Allowing for light lost on the cap, the parabolic reflector can be designed to collect about 70 per cent of the total light energy emitted, and under fair average conditions it can be assumed to reflect 40 per cent of this. Thus, about 28 per cent is transmitted to the beam, and if one-quarter of this is accounted for by the central 7° wide beam, and the remaining three-quarters by the wide angle beam up to a limit of 40° on either side of the axis, it can be asserted that the candle-power in the central beam will average about 1600, and the mean candle-power in the wide angle beam will be about 32, as produced by the reflector, to which, of course, must be added the 24 due to the naked source, making a total mean candle-power in the wide angle beam of 56. This represents quite good practice. From the figure quoted for the candle-power corresponding to a complete flash in a 10-inch headlight it will be seen that, even in the most powerful part of the beam, this 10-inch headlight will only afford about $5\frac{1}{2}$ per cent of a "complete flash." The dazzle effect of such an intensely bright source as the incandescent filament is responsible for the illusion that the whole aperture of a good electric headlight is filled with a "complete flash" when viewed axially from in front. By looking at it with a good telescope, provided with an optically worked dark glass, it will be found that only twisted thread-like lines of brightness are seen on the surface of the reflector.

The electric headlight, therefore, with parabolic reflector is an example of a projector with a quite large "focal sphere" affording only very "partial flashing," with a comparatively open spiral coil of incandescent filament

confined, when properly adjusted, within the "focal sphere." The parabolic reflector is carried out to include an "angle of collection" of something like 240° to 270°, and the large forward end of the reflector is responsible for the intense narrow angle central beam, the middle zones for the less intense beam immediately surrounding it, and the back part of the reflector behind the bulb is responsible only for scattered light, forming in association with the naked source and reflections from the glass containing bulb the marginal wide angle beam.

§ (8) The Parabolic Reflector and Electric Searchlights.—Searchlights form perhaps the most typical instance of projection apparatus, since it is the function of a searchlight projector to produce the most powerful distant illumination in a predetermined and controllable direction.

To do this a source of the highest possible intrinsic brightness has to be employed, used in conjunction with a highly efficient parabolic reflector, made as large in aperture as possible, and of as high an efficiency as possible.

This means the combination of an arc light with a *glass* parabolic reflector silvered on the back according to the plan shown in *Fig.* 5.

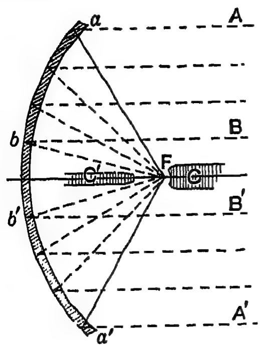

Fig. 5.

The carbons C, C′ are shown disproportionately large, but it will be noticed that the parabolic reflector is carried out to an "angle of collection" of about 120°, and this enables fully 70 per cent of the total light energy emitted by the arc to be collected by the mirror. There is no practical advantage to be gained by trying to exceed this "angle of collection," even if such a mirror could be made to stand the heat of the arc. The negative carbon C′ has its conductivity artificially increased, and is made as small in cross-section as possible, so as to keep its central shadow, *bb′* on the mirror, of minimum size, and for the same reason the arc is made as long as is practicable.

To obtain the great intensity required by modern searchlights, the diameter *aa′* of the front aperture is made in some cases as large as 60 inches, but the difficulty of grinding and polishing, with the necessary accuracy, so large a parabolic shape is so great that there is a tendency for such large projectors to give disappointing results in comparison with the more usual size of 36 inches. The standard focal length for a 36-inch mirror is 17 inches, and this corresponds to an angle of collection of 110°. A useful source to employ with such a mirror would be an arc having a 1¼-inch diameter positive carbon, rated to consume 150 amps. at 60 volts. The brightest part of the crater on such a positive carbon would be limited to a diameter of less than ½ inch. With a source of this size, it would mean that the central zones of a perfect parabolic reflector nearest to it would project a beam of about 1½° and the outer zones a beam of about ¾° angular divergence. The central crater would have an intrinsic brightness of about 100,000 candles per square inch. The mean spherical candle-power within the angle of collection of such a source would be about 18,800 candles, and *if the whole aperture of the mirror were flashed with the intrinsic brightness of the crater* the resultant candle-power would be more than 100 million. But this 100 million is reduced by obstructions such as the negative carbon and the carbon supports and holders. It is also reduced by the losses on going through the mirror, the colour of the glass, which is quite important in such large mirrors, and the imperfect reflective power of even the best glass silvered surface. It is also necessary to protect the arc from the effects of wind; and to do this the front of the projector is glazed with parallel strips of glass. This gives rise to further light losses, and, taken in the aggregate, it can be demonstrated that in actual practice such transmission losses cannot be less than 40 per cent, and may very well be considerably more.

This would give a *maximum possible* intensity of 60 million candles in the projected beam, provided the diameter of the focal sphere afforded by the mirror was really considerably less than the half-inch which is the approximate diameter of the intense central crater on the positive carbon. Such accuracy, however, is not attained in practice, and in consequence the whole unobstructed aperture of the projector is *not* filled with a flash corresponding to the central crater, but parts of it are flashed with a brightness corresponding to the surrounding glowing carbon, which is *very much less* bright. Local errors in shape increase the divergence of the projected beam. In practice they about double the value of the maximum divergence already obtained from purely theoretical

considerations, and further reduce the intensity of the brightest parts of a carefully focussed beam to something like 30 to 40 million candles. Imperfect focussing may still further reduce the intensity of the projected beam, and correspondingly increase the divergence. As a matter of fact an intensity of 60 million candle-power for a 36-inch searchlight has been actually exceeded in practice, by employing specially treated carbons for which an intrinsic brightness of 200,000 candles per square inch has been attained.

It is often stated that the high figures quoted for the candle powers of searchlights are meaningless, because the candle-power is so completely dependent on the state of the atmosphere. Since candle-power represents a *rate* at which light energy is sent out from a source per unit of solid angle, it can have nothing to do with the state of the atmosphere. These fallacious notions are all due to the fact that it is not practicable to compare a searchlight with the 30 or 40 million candles to which (in a predetermined direction and at sufficiently great distances) it is undoubtedly equivalent, whatever the state of the atmosphere.

The state of the atmosphere only comes in when the illumination produced at a very great distance from a searchlight is compared with the illumination produced quite close to a small standard source. It would be very much better if manufacturers of searchlights would give definite guarantees as to what the actual size of the "focal sphere" [1] for their mirrors was, under running conditions, and also their transmission losses. These readily measurable quantities give the best criteria for comparing the efficiency of one projector with another, quite apart from arc efficiency.

Another fallacy to be disposed of in connection with searchlights is the oft-repeated statement that the ideal really aimed at is a perfectly parallel beam projected from a point source. The *idea* is that such a beam would afford constant illumination at all distances, and the divergence of the beam of any practical searchlight is taken as a measure of its inefficiency, because it leads to the falling off in illumination according to the inverse square law.

It is evident that any *efficient* projector must produce a complete flash at all useful long ranges, and hence as the range in any predetermined direction is increased, the falling off in illumination must follow precisely the same laws as would hold for the equivalent candles of that flash, whatever atmospheric conditions prevail.

Constant illumination from a parallel beam at varying ranges requires the use of a source suitably focussed and sufficiently small to afford a partial flash of constant "apparent size." This involves carrying partial flashing to an absurd limit.

[1] For definition see § (4).

In all that has gone before, the range has been assumed to be great in relation to the size of the projector; in fact, the whole theory has been built upon the assumption that the distant view points considered are such that ray directions from them form a system of practically parallel rays over the whole front aperture of the projector.

Searchlight projectors, however, are so large, and the sources used in them so relatively small, that it is quite easy to take fairly distant view points, the ray directions from which form an appreciably divergent system when taken over the whole aperture of the projector. Obviously, the theory breaks down as soon as the departures from parallelism are such that a percentage of the rays, when "traced" through the projector to the source, miss the source altogether instead of ending upon it.

The "focal sphere," however, corresponding to such fairly distant view points is practically identical in size with the true "focal sphere" corresponding to very distant view points; but its position is displaced towards the view point by a very small amount.

Thus, all the characteristics of the "light patch" on a far distant screen can be reproduced on a much nearer screen simply by focussing, *i.e.* by displacing the position of the source by the necessary small amount to correspond with the displaced position of the "focal sphere."

For all ranges outside 1000 yards the focussing displacement for a 36-inch projector is negligible, but to focus on an object at 400 yards' distance requires slightly less than $\frac{1}{32}$-inch focussing displacement of the arc.

Thus, the figure of 30 to 40 million candles found for the beam from a 36-inch searchlight still holds for comparatively near view points if the carbons are properly focussed, but in this case the beam, leaving the lip of the projector as seen by the operator, may very well be convergent.

The beam taken as a whole, however, is not convergent, for the rays cross over after passing the point focussed upon, and form a rapidly divergent beam corresponding to partial flashing at all really distant view points.

As regards the angle of the beam actually projected by practically useful searchlights for long-range work, it usually lies between 2° and 3°, and anything less is not of very much use for searching for objects even at extreme ranges. At three miles range the light patch produced by a 3° beam is about 800 feet in diameter. For comparatively near ranges, however, this angle of divergence gives too

small a width to the light patch projected; consequently, vertical cylindrical elements are fitted to the front window of the projector. The beam traversing these cylindrical elements is spread out evenly in a horizontal direction so that the horizontal angular width of the beam is greater than the vertical angular width by the divergence due to the cylindrical lenses. The cylindrical elements may have a divergence of as much as 30°, and if this were applied to a 3° beam the resulting intensity would naturally be reduced to at least a tenth of its normal value. Instead of affording a complete flash, each cylindrical lens would only show a vertical strip one-tenth of its width flashed; the position of the flashed strip moving across each cylindrical lens from one side to the other as the view point traverses the beam.

§ (9) The Parabolic Reflector and Electric Signalling Lamps.—What is desired in a signalling lamp is to direct an intermittent beam from a person A to a person B so that while B receives a series of flashes as few other people as possible shall receive them.

Obviously everybody in the line AB produced who has an unobstructed view of A *must* see the flashes, but if the beam projected has a very small divergence, few people outside the line AB may see anything of the signalling. At first sight this would appear to call for the perfectly parallel beam affording a "light patch" equal in size to the front aperture of the signalling lamp. It is not so, however, because A who is sending the signal has to *aim* his beam at B by means of some sighting device, and it is impossible to aim a beam with *mathematical* accuracy. When all the possible errors in the lamp are taken into account—errors due to a slightly displaced source—personal errors of the man misjudging his aim—errors due to the uncertainty of the precise location of B and vibration effects due to wind, etc., it will be found that a certain definite though quite small angle of divergence in the beam is required (possibly only 1°). If the signalling lamp instead of being clamped to a stand is held in the hand, and so aimed, it will have to afford a very much wider angle of divergence, say 4°, and if it is to be used as a hand lamp on board ship or on aircraft it must have an angle of divergence of at least 6° to be sure of keeping B within the flash.

For such a lamp, a so-called half-watt electric bulb (tungsten filament incandescent in argon) is a very convenient source. This must be worked at a very high efficiency if any considerable range is to be afforded in *daylight*.

As would be expected, there is an upper limit to the size the projector can have, and if a parabolic reflector is to be used it must only be carried out, as in *Fig.* 6, as far as the *latus rectum*. That is to say, the source (which is at the focus F) must be in the plane AA′ of the front aperture, as the following consideration will show.

It has been shown that the front edge AA′ of the reflector projects the narrowest beam, and with a spherical source the apparent size of the "light patch" projected from this front edge is the same as the "apparent size" of the spherical source as viewed from any

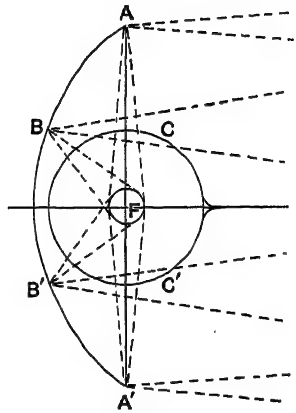

Fig. 6.

point on it. This apparent size is greatest when AF is least, *i.e.* if the diameter AA′ is given, F must be in the plane of the circle AA′.

Of course, the incandescent filament cannot be wound so as to simulate a continuous incandescent sphere, but a very close axial spiral coil (two such coils being shown in *Fig.* 3) will do, if its diameter is made large enough to afford the necessary minimum angle required for the signalling beam, and its length be made long enough, so that the view of the coil as seen from the inner edge BB′ of the annulus actually used for flashing the signal, shall just not show any black centre due to looking right through the axial incandescent cylinder formed by the filament. For reasons already pointed out, the parabolic cap BB′ is practically useless owing to the obstruction presented by the bulb CC′.

For larger and more powerful signalling lamps the electric arc is the best source to employ on account of its very high intrinsic brightness; and electric searchlights, especially in the smaller sizes, are fitted with shutters whereby the beam can be almost instantaneously occulted so as to permit of their being used as daylight signalling lamps.

Since the outer edge AA′ of the reflector is twice the distance from the source that the vertex is, there is a tendency for the beam corresponding to complete flashing to be half the angular width of the whole beam projected.

Such a condition is wasteful since the signalling beam should be equally intense all over, within the limits imposed by aiming considerations, and of zero intensity outside that limit. To secure this, however, it has been shown that it is necessary that the "equivalent bending surface" [1] (which in this case is the parabolic reflector itself) shall be a sphere with F as centre.

§ (10) THE MANGIN MIRROR FOR HEADLIGHTS.—The Mangin mirror is shown in *Fig.* 7, and is a good example of an optical element where the "equivalent bending surface" [1] for parallel axial rays can be made *approximately* spherical with the focus as centre.

Rays $A_1 B_1$, $A_2 B_2$, $A_3 B_3$, etc. (*Fig.* 7) parallel to the axis $A_0 B_0 C_0$ are refracted at the first surface B_1, B_2, B_3, etc., the outer rays being very much more strongly bent outwards than the inner rays, in such a manner

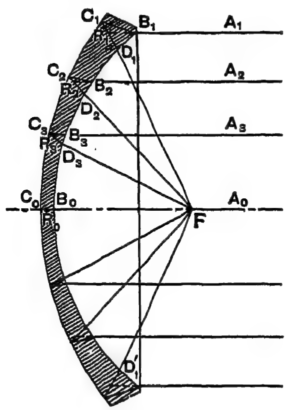

FIG. 7.

that after reflection at the back of the lens mirror at the points C_1, C_2, C_3, etc., they pass almost normally through the first refracting surface again at points D_1, D_2, D_3, etc., *i.e.* they concentrate after reflection to a point F not far removed from the centre of the first surface. An examination of *Fig.* 6 will show that the "equivalent bending surface" determined by the points R_1, R_2, R_3, etc., approximates to a sphere with F as focus.

It is not surprising, therefore, that such a lens mirror affords an extremely abruptly defined "light patch" when used in conjunction with any small axial disc source with its plane perpendicular to the axis of the lens mirror. The "apparent size" of the "light patch" projected is the same as the "apparent size" of the disc source as viewed from the vertex R_0 of the "equivalent bending surface." (This is situated on the axis somewhere within the central thickness B_0, C_0 of the lens mirror.)

[1] For definition see § (4).

For maximum efficiency it is necessary to design the lens mirror so that R_0 is as near to the focus F as the aperture of the mirror permits. As in the case of the parabolic reflector, maximum efficiency is only attained by contriving that the plane of the front edge B_1, B'_1 of the mirror should contain the focus F, but this is not practicable. It is easy, however, to make the angle D_1, F, D_1' as big as 130° or even 140°, and still afford an extremely well-defined "light patch" from any small flat source, and the loss, of course, is not great, because, unlike a spherical source, the flat disc source sends out less and less light at any considerable inclination to the axis; in fact, an infinitely thin flat disc source would send out no light perpendicular to the axis because, when viewed in that direction, it has no "apparent size." The useful "angle of collection" of 140° is too great for such sources as acetylene flames, 120° being about the limit of safe working owing to the tendency of the hot gases rising from the flame to crack the edge of the mirror. The combination of a Mangin mirror, however, with an "angle of collection" of about 120°, and a good flat acetylene flame at its focus, is a very effective piece of projection apparatus for projecting a wide angle beam of uniform intensity. Until the introduction of the electric headlight, this was the combination most in favour for motor cars. A lens mirror with a 10-inch flashing aperture would afford a candle-power in the beam corresponding to "complete flashing" of 1700, assuming 60 per cent reflective efficiency, and with a 36 candle-power flat circular flame, *i.e.* of 1 square inch in area, and an "angle of collection" of 120° for the mirror, this will be spread over a total angle of nearly 13° in the projected beam.

§ (11) THE MANGIN MIRROR FOR SIGNALLING LAMPS.—As has already been shown, signalling lamps require to project a much more powerful beam than motor-car headlights and confined to a much narrower angle. The acetylene flame has to be discarded, therefore, and something like a "complete flash" afforded with a Mangin mirror used in conjunction with a high-efficiency tungsten filament incandescent in argon. The condition to be satisfied is that everywhere within the narrow angular limits imposed for the signalling beam the ray directions traced from the observer's eye through the Mangin mirror to the focus shall terminate on incandescent filament.

For an axial "view point" any annular zone of the Mangin gives a cone of rays which accurately concentrate to a point on the axis. The variation of the position of this point is, in a well-designed Mangin mirror, very small indeed, though not small in relation to the

dimensions of a really closely-wound incandescent coil of reasonably small candle-power. The smallest possible electric source that will give a "complete flash" for an axial view point of any particular Mangin mirror is therefore seen to be a closely-wound axial coil surrounding that short length of the axis within which the "focal points" for all the different zones of the mirror lie.

In such a case the angular limit of the beam is determined by the "apparent size" of the diameter of the coil as seen from the vertex of the "equivalent bending surface" (a point situated somewhere within the central thickness of the mirror).

It should be noted that, as has already been shown, the flash is not complete except in the annulus surrounding a central area equal to the diameter of the electric bulb, and this useful annulus must be such that from no point on its inner edge shall it be possible to look right through the incandescent cylinder formed by the source.

A well-designed Mangin mirror with a small axial coil conforming to the above condition affords the most efficient portable signalling lamp for daylight work, as the following considerations will show.

A suitably designed Mangin mirror of 6 inches clear flashing aperture and with 130° "angle of collection" can be manufactured so that its "focal sphere"[1] is less than ·05 inch. Thus with such a mirror an axial coil ·1 inch long and ·04 inch diameter will afford a "complete flash" in it. The coil when viewed from its side has the "apparent shape" of a rectangle ·1 by ·04 which equals in area ·004 square inch.

Assuming an "intrinsic brightness" of 15,000 this would give a candle-power of 60, which can be quite safely confined within a 2-inch-diameter containing bulb. This means that an annulus having an area of over 25 square inches will be flashed with an "intrinsic brightness" of say 9000 (allowing 60 per cent transmission efficiency for the mirror), and a maximum candle-power in the beam of over 225,000 will be obtained. Thus it is evident that a well-designed small electric signalling lamp can be made greatly to excel the intensity produced by a relatively much larger motor-car electric headlight.

§ (12) The Mangin Mirror for Searchlights.—From the table of "intrinsic brightnesses" already given, it is evident that, even when full allowance is made for the effects of bulb obstructions, an oxy-acetylene projector would have to be made about twice as large as a high-efficiency projector with half-watt focus electric lamp, to afford the same range. In spite of this disadvantage as regards the relatively low "intrinsic brightness," the oxy-

[1] For definition see § (4).

acetylene-cum-pastille is found to be a very useful source for larger units starting at 12 inches in diameter up to say 2 feet in diameter, for the reason that when a total candle-power in the source of about 150 to 200 is exceeded, all the essential conveniences of the electric incandescent filament lamp begin to disappear.

It is the great advantage of the Mangin mirror that the surfaces are spheres and these can be polished true to shape with *extreme accuracy*. It is quite impossible to polish a parabolic shape to the same accuracy. That is why for the smaller units, where the thickness of the glass does not matter, the Mangin mirror is preferred to the glass parabolic reflector.

Taking a medium size of 20 inches in diameter, it is easy to design a Mangin mirror of this diameter with an angle of collection of about 127° whose "focal sphere"[2] (after making full allowance for colour dispersion and errors of manufacture) shall be less than ·2 inch.

This 20-inch mirror used in conjunction with a pastille ·8 inch in diameter would (assuming 60 per cent for its transmission efficiency and 5000 candle-power per square inch for the intrinsic brightness of the pastille) afford a beam whose maximum intensity would exceed 940,000 candle-power, and whose angle of divergence would be nearly 5°.

As has already been pointed out, however, for the largest and most powerful signalling lamps the electric arc must be used, and though the Mangin mirror is a convenient optical element to employ for the smaller projector, for the 24-inch sizes the thin glass silvered parabolic reflector is the most efficient, and from what has gone before it is evident that a beam having a maximum intensity of something like 15 million candle-power should be given by a 24-inch searchlight, even after making allowance for the obstruction due to the shutter employed for signalling.

§ (13) The Condenser Lens.—When a lens is used to bend the directions of ray paths rather than to produce *images*, it is termed a "condenser lens." Such condenser lenses usually consist of very deeply curved plano-convex lenses, either taken singly or in pairs, with their flat surfaces outside and their curved surfaces adjacent. *Fig.* 8 shows the more

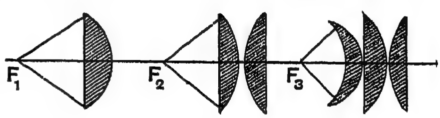

Fig. 8.

usual sections of single, double, and triple condenser lenses with their associated foci F_1, F_2, F_3.

[2] For definition see § (4).

In each case, however, ray directions drawn parallel to the axis are not bent to a true "focal point" or even anything approximating to a point, but the outer rays are more strongly bent than they should be, with the result that in every case the condenser system is found to possess a comparatively large focal sphere.[1]

In fact, a 4-inch diameter single condenser lens having an angle of collection of only 60° would have a focal sphere of ·4 inch in diameter as contrasted with a Mangin mirror which could be made of the same diameter with double the angle of collection and having a focal sphere of only ·03 inch.

For this reason a condenser lens is a bad and inefficient optical device for projecting a powerful beam of moderate divergence from very small bright sources.

Railway signals, however, afford a good example of the successful employment of simple condenser lenses giving wide angle beams of moderate intensity from relatively large and low-intensity flame sources.

The condenser lenses fitted to pocket flash-lamps are not in any sense focussed, and as their flashing is so imperfect, they hardly fall within the category of projection apparatus.

One of the most important uses of condenser lenses, however, lies in connection with the projection of images of transparent objects on a screen.

§ (14) Lantern Projection of Images on a Screen.—The less usual form of lantern projection, viz. the projection of solid opaque objects in their natural colours, will be considered first, because it is the simplest in theory (though the most difficult in practice).

For the sake of simplicity it will be assumed that a sheet of perfectly white paper is laid horizontally at AB (*Fig.* 9) on which perfectly black letters are printed. The lens C placed at a suitable focal distance vertically above it will, in conjunction with a 45° mirror D, project an image A′B′ of AB on to a vertical screen as indicated.

The 45° mirror is needed, because otherwise the image projected would be laterally inverted and the letters would be unreadable except from behind the screen.

The image will only be visible if AB be sufficiently strongly lit and the room be darkened so as to shut off all extraneous light from the screen A′B′ except that coming from the lens C.

To illuminate AB sufficiently strongly, two sources S and S′ may be imagined placed on either side of it and as close to it as possible, giving an average illumination on AB of 20,000 foot candles.

A good "angle of collection" for the lens C would be 14°, which corresponds to a lens of 12 inches focus with an aperture of 3 inches diameter.

[1] For definition see § (4).

Since a hemisphere of 12 inches radius has an area of 905 square inches it is evident

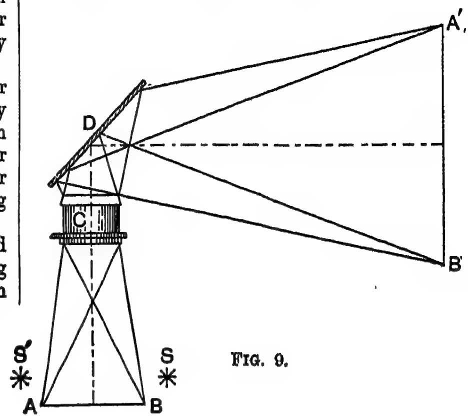

Fig. 9.

that if the perfectly white parts of AB scatter all the light received equally in all directions, the flash in the lens C corresponding to such a white part will have an "intrinsic brightness" of 20,000/905 candles per square inch if no transmission losses are assumed.

Now if the area illuminated on the screen is one hundred times the area of AB, then the apparent diameter of the flash seen in the lens from A′B′ will be one-tenth the "apparent diameter" of the aperture of the lens as seen from AB, *i.e.* it will be ·3 inches diameter at 12 inches' distance. The area of a ·3 diameter circle is about ·0707 square inches, and if a transmission efficiency for the lens C and mirror D of 60 per cent be assumed, the illumination of the screen A′B′ corresponding to *perfectly* white parts of AB is seen to be 12,000/905 × (·0707) foot candles.

This is equal to about ·94 foot candles, and shows how poor the result is, even with an illumination of 20,000 foot candles at AB.

For projecting a transparent object, however, the illuminant can be used in a much more economical manner; for if a source S (*Fig.* 10) in conjunction with a condenser P (usually two plano-convex lenses arranged as in the figure) be so arranged on the axis of the projector lens C so that the image of the source produced by P is concentrated within the lens aperture, it is obvious that any transparent object placed between C and P will, from the point of view of the image of S within the lens aperture, show its clear parts as of the same "intrinsic brightness" as the source S (as seen flashed in the condenser P). Hence, a lantern slide placed upside down at AB, and so that any lettering on it is readable from the same side of it as the condenser P,

will be projected by the lens C so as to be the right way up and with readable lettering provided the focal planes are properly adjusted. But in this case the brightness of perfectly transparent parts of AB is the "intrinsic brightness" of the source S as flashed in the condenser lens, which, of course, is very much greater than that of any illuminated white sheet.

The superiority of the illumination obtained by this method of projection is so great that only when very large magnifications are attempted are lenses of large aperture with the most intense sources needed.

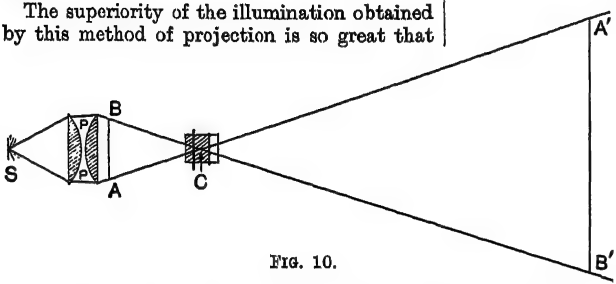

FIG. 10.

Such a case, however, is furnished by the cinematograph projector, where a picture approximately the size of a postage stamp has to be magnified so that its *area* is increased more than forty thousand times. This, of course, calls for the most intense source available, viz. the electric arc.

§ (15) THE CINEMATOGRAPH PROJECTOR.[1]—Since the cinematograph projector must be placed in a fire-proof chamber at the back of the building, its distance from the screen is necessarily great, and in modern picture-houses 90 feet is quite usual. Taking this distance of 90 feet, the width of the picture shown should be at least 17 feet, which is 218 times the width of the film picture and requires the projector lens to have a focal length of about 5 inches.

A rapid projector lens of this focal length might be assumed to have a clear aperture of $1\frac{1}{2}$ inches. Thus, the film picture is actually smaller than the lens used for projecting it, and its area is barely four times that of the crater of the arc used as the illuminant. Lantern slides have been standardised, so that a $4\frac{1}{2}$-inch diameter condenser will easily cover them, and though the problem of the cinematograph projector is so different from that of the ordinary lecture lantern, yet hitherto the same-sized condenser lenses have always been used.

Fig. 11 is drawn correctly to scale one-tenth actual size, and the upper view shows the general nature of the beam projected by a double plano-convex condenser P of 4 inches clear aperture from the crater of an arc S $\frac{1}{2}$ inch in diameter placed 3 inches behind the rear surface of the condenser P, producing a minimum cross-section in the beam at AB (termed the "waist"), of $1\frac{5}{8}$ inches in diameter, 12 inches in front of the condenser. The lower view shows the beam leaving the aperture AB, also the beam leaving the lens C when these are interposed.

The lens C for projecting the image is shown diagrammatically, indicating the clear aperture of the lens elements available for transmitting the beam. The aperture of the extreme rear lens D nearest the gate AB is assumed to be $1\frac{1}{2}$ inches and situated 4 inches in front of AB, the total length of the lens C being assumed as 2 inches.

It is necessary that the "waist" should have a diameter so much in excess of that required to cover the film picture because of the tendency of the arc to shift its position in a variable and uncertain manner; also the illumination of the marginal portions of the "waist" cannot be made as bright as the more central portions.

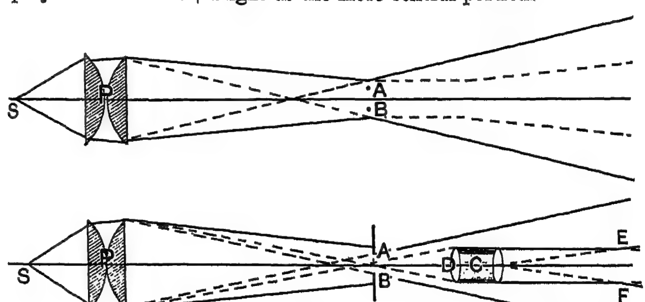

FIG. 11.

It is evident that in no other position in the beam can the film be so intensely illuminated as when situated at the "waist," and this position ensures that all except the marginal parts of the film picture receive a "complete flash" from the condenser.

Consider a small pinhole placed centrally at AB on an otherwise opaque film. The beam from the condenser P passing through this pinhole will cover a $1\frac{1}{2}$-inch diameter circle on the back lens D of the projector lens, and hence will all be collected and transmitted to the screen. If the pinhole

[1] See article "Kinematograph."

be displaced away from the centre, the circular area intercepted by the beam passing through it on to the back lens D moves away from the centre so much that a position is very soon reached in which the projector lens C fails to collect all this light, so that some of it is lost. This loss, however, only affects the marginal portions of the picture.

On the screen the central pinhole will be shown as a white spot, whose diameter will be 218 times that of the pinhole. Since all the light passing through the condenser P to this pinhole also passes through the projector lens C to the screen, it follows that the apparent diameter of the flash seen in the lens C from the screen must be $\frac{1}{218}$ of the apparent diameter of the flash seen in the condenser lens P from the film picture AB.

Thus the illumination of the centre of the screen, in this case corresponding to the whitest parts of the picture, is that produced by a circle $\frac{4}{218}$ inch in diameter (*i.e.* ·000264 square inch in area) at a distance of 1 foot, shining with an intensity of the intrinsic brightness of the arc as reduced by the transmission losses of the whole projector system P and C and the film at the "gate" AB. The mean "intrinsic brightness" of the flash may easily fall below 35,000, allowing for the obstruction of the negative carbon and parts of the condenser not being flashed by the intense central crater of the arc. Multiplying this figure by the above area of ·000264 square inch the illumination of the screen is obtained expressed in foot candles, viz. 9¼.

This result, however, neglects the effect of the shutter employed to cut off the beam whilst changing from one picture to the next. The shutter is periodically interposed where the beam passing from the lens C to the screen is narrowest. This occurs at the image EF of the aperture of the condenser P in the lens C, and in the case under consideration it would be about 6 inches in front of it.

The period of occultation makes the effective illumination on the screen at the most only 60 per cent of what it is with the film stationary and the shutter open. Thus with an ordinary carbon arc 3 inches behind a 4-inch diameter condenser the illumination on the screen corresponding to perfectly transparent parts of a moving picture should be 5½ foot candles. This would give a good bright picture in a well-darkened room.

§ (16) Projection of Microscopic Objects.—This is simply one stage further removed from ordinary lantern projection than the cinematograph projector. Obviously if the linear magnification aimed at is, say, 500 times, the object enlarged can only be very small. But since the apparent diameter of the flash as seen from the screen in the projector lens is only 1/500 of what it is as seen from the object in the condenser lens, this class of work calls for a big angle of convergence from condenser lens to the image of the arc on the object, and a correspondingly big angle of collection for the projector lens employed. The image of the arc produced by the condenser lens need not be large, especially in view of the fact that the field covered by a wide aperture projector lens is small. Consequently the arc need not be placed so close up to the condenser as in cinematograph projection, and a good microscope objective serves very well as a projector lens. The arc not being close up to the condenser makes it possible to use an elaborately designed condenser which will afford a complete flash of the hottest parts of the crater even for the large angle of collection of a good-quality microscope objective. This condition is not satisfied by ordinary condensers, and this explains why the satisfactory projection of highly enlarged views of microscopical subjects involves the careful design of the condenser as well as the projector lens used in conjunction with it.

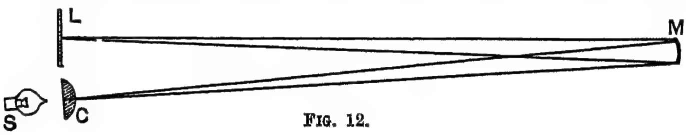

Fig. 12.

§ (17) Scale-reading Projection for Sensitive Instruments.—Under this head must be classed sensitive galvanometers, and all instruments where the angular rotation of the recording element in the instrument is used to make a mirror turn through an angle and so cause the image of an illuminated mark to move through a relatively large distance on a screen with the least possible moment of inertia in the moving parts of the instrument.

The most usual arrangement is shown diagrammatically in *Fig.* 12, and consists of a source S placed behind a condenser lens C, so placed that the image of the source (or more correctly the "waist" of the beam projected from S by C) falls on the concave mirror M, which is necessarily made exceedingly thin and of minimum weight, while a thin opaque vertical line traced on the flat side of C forms an image of itself on the scale L (supposed perpendicular to the plane of the paper). The condenser lens C and the scale L are generally placed equidistant from

the mirror M, whose radius, therefore, is made equal to the scale distance from mirror M to scale L.

Thus a round spot of light is received on the scale screen L with a fine vertical line traced across it. This round spot is the image of the flashed condenser lens produced by M. As usual, however, the question of contrast, or illumination at L, is best settled by placing the "eye" there and noting what it sees. Obviously, for maximum efficiency the whole of the mirror M must be seen as flashed with the "intrinsic brightness" of the source for any point adjacent to the image of the vertical line and as completely not flashed at all for "view points" on this margin. The latter condition can only be satisfied if the mirror M is accurately worked to the spherical shape and the width of the line on C not too fine to allow for the aberrations of the mirror when used at a slight inclination to true normal incidence. The former condition, however, is only satisfied if for all "view points" on the surface of the mirror M the line on C is seen against a background of incandescent surface.

With small electric battery lamps and simple condenser lenses this condition is never even remotely fulfilled, and all that can be provided is that the best and brightest part of the very coloured image of the incandescent filament projected by the condenser lens C is focussed on the mirror M. Thus the eye at L sees a coloured flash in M the "intrinsic brightness" of which is very much less than the incandescent filament.

A device for making sure of using the whole aperture of the mirror is to project on to L the image of a straight portion of the incandescent filament formed by M and to dispense entirely with the condenser lens. In this case, provided only the mirror M is made accurately enough to concentrate ray directions traced from a point on L so that they *all* terminate on such an extremely narrow object (only a few thousandths of an inch) as the filament in a small electric lamp, maximum efficiency will be attained. This accuracy is not, however, possible with commercially obtainable thin galvanometer mirrors, so that in this case, again, partial flashing alone is possible, and maximum efficiency cannot be attained.

The best way to insure maximum efficiency is to make the mirror M (*Fig.* 13) perfectly flat on both sides, because in such forms they can be made much more optically perfect though very thin. The mirror M then simply functions as a device for turning the axis of the projected beam through an angle.

The projector for providing the index mark focussed on the scale L, consists of a separate unit and is arranged on the plan of the cinematograph projector, but using an electric lamp S as a source. The incandescent filament wound as a close spiral coil projects an exceedingly bright image of itself on to the vertical cross-wire N, by means of the condenser lens P, and the image of the cross-wire thus strongly illuminated is projected by the achromatic objective C, so that after reflection at M, it focusses sharply on the scale L.

The sharpness of the image received at L is dependent on the ability of the lens C to afford a complete flash of an exceedingly fine cross-wire at N.

Achromatic objectives, however, are commercially obtainable which will satisfy this flashing test; and provided the mirror M is made accurately flat, this system makes it possible to get a clearly defined index mark on the scale L affording sufficient contrast to be read even in a well-lit room in broad daylight. Moreover, the result is entirely unaffected by the angle turned through by the mirror,

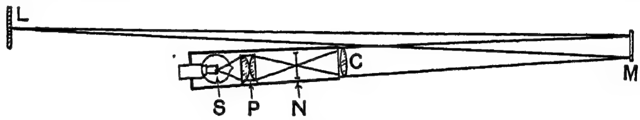

FIG. 13.

whereas a concave mirror has known and traceable aberrations for beams incident upon it at any appreciable angle to the normal or axial direction.

Quantum Limit to a spectrum of X-rays. Planck's quantum relation states that the maximum voltage applied to an X-ray tube multiplied by the electronic charge is equal to the frequency of the shortest wave multiplied by Planck's universal constant. Measuring the limiting wave-length the applied voltage can be found. See "Radiology," § (19).

QUANTUM THEORY

§ (1) **The Quantum.**—It has been found possible to account for many of the phenomena of physics by starting from the dynamical laws of Newton or the electromagnetic laws of Maxwell, together with such extensions of them as relativity theory. Certain phenomena will not, however, fit in, and this in a way that requires not merely a modification of those laws, but some fundamental revolution in our view of nature. The revolution has not yet been made in that no one has suggested any scheme which should cover both the discrepant phenomena and the classical mechanics, but the quantum theory constitutes a first step. At present this theory is hardly more than a working rule, but its wide applicability guarantees that it is leading in the right direction.

The Quantum Theory is definitely contradictory to the laws of mechanics, and this gives an arbitrary quality to some of its applications, in that mutually exclusive ideas are borrowed from both sides and combined. Such a procedure would of course not be tolerated but for the fact that on the negative side its absolute necessity has been demonstrated and on the positive its use will give right results. There is now a considerable body of experience showing in what regions the quantum is required and in what the classical mechanics will prove sufficient. The principal fields in which the quantum theory has achieved success are (in historical order): (1) Planck's theory of radiation, (2) Einstein's theory of the photoelectric effect, (3) the work of Einstein, Debye and others on the specific heats of solids, (4) Bohr's theory of spectra, much the most remarkable of all. It has also been applied, with only moderate success, to the problem of the equation of state of gases. Here, while it explains the phenomena of specific heat quite well, the classical mechanics seem on the whole capable of dealing with the law of pressure. The kindred problems for which the classical mechanics appear to be adequate without the quantum are such as the diffraction, interference, dispersion, and anomalous refraction of light waves, the scattering of light by small particles and of X-rays by electrons, and such matters as the molecular theory of the viscosity of gases.

The essential fact of the quantum theory is the existence of a certain universal constant, the quantum, discovered by Planck and denoted by h. Its physical dimensions are mass $\times$ (length)^2 $\times$ (time)$^{-1}$, that is the same as energy multiplied by time (the "action" of general dynamics) or as angular momentum. Its magnitude is $6{\cdot}5 \times 10^{-27}$ erg. sec. The rule for its use may be stated generally as follows. If a system can vibrate with a frequency of ν vibrations per second, then the energy associated with this vibration can only be exchanged with other systems in quantities which are exact multiples of $h\nu$. Thus radiation of frequency ν will be absorbed by matter in amounts $h\nu$, and conversely if an electron radiates energy E the wave will have frequency E/h. This rule lacks precision and is inadequate for Bohr's spectrum theory (see below), but it covers all the other applications and they will show how it is to be interpreted. Of these the simplest is the photoelectric effect, and though it was not the first development in order of time, yet it will be convenient to treat of it here first.

§ (2) **Photoelectric Effect.**—In the photoelectric effect [1] light falls on a metallic surface and electrons are in consequence emitted from the surface. Let the frequency of the light waves be ν, then according to the quantum rule the electrons come off with energy $h\nu$. This is in fact observed to happen, though the effect is complicated by subsequent collisions which reduce the speed of the electrons, and above all by the presence of an electric field at the surface which prevents their egress or reduces their emergent velocity. Thus the energy of none of the electrons is observed to be greater than $h\nu - E_0$, and there is a minimum frequency E_0/h for the light beyond which none are obtained. The energy of the electrons is quite independent of the intensity of the source of light, which only affects their number.

An enormously exaggerated photoelectric effect is obtained from the X-rays, as these are electromagnetic waves with frequencies about 5000 times as great as those of visible light. In this case the electrons are emitted with a very high velocity and E_0 is insignificant. The converse process has also been observed,

[1] See "Photoelectricity," Vol. II.

electrons falling on a surface with energy E give rise to X-rays and none of these have a frequency greater than E/h. That lower frequencies are also observed is due to the fact that many of the electrons do not lose all their energy in a single step. In the hands of Millikan[1] this process has been made very successful for determining the value of h.

It is hardly necessary to insist on the inadequacy of classical mechanics to deal with the photoelectric effect. In the first place the effect would naturally be attributable to some sort of resonance, whereas its character is quite different. Also on the classical theory an electron should only be able to absorb energy which passed in its immediate neighbourhood, and it is easily calculated that for feeble sources of light this energy is so small that it would take years for the electron to accumulate the amount of energy which it in fact exhibits at once. Before the advent of the quantum theory attempts were made to overcome this difficulty by a quasi-corpuscular theory of light. Any such theory, however, encounters the insuperable objection that the same light which produces the photoelectric effect can also exhibit interference and all the other phenomena which connote that it is extended in the form of continuous waves. The combination of these two apparently mutually exclusive ideas of continuity and discontinuity is typical of the quantum theory.

§ (3) Partition of Energy.—For dealing with radiation and specific heats the idea of temperature must be introduced and associated with the quantum. In this connection the fundamental question is that of the partition of energy, which may be stated as follows. If a system of a large number of degrees of freedom can be separated into parts, what will be the average energy of each of those parts? It will be sufficient here to limit the generality to the case where the energy can be expressed as the sum of a set of squared terms. In this case classical mechanics gives the answer that every squared term takes on the average as much as every other, an amount $\frac{1}{2}kT$, so that a vibratory degree of freedom (for which the energy is half kinetic and half potential) has kT. Here T is the absolute temperature and k the "atomic gas constant," that is the ordinary gas constant divided by the number of molecules in a gramme-molecule. This is called the theorem of the Equipartition of Energy. But the quantum theory gives a very different law of partition and in the theory of radiation and of specific heats it is this other law that is important. According to this law, if there is a vibrator in the system which can only exchange energy in finite units and if ϵ be the value of this unit, then the average energy of this vibrator is not kT, but $\epsilon/(e^{\epsilon/kT}-1)$.

[1] See "Photoelectricity," § (3), Vol. II.

The formal proof of this expression is a rather complicated matter, depending as it does on difficult considerations of probability. It will suffice here to deduce it by analogy from the case of classical mechanics, where the corresponding theorem can be fully established. Suppose a system composed of a set of vibrators, each of any frequency, which are capable of exchanging their energy say by means of a few freely moving molecules, which can collide with them. Except for the few moments when collisions are occurring, each vibrator has a definite energy half kinetic and half potential, and every now and then this energy is altered by a collision. If the vibrator is observed for a very long time the energy will take on various values, but some more frequently and for longer than others. The probability that the vibrator has energy between E and $E+dE$ is defined as the fraction of the total time during which its energy lies between those limits. Then it is a demonstrable consequence of the laws of dynamics that this probability has the value $Ae^{-E/kT}dE$, where A is a constant that is readily determined to be $1/kT$. The average energy of the vibrator is therefore $\int_0^\infty E.Ae^{-E/kT}dE$. The value of this expression when integrated is kT, which is independent of E, and this is the theorem of the equipartition of energy. But if, as in the quantum theory, energy can only be taken up in finite units the formula for the probability must be altered, as E is no longer infinitely divisible, but can only be a multiple of ϵ. By analogy with the classical theory we therefore say that the probability of a vibrator with $n\epsilon$ of energy is $A'e^{-n\epsilon/kT}$, where A′ is a constant, provided that n is an integer, and is zero if it is not. By summing the probabilities of all possible arrangements A′ is seen to have the value $1/(1-e^{-\epsilon/kT})$ and the average energy is now found to be $\epsilon/(e^{\epsilon/kT}-1)$. This is the partition formula resulting from Planck's theory. If ϵ is small the expression reduces to kT the equipartition value, but for larger values of ϵ there is less energy. If ϵ is much larger than kT, the partition amount is approximately $\epsilon e^{-\epsilon/kT}$, which is very small compared with kT.

This result has been obtained by extending the form from the case where equipartition holds. An example will suffice to show the probability basis on which it really rests. Consider a system composed of four vibrators, of which two, A and B, can hold energy units ϵ, while the other two, C and D, require units 2ϵ, and suppose that the total energy of the system is 4ϵ. The rule for the application of prob-

ability is then that equal probability attaches to every possible different distribution of the energy, in which no distinction is to be made as to the identity of the units of energy. Thus if *a*, *b* and *c*, *d* denote respectively units ϵ on A, B and units 2ϵ on C, D, then all the possible arrangements are: *aaaa*, *bbbb*, *aaab*, *abbb*, *aabb*, *aac*, *aad*, *bbc*, *bbd*, *abc*, *abd*, *cc*, *dd*, *cd*, and each of these is to be counted as equally likely. Then the average energy on A or B is $\frac{1}{1}\frac{2}{3}\epsilon$ and on C or D is $\frac{1}{1}\frac{3}{3}\epsilon$. This illustrates the tendency for the energy to go into the vibrations which have the smaller units. The same process carried out with large numbers leads precisely to the above partition formula. That the probability basis is correct is confirmed by the fact that in mechanics energy is infinitely divisible, and if that is taken to be so in the above work, then the ordinary equipartition formula results.

Thus, since ϵ has the value $h\nu$, the consequence of the quantum theory is that if a vibratory system has frequency ν, and is at temperature T, its average energy is not kT, but

$$\frac{h\nu}{e^{h\nu/k\mathrm{T}}-1}.$$

§ (4) Radiation.—It was in his study of the radiation problem that Planck discovered the quantum, and it was in the same connection that Poincaré demonstrated rigorously the inadequacy of the older mechanics. A very considerable amount can be discovered about radiation by the application of thermodynamics, a branch of physics that must certainly be considered more fundamental than dynamics. It can be shown (see "Radiation," § (5), (ii.)) that there must be a universal formula describing the equilibrium of energy between radiation and matter in an enclosed space, and that this formula must be of the form

$$\mathrm{E}_\lambda=\frac{1}{\lambda^5}f(\lambda\mathrm{T})$$

(this is Wien's Displacement Law), where $\mathrm{E}_\lambda d\lambda$ is the energy (isotropic) per cubic centimetre in the spectral region between λ and $\lambda+d\lambda$, and T is the absolute temperature. All the thermodynamical conditions, however, are satisfied by any continuous function f, and so it is necessary to have recourse to other principles in order to find the form of f. In making use of the quantum to find the radiation formula it will be therefore allowable to choose any specially convenient system, and the apparent artificiality of the one chosen will be without influence on the result, for thermodynamics guarantee that this must also be the general formula.

The system chosen consists of a rectangular box with perfectly reflecting sides in which a small piece of matter is placed. This matter will radiate until the radiation in the box is in temperature equilibrium with it, that is until the radiation is the "complete" or "black" radiation corresponding to the temperature of the matter. If the matter is now withdrawn the radiation will be reflected backwards and forwards from the walls unchangeably, and can be easily analysed into a set of independent vibrations. The partition law can then be used to assign the average energy in each vibration.

Let the sides of the box be α, β, γ. Then the vibrations are described by means of the electric and magnetic forces, the typical expression being

$$\mathrm{X}=\Sigma\mathrm{A}_{lmn}\cos\frac{l\pi x}{\alpha}\sin\frac{m\pi y}{\beta}\sin\frac{n\pi z}{\gamma}\cos 2\pi\nu(t+\epsilon),$$

where l, m, n are integers, and ν is the frequency. By examining the electromagnetic equations it is found that

$$\frac{l^2}{\alpha^2}+\frac{m^2}{\beta^2}+\frac{n^2}{\gamma^2}=\frac{4\nu^2}{c^2}$$

(c is the velocity of light), and that there are two independent vibrations for each l, m, n corresponding to the two directions of polarisation. Now each vibration can be represented by marking the corresponding value l, m, n in a three-dimensional space. Then the number of vibrations for which ν is less than ν_0 is the same as twice the number of points marked inside the positive octant of the ellipsoid of semi-axes

$$\frac{2\alpha\nu_0}{c},\ \frac{2\beta\nu_0}{c},\ \frac{2\gamma\nu_0}{c}.$$

This number is

$$\frac{8\pi}{3}\alpha\beta\gamma\frac{\nu_0^3}{c^3}.$$

The number of vibrations with frequencies lying between ν and $\nu+d\nu$ is found by differentiation of this, and is

$$8\pi\,\alpha\beta\gamma\frac{\nu^2d\nu}{c^3}.$$

By the partition law each of these has average energy in amount $h\nu/(e^{h\nu/k\mathrm{T}}-1)$ and so the total energy in the box in frequencies between ν and $\nu+d\nu$ is

$$8\pi\,\alpha\beta\gamma\frac{\nu^2d\nu}{c^3}\frac{h\nu}{e^{h\nu/k\mathrm{T}}-1}.$$

If $\mathrm{U}_\nu d\nu$ is the energy per unit volume between ν and $\nu+d\nu$, then

$$\mathrm{U}_\nu=8\pi\frac{\nu^2}{c^3}\frac{h\nu}{e^{h\nu/k\mathrm{T}}-1}.$$

To change into the more usual form with wave-lengths instead of frequencies it is only necessary to apply the equations $\nu=c/\lambda$ and

$U_\nu d\nu = E_\lambda d\lambda$, and the result is Planck's radiation formula

$$E_\lambda = \frac{8\pi hc}{\lambda^5(e^{hc/k\mathrm{T}\lambda}-1)}.$$

If the equipartition law held, the formula of Rayleigh[1] would be given, viz.

$$E_\lambda = \frac{8\pi k\mathrm{T}}{\lambda^4}.$$

This formula is manifestly impossible as it implies infinite energy in the infinitely short wave-lengths, but it is inevitably deduced by every method that is based on classical mechanics. For the discussion of Planck's formula see "Radiation," § (6). Here it suffices to say that by determining the k of his formula from experiments Planck obtained one of the earliest really good values for the Avogadro constant. The values for h and k as determined by recent experiments are given by $h = 6{\cdot}55 \times 10^{-27}$ erg. sec. and $k = 1{\cdot}372 \times 10^{-16}$ erg./deg.

An attempt was made by Planck in his "Second Quantum Hypothesis" partially to reconcile quantum mechanics with ordinary mechanics by supposing that vibrators absorb energy continuously, but emit it in units. This theory leads to the same radiation formula as the other, but when applied in other directions it seems on the whole to raise more difficulties than it puts to rest. There is little doubt that no reconciliation in this way is possible, and most of the subsequent developments of quantum theory have proceeded on Planck's First Hypothesis, in which both emission and absorption are discontinuous processes.

§ (5) Specific Heats of Solids.—Before the advent of the quantum theory the problem of specific heats encountered great difficulty. For it is clear from the emission of spectra, etc., that there are at any rate a considerable number of degrees of internal freedom in an atom, and each of these should require its full share of energy on the equipartition principle. The quantum removes this difficulty in that, if the frequencies corresponding to these degrees are high, the partition rule will, at ordinary temperatures, require very little energy for them. Subject, then, to this new condition, the theory fits very well. Thus the specific heat at constant volume of a monatomic gas is simply due to the kinetic energy of translation of its atoms. For N atoms it will be $\frac{3}{2}k$N. For most diatomic gases two further degrees of freedom must be added, as the molecule may rotate about two axes perpendicular to the line joining its atoms; the specific heat is therefore $\frac{5}{2}k$N. In solids the atoms must be supposed to have three degrees of potential energy as well as three of kinetic, and so the specific heat for N atoms will now be $3k$N. This is the law of Dulong and Petit—that the atomic weight multiplied by the specific heat is the same for all the elements. Now there are certain well-known exceptions[2] to this law; diamond has a specific heat far below the value it should have. It was also discovered that all the other elements have much too low specific heat when the temperature is very low; and conversely that at a temperature of 600° C. diamond is nearly normal. The elucidation of these facts has been one of the successes of the quantum theory. It should be remarked that here we shall only treat of specific heat at constant volume. This often differs considerably from the observed quantity specific heat at constant pressure, but if the compressibility and thermal expansion are known the one can be deduced from the other by thermodynamics.

The first attack on the problem was due to Einstein. Rubens had shown that such solids as rock-salt have a very strong absorption band for light in the far infra-red. This is to be attributed to the vibrations of the atoms in the crystal and tells us their frequency ν, and so provides a means of applying the quantum partition rule. Instead of being $3k$T, the average energy of an atom should be $3h\nu/(e^{h\nu/k\mathrm{T}}-1)$ and so, by differentiating, the specific heat of N atoms will be

$$\frac{3(h\nu)^2 e^{h\nu/k\mathrm{T}}}{k\mathrm{T}^2(e^{h\nu/k\mathrm{T}}-1)^2}\mathrm{N}.$$

This formula represents the falling off of the specific heat at reduced temperatures, and vanishes at the absolute zero as it should, but at very low temperatures it gives values that are well below the experimental. An improvement was made by the empirical formula of Nernst and Lindemann, who replaced half the expression by a similar term involving $\nu/2$ instead of ν. This represents the experimental results much better, but still gives low values at the very low temperatures; moreover, there seems no theoretical reason for the presence of the octave terms.

The theory was greatly improved by Debye. The atoms of the solid are not to be regarded as having a single definite frequency, but will vibrate according to a set of normal modes that can be calculated from the theory of elasticity. Now if it were correct to suppose that the substance was a continuous elastic medium, it would follow by a method similar to that already used in the radiation problem that the number of degrees of freedom of vibration with frequencies between ν and $\nu + d\nu$ was

$$4\pi\left(\frac{1}{a_1^3}+\frac{2}{a_2^3}\right)\nu^2 d\nu,$$

where a_1 and a_2 are respectively the velocities of transmission of longitudinal and transverse waves. This number, of course, becomes infinite with ν, but it is obvious that there are really only a finite number of degrees of

[1] "Remarks upon the Law of Complete Radiation," *Phil. Mag.*, 1900, xlix. 539.

[2] See "Calorimetry, Quantum Theory," Vol. I.

freedom—3N for N atoms. Debye's method consists in supposing that all the frequencies below a certain value ν_m occur, and beyond these none. ν_m is determined by the condition that there shall be only 3N degrees of freedom in all, that is by the equation

$$\frac{4}{3}\pi V\left(\frac{1}{a_1^3}+\frac{2}{a_2^3}\right)\nu_m{}^3=3N,$$

where V is the volume containing the N atoms. Applying the quantum partition principle, the energy is given as

$$\int_0^{\nu_m} 4\pi V\left(\frac{1}{a_1^3}+\frac{2}{a_2^3}\right)\frac{h\nu}{e^{h\nu/kT}-1}\nu^2 d\nu$$

or

$$9N\int_0^{\nu_m}\frac{h\nu^3 d\nu}{(e^{h\nu/kT}-1)\nu_m{}^3}.$$

The differentiation of this expression by the temperature gives the specific heat at constant volume. If a "critical temperature" Θ is defined by the equation $k\Theta=h\nu_m$ (Θ may be calculated from a_1 and a_2, that is from the elastic constants), then the specific heat may be written as

$$3kf\left(\frac{\Theta}{T}\right)N,$$

where

$$f\left(\frac{\Theta}{T}\right)=3\left(\frac{T}{\Theta}\right)^3\int_0^{\frac{\Theta}{T}}\frac{x^4e^x}{(e^x-1)^2}dx.$$

When T is large f becomes equal to unity. For small temperatures, on the other hand, the specific heat becomes

$$3\,.\,k\,.\,77{\cdot}94\left(\frac{T}{\Theta}\right)^3 N.$$

This equation is verified fairly satisfactorily by experiment.

Debye's method of counting the vibrations is avowedly only rough, and his estimate is least accurate in precisely the place where the greatest accuracy in counting is needed, that is for the frequencies near ν_m. An improvement has been made by Born and Karman, who have succeeded in calculating the actual normal modes of vibration of a rock-salt crystal. They obtain the necessary constants from the elastic properties, and get values for the specific heat even better than Debye's. The actual comparison with experiment is described in the article in Vol. I. on "Calorimetry, Quantum Theory."

The fact that the specific heat at low temperatures is proportional to the cube of the temperature implies that the entropy near the absolute zero is a finite quantity; and by choice of the arbitrary constant which occurs in the definition of entropy it may be taken to be zero at the absolute zero. This is intimately related with Nernst's heat theorem, which has had such important consequences in physical chemistry.

§ (6) Specific Heat of Gases.—The application of the quantum to the specific heats of gases is not so satisfactory as for solids, partly because the experimental data are much less accurate, so that a discrimination between rival theories is not so easy. At both high and low temperatures the specific heat changes. At the high it increases—a certain part of the increase is attributable to dissociation, but it appears also that some of it is due to a participation in the energy by some of the internal degrees of freedom of the molecule. At low temperatures a very remarkable process occurs in the diatomic gases. Thus diatomic hydrogen at 40° abs. has all the characters of a monatomic gas—its specific heat at constant volume is $\frac{3}{2}k$N, and the ratio of the specific heats is $\frac{5}{3}$, instead of the ordinary values $\frac{5}{2}k$N with a ratio $\frac{7}{5}$.

The molecules of a diatomic gas can take energy in three ways. There is, first, the translational motion of the whole molecule; as would be expected, this method appears to be the same for all types of molecules. Secondly, there are the internal vibrations; the most important of these is the vibration in which the two atoms oscillate along the line joining them. It appears that for the permanent gases this vibration has too high a frequency for it to acquire any energy at all at ordinary temperatures, though it probably plays a part in the rise of specific heat at high temperatures. The third factor is the rotation of the molecules, and the treatment of degrees of freedom depending on rotation is a much more doubtful question. One of the most interesting methods is the following. Suppose a molecule to be rotating with a frequency ν, then its angular velocity is $2\pi\nu$. If I is its moment of inertia the kinetic energy is $\frac{1}{2}I(2\pi\nu)^2$. If the quantum principle is applicable this must be equal to $\frac{1}{2}nh\nu$, where n is an integer. (The reason for the factor $\frac{1}{2}$ will be seen in § (7) from the rule for the quantisation of orbits.) Now suppose that I is independent of ν, though there does not seem to be any cogent reason why this should be so in view of the varying centrifugal force. Then, since $\nu=nh/4\pi^2 I$, the molecule is only permitted to rotate with frequencies which are multiples of $h/4\pi^2 I$. There is evidence that frequencies of this type do exist from the presence of absorption bands in the far infra-red. The permissible energies of rotation will be $n^2h^2/8\pi^2 I$. Several methods have been tried for finding the specific heat from this. That which seems preferable theoretically is due to Ehrenfest. He works out the partition law *ab initio* in the same sort of way as that sketched in § (3), and it leads to the following formula for the total energy of N molecules:

$$\frac{e^{-\sigma}+4e^{-4\sigma}+9e^{-9\sigma}+\;.\;.\;.}{1+e^{-\sigma}+e^{-4\sigma}+e^{-9\sigma}+\;.\;.\;.}\sigma kTN+\frac{3}{2}kTN,$$

where $\sigma = h^2/8\pi^2 IkT$. The specific heat follows by differentiation. There are other theories, which give as good or nearly as good agreement with experiment—for instance, those of Bjerrum and of Krüger.

Various attempts have also been made to introduce the quantum in connection with other properties of gases. For instance, Tetrode and Keesom have examined the result of quantising the acoustic vibrations of a gas. This, of course, destroys the validity of the Maxwell law of distribution of velocities, and the equation of state is modified. The attempt is not very successful, and the resulting equation differs from the actual at least as much as that obtained from classical mechanics.

Mention should also be made of some theories of Planck, Sackur, and Tetrode, who have tried to introduce the quantum in a still more fundamental way by using it to define the probability basis which controls the distribution of molecules. The object was to calculate the condensation point of a gas, but none of the theories have been very successful.

§ (7) Spectrum Theory.—It will suffice merely to indicate the general outline of the Bohr's theory of spectra, which is the most remarkable application of quanta yet made. The spectra of many of the elements have been analysed into fairly simple formulae, and these formulae are completely different from those found in the ordinary theory of vibrations. For the frequency of each line is given by taking the difference of a pair of *terms*, and the separated terms usually fall into an algebraic series of some kind. This rule for constructing lines from terms is called the Combination Law of Ritz. For example, the series-terms for the primary hydrogen spectrum are of the form N/n^2, where N is a constant and n any integer, and so the lines are

$$N\left(\frac{1}{n^2} - \frac{1}{n'^2}\right).$$

The famous Balmer[1] series is the particular case where $n=2$, while n' has all integral values greater than 2. Spectrum work is usually carried out not in frequencies, but in reciprocal wave-lengths; the constant N/c is called Rydberg's constant. Now in dealing with the photoelectric effect it was seen that a loss of energy E was associated with radiation of frequency E/h. Therefore if an atom of initial energy E_1 radiates, and in consequence has its energy reduced to E_2, the radiation will be of frequency $(E_1 - E_2)/h$. Thus the quantum theory directly explains the meaning of the combination law; if any series-term is multiplied by h the result is the energy either before or after the emission.

[1] See also article "Spectroscopy, Modern," Vol. V.

The reverse argument applies for the absorption of radiation. Thus if an atom is in the arrangement corresponding to energy E_2, and is irradiated with radiation of frequency $(E_1 - E_2)/h$, it may absorb it and thereby rise to the arrangement with energy E_1.

This use of the quantum is only half the solution, however; for it is still necessary to find the arrangements corresponding to the series *terms*, and the laws of ordinary mechanics will not determine them definitely. For example, the hydrogen atom consists of a nucleus and one electron, which describes an elliptic orbit about it, and this it may do with any radius and any energy whatever. So in order to make the energy of the atom definite a second use of the quantum must be made. This consists in "quantising the orbits," which means that some of the orbital constants are determined by the quantum, so that of the infinity of orbits possible on dynamical principles only a certain limited series is permissible. For example, consider first only the circular orbits which the electron may describe. The electron can absorb or emit energy in multiples of $h\nu$; in addition to this the further condition is assumed that the angular momentum is to be a multiple of $h/2\pi$. This is a consequence of the rule of quantisation applied to this case. Thus if a is the radius and v the velocity of the electron, the motion is given by

$$\frac{mv^2}{a} = \frac{e^2}{a^2},$$

where e is the electric charge of electron and nucleus, and m is the mass of the electron. The quantisation gives $mva = nh/2\pi$. From these equations it follows that

$$a = \frac{n^2h^2}{4\pi^2e^2m} = n^2a_1,$$

and the energy is

$$E_n = -\frac{2\pi^2e^4m}{h^2}\frac{1}{n^2}.$$

Thus, if the electron shifts from the orbit of radius n^2a_1 to that of radius n'^2a_1 there will be an emission of the line defined by

$$\nu = \frac{2\pi^2e^4m}{h^3}\left(\frac{1}{n'^2} - \frac{1}{n^2}\right).$$

This is precisely Balmer's expression, and the agreement is numerical. Thus the Rydberg constant for hydrogen is directly observed to be 109677·691 cm.$^{-1}$; if the most accurate known values of e, m, h, and c are substituted in the above expression the result is $1{\cdot}095 \times 10^5$ cm.$^{-1}$. The value of a_1, the least permissible radius, is about $0{\cdot}5 \times 10^{-8}$ cm., which is of the same order as the known size of atoms.

This is the substance of Bohr's original discovery. The second great advance is the extension of the principle by Sommerfeld to

the case of more complicated orbits. In these cases the principle of quantisation can best be expressed in the language of general dynamics. Thus in a periodic or quasi-periodic motion let q be one of the co-ordinates which define the motion, and p the corresponding momentum; then q and p will fluctuate about certain values during the period. The relation which expresses the quantisation of the orbit is $nh=\int pdq$, where the integral is taken round one period, and this is to be applied for each of the variables q. In the previous example q was the vectorial angle and ranged from 0 to 2π, and p, the angular momentum, is therefore a multiple of $h/2\pi$.

In elliptic motion the quantisation is naturally more complicated, as it applies to both θ and r. The angular momentum is again constant, so that the quantisation gives $p_\theta=n_1h/2\pi$. The radial momentum is

$$m\frac{dr}{dt} \quad \text{or} \quad \frac{p_\theta}{r^2}\frac{dr}{d\theta},$$

and the quantum relation for this is

$$n_2h=\int p_r dr=\int\frac{p_\theta}{r^2}\left(\frac{dr}{d\theta}\right)^2 d\theta,$$

where the integration is to be taken from the minimum of r to its maximum and back again, that is once round the ellipse. Now if a is the half major axis and ϵ the eccentricity, the equation to the ellipse is $a(1-\epsilon^2)/r=1+\epsilon\cos\theta$ and p_θ is given by the relation $p_\theta{}^2=e^2ma(1-\epsilon^2)$. Substituting for r in terms of θ and performing the integration we have $n_2h=p_\theta\,.\,2\pi[(1-\epsilon^2)^{-\frac{1}{2}}-1]$. Hence the permissible orbits are those for which

$$\frac{n_1}{n_1+n_2}=\sqrt{1-\epsilon^2}$$

and $$a=\frac{(n_1+n_2)^2h^2}{4\pi^2e^2m}=(n_1+n_2)^2a_1.$$

The total energy is found to be

$$E_{n_1,\,n_2}=-\frac{2\pi^2e^4m}{h^2}\frac{1}{(n_1+n_2)^2}$$

As n_1 and n_2 are integers, each permissible orbit has major axis equal to the diameter of one of the circular orbits obtained above, and this diameter determines the energy, but the eccentricity can only have certain prescribed values. For example, if $n_1+n_2=3$, we have three, and only three, different orbits: (1) $n_1=3$, $n_2=0$, a circle of radius $9a_1$; (2) $n_1=2$, $n_2=1$, an ellipse of which the semi-axes are $9a_1$, $6a_1$, and the eccentricity is $\sqrt{5}/3$; (3) $n_1=1$, $n_2=2$, an ellipse of semi-axes $9a_1$, $3a_1$, and eccentricity $\sqrt{8}/3$. The case $n_1=0$, $n_2=3$ is supposed to be inadmissible, as it would involve a collision of the electron with the nucleus. The red hydrogen line $N(1/2^2-1/3^2)$ is thus made up of six components derived from the change from any one of these three orbits to either of the orbits $n_1'=2$, $n_2'=0$, or $n_1'=1$, $n_2'=1$.

Sommerfeld also took into account the fact that the mass of the electron is a function of its velocity. This modifies the orbits in such a way that the ellipses have slightly different energies. The consequence is that each line of the Balmer series has a fine structure of a type he was able to predict, which has been confirmed by experiment. The method has also been applied, with complete success, to the influence on spectra of electric and magnetic fields, the Stark and Zeeman effects. For these cases, in order to predict the polarisation of the component lines, it is necessary to introduce supplementary principles. Sommerfeld has suggested a "principle of selection" (*Auswahlprinzip*) depending on the idea of the momentum of radiation. In addition to giving a polarisation rule, it has the consequence that certain lines, which would on the original theory have been expected, will not be found, as is experimentally the case. An alternative, which appears preferable, is Bohr's "principle of correspondence." It is not possible to describe this here, but the general idea is that the behaviour of a quantised system may be predicted by assimilating the result which would be obtained when the number of quanta is large, to the result given on the principles of classical mechanics.

As points of further interest in the theory, mention may be made of the fact that ionised helium gives a spectrum precisely the same as hydrogen, except that the constant N is changed. Here, as in hydrogen, there is a single electron moving round a nucleus, but now the nuclear charge is $2e$. Hence the permissible orbits are all half the size of the others, and the corresponding energies are four times as great. The new N is almost but not quite exactly four times as great as the old, and the departure from exactness has been explained very satisfactorily. It is attributable to the fact that the mass of the nucleus is not infinite compared to that of the electron, so that the nucleus itself has a small motion. As the helium nucleus is four times as heavy as the hydrogen, there will be a difference in the two motions, with a resulting effect on Rydberg's constant. It is possible in this way to evaluate the ratio of the mass of an electron to that of a hydrogen atom from purely spectroscopic data. Another point of interest is that the X-ray spectra can be analysed into terms, many of which fit into series of exactly the same form as those of hydrogen and helium, and these lines exhibit the same fine structure too, but that the separation of the components is much greater. A very considerable theory of these spectra exists.

By using (α) Rydberg's constant, (β) the difference of this constant for hydrogen and helium, (γ) the "constant of fine structure" and the value of the velocity of light, it is possible to work out from spectroscopic data alone all the fundamental elementary constants e, m, and h. Of the three relations (α) is known so accurately that the precision depends entirely on the other two. Of these (β) determines what is in effect e/m in terms of the small difference between two large, but accurately known, numbers; its precision is about equal to that from direct methods. (γ) gives a relation between e and h in terms of the separation of the lines in the fine structure, and the observations are exceedingly difficult. The resulting values from the three relations are nearly as good as those by other methods.

TABLE OF VALUES OF THE QUANTUM

$h \times 10^{27}$.	Method.	Notes.
$6{\cdot}551 \pm 0{\cdot}009$	Total radiation	A
$6{\cdot}557 \pm 0{\cdot}013$	Spectral radiation	B
$6{\cdot}578 \pm 0{\cdot}026$	Photoelectric effect	C
$6{\cdot}555 \pm 0{\cdot}009$	X-rays	D
$6{\cdot}579 \pm 0{\cdot}021$	Ionisation potential	E
$6{\cdot}526 \pm 0{\cdot}200$	Spectroscopic data	F
$6{\cdot}547 \pm 0{\cdot}009$	Semi-spectroscopic data	G

A is determined by taking k known in the formula for the total radiation.

B is determined from the position of the maximum intensity of black radiation at any temperature.

C is found directly from observations on the photoelectric effect.

D is determined from the minimum wave-length of X-rays excited by electrons of known energy.

E depends on observations that are half spectroscopic. From spectroscopy the energy of an atom may be known. The ionisation potential gives another measure of this, as it shows the energy necessary for the removal of an electron.

F is determined by the purely spectroscopic method involving the above relations α, β, γ.

G is determined by the use of (α) and (β) as in F, but (γ) is replaced by using the known value of e.

Of these methods all except F depend on assuming Millikan's value $4{\cdot}774 \times 10^{-10} \pm 0{\cdot}009$ E.S.U. for e, the electronic charge; but the close agreement between A and B is a direct support for that value.

C. G. D.

BIBLIOGRAPHY

For most of the quantum theory it is unnecessary to refer to the original papers, as they have been incorporated in many books. Among others the following are works that may usefully be consulted.

La Théorie du rayonnement et des quanta (Gauthier Villars, Paris, 1912) is an account of a congress held at Brussels in 1910 of leading physicists. All the earlier aspects of the quantum theory are very fully discussed.

Report on Radiation and the Quantum Theory, by J. H. Jeans (Lond. Phys. Soc., 1914), is a concise account of the whole field of the quantum theory, except that spectrum theory has developed a great deal further since its publication.

A System of Physical Chemistry, vol. iii., by W. C. McC. Lewis (Longmans, Green & Co., 1919), gives a very detailed, but uncritical, account of many parts of the quantum theory, without the use of much mathematics.

Atombau und Spektrallinien, by A. Sommerfeld (Vieweg, 1919), gives a very complete account of atomic physics, with special reference to the Bohr theory of spectra.

The Dynamical Theory of Gases, by J. H. Jeans, Third Edition (Camb. Univ. Press, 1920), contains a few chapters dealing mathematically with the chief points of the theory.

Report on the Quantum Theory of Spectra, by L. Silberstein (Adam Hilger, 1920), is a short but complete account of spectrum theory.

References to original papers will be found in these works. Bohr's "Correspondence Principle" is dealt with in two papers "On the Quantum Theory of Line Spectra" by N. Bohr (*D. Kgl. Dansk. Vidensk. Selsk. Skr.*, 1918); the papers are in English.

QUARTZ, OPTICAL ROTATORY POWER OF

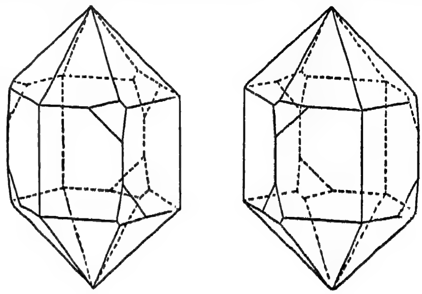
§ (1) HISTORICAL.—The phenomenon of optical rotatory[1] power was discovered by Biot, who communicated to the Institute of France on November 30, 1812, a memoir of 371 pages, "On a New Kind of Oscillation which the Molecules of Light experience in traversing certain Crystals." Arago, in 1811,[2] had found that a plate of quartz, interposed between a polariser and analyser, was capable of depolarising the light in such a way that transmission took place where previously there had been complete extinction. The transmitted light was not white but coloured. Thus with increasing thickness of the plate the colours changed progressively through the series—yellow, orange, rose-red, violet, blue, and green. These colours were shown by Biot to be due to a rotation of the plane of polarisation, which increased (i.) with the thickness of the plate, (ii.) with change of colour from red to violet. It was therefore impossible, when a beam of polarised light had passed through a quartz plate, to extinguish all the colours simultaneously. The tints which Arago observed were due to the selective extinction of light which had been rotated through 180° (or a multiple of 180°) by the plate of quartz. Thus a plate about

[1] See also "Polarised Light," § (20), and "Polarimetry," § (1).

[2] *Mem. Inst.*, 1811, pp. 93-134.

4 mm. thick which rotates the plane of polarisation of violet light through 180° gives rise to a yellow tint. As the thickness of the plate increases the absorption band moves towards the red end of the spectrum, but before it has disappeared into the infra-red a second absorption band moves in from the ultra-violet, so that a plate of quartz about 9 or 10 mm. thick gives an extinction both at the red end of the spectrum, where the plane of polarisation is rotated through 180°, and in the blue or violet region, where it is rotated through 360°. These extinctions at the two ends of the spectrum give rise to the green colour, which is the last member of the series of colours recorded above. Thicker plates give extinctions which increase progressively in number and in the closeness with which they are packed in the spectrum. No marked coloration is then observed in the transmitted light, although the absorption bands can be seen very clearly with the aid of a spectroscope. A quartz plate, 3·65 mm. in thickness, produces a rotation of 90° in the bright orange-green region of the spectrum, a little on the yellow side of the green mercury line of wave-length 0·5461 μ, which gives a rotation of 93° in a plate of this thickness. When the polariser and analyser between which the quartz plate is inserted are parallel instead of crossed the brightest part of the spectrum is extinguished and a rose-violet colour, known as the *neutral tint*, is produced which is very sensitive to small changes in the setting of the polariser or analyser, or in the thickness of the plate. This fact was formerly utilised in the construction of *polarimeters* for measuring the rotation of polarised light in various media.

§ (2) Crystalline Form.—The typical crystals of quartz have the form of a hexagonal prism capped by two hexagonal pyramids, and are therefore referred to the "hexagonal system" in which the faces are located most conveniently by their intercepts on a vertical principal axis and three horizontal axes inclined at 60° to one another. A closer examination shows the presence on some crystals of small facets (*Fig.* 1, (*a*) and (*b*)) which reduce the symmetry of the crystal by destroying the six vertical planes of symmetry intersecting in the principal axis, which are present in the simple hexagonal prism. Even when these facets are absent the lower symmetry of the quartz crystals can be shown by studying the tiny "etched-figures" obtained by the action of hydrofluoric acid on the crystals. When these factors are taken into account it is seen that the quartz crystals are not "holohedral" but "tetartohedral," the smaller facets including only six facets of each form instead of twenty-four as in the holohedral system of symmetry, where each face of the hexagonal prism would carry a facet on each corner. The symmetry of the quartz crystal is in fact restricted to one vertical axis of threefold symmetry, and



(*a*) (*b*)

Fig. 1.—(*a*) Dextrorotatory Quartz; (*b*) Laevorotatory Quartz.

three horizontal axes of twofold symmetry; these axes of symmetry coinciding with the four crystallographic axes used in locating the faces in the hexagonal system. Since no centre of symmetry and no plane of symmetry is present, the crystals can exist in two enantiomorphous forms as in *Fig.* 1, (*a*) and (*b*). The optical rotatory power of quartz is observed in plates cut perpendicularly to the principal axis, and these two types of crystals rotate the plane of polarisation of light to an equal extent but in opposite directions; twin crystals containing both forms of quartz are also found. Herschel, who discovered the relationship between the crystal form and rotatory power of quartz, reversed Biot's convention by describing as dextrorotatory a plate of quartz which turns the plane of polarisation to the right *as viewed from the polariser, i.e.* in the opposite direction to dextrorotatory camphor or sugar, which rotate the plane of polarisation to the right *as viewed from the analyser*, since in the case of organic compounds Biot's convention is always followed. Herschel's convention is still used by opticians, but in *Fig.* 1 Biot's convention is used.[1]

§ (3) Rotatory Dispersion. (i.) *Biot's Law.*—Biot's investigations revealed the existence of two types of *optical rotatory dispersion*, as indicated in the following data:[2]

	Quartz.	Tartaric Acid.
Red	18·00°	38° 7′
Yellow . . .	21·40°	40° 20′
Orange . . .	23·99°	42° 51′
Green . . .	27·86°	46° 11′
Blue. . . .	32·31°	44° 40′
Indigo . . .	36·13°	42° 9′
Violet . . .	40·88°	39° 38′

[1] *Nature*, 1922, cx. 808.
[2] *Mém. Acad. Sci.*, 1838, xv. 236.

In the case of quartz the rotations increased progressively as the wave-length diminished, and Biot concluded that "the rotation of the different simple rays is reciprocal to the square of their wave-lengths"; [1] in the case of tartaric acid the rotations passed through a maximum in the green. Turpentine and cane-sugar appeared, however, to be identical with quartz in their rotatory dispersion, since the optical rotations which they produced could be neutralised completely with the help of a quartz plate of opposite sign and suitable thickness acting as a *compensator*; this fact has been utilised in the construction of *saccharimeters*, in which the strength of a solution of sugar is determined by balancing its optical rotation with that produced by a variable thickness of quartz.

(ii.) *Drude's Theory.*—Biot's law, $\alpha=k/\lambda^2$, was proved by more exact measurements to give only an approximate representation of the variations with wave-length of the rotatory power of quartz, cane-sugar, etc., and was modified by Boltzmann, whose equation may be expressed as $\alpha=k_1/\lambda^2+k_2/\lambda^4$. This equation was purely empirical and did not provide an adequate expression of the deviations from Biot's law; Drude, in his *Theory of Optics* (1900), put forward an equation based upon the electronic theory of radiation which accounts for the observed facts in a satisfactory manner. Drude's equation for light which does not approximate in frequency to that of the electrons of the optically-active medium takes the form

$$\alpha=\frac{k_1}{(\lambda^2-\lambda_1^2)}+\frac{k_2}{(\lambda^2-\lambda_2^2)}\ \cdots\ +\frac{k_n}{(\lambda^2-\lambda_n^2)},$$

where $\lambda_1^2, \lambda_2^2, \ldots \lambda_n^2$, are the wave-lengths corresponding with the various "free-periods" of the electrons of the medium, and k_1, k_2, k_3 are constants.

§ (4) EXPERIMENTAL VERIFICATION.—The writer has shown that a single term of Drude's equation provides an adequate expression both of the optical and of the magnetic rotatory dispersion in a large range of organic compounds,[2] whilst the phenomena of anomalous rotatory dispersion as observed, for instance, in the esters of tartaric acid are covered completely by making use of two terms of opposite sign.[3] In the case of quartz, a single term of Drude's equation serves to express the rotations to about 0·040° per mm. over a considerable range of the spectrum, as shown in Table I., where $\alpha_1=k(\lambda^2-\lambda_0^2)$, $k=7{\cdot}1764$, $\lambda_0^2=0{\cdot}01677$;[4] but Drude himself used two terms in order to cover the data given by Gumlich [5] for wave-lengths ranging from 2·140 μ to 0·21935 μ. In this equation he assumed the free periods, as deduced from measurements of refractive dispersion, etc., to be given by

$$\lambda_1^2=0{\cdot}010627,\quad \lambda_2^2=78{\cdot}22,\quad \lambda_3^2=430{\cdot}6.$$

It appeared, however, that the two free periods corresponding to radiations in the infra-red did not affect the rotations in the range covered by the observations of Gumlich, so that $k_2=k_3=0$. On the other hand, Drude found it necessary to introduce a term k'/λ^2 to express the fact that the rotations appeared to be influenced by ions "whose natural periods are extremely small, much smaller than those corresponding to λ_1," so that no constant corresponding to λ_1^2 or λ_2^2 need be introduced into this term of the equation. The equation thus deduced took the form

$$\alpha_2=\frac{k_1}{(\lambda^2-\lambda_1^2)}+\frac{k'}{\lambda^2},$$

where $\lambda_1^2=0{\cdot}010627, k_1=12{\cdot}200$, and $k_2=-5{\cdot}046$.

In the series of eighteen rotations quoted from Gumlich, which ranged from 1·60° to 220·72° per mm., the equation gave a maximum deviation of 0·28°/mm., and an average deviation of 0·06°/mm. between the observed and calculated values as set out in Table I.

A series of readings to six significant figures of the rotatory power of quartz, made with the help of a column of dextro-quartz 181 mm. in length, and a column of laevo-quartz 226 mm. in length,[6] showed that the two-term formula employed by

[1] *Mém. Acad. Sci.*, 1817, ii. 49, 57, and 135; paper read Sept. 22, 1818.
[2] *Trans. Chem. Soc.*, 1913, ciii. 1067, and 1919, cxv. 300.
[3] *Ibid.*, 1915, cvii. 1187.
[4] Rupe und Akermann, *Annalen der Chemie*, 1920 ccccxx. 11; compare Lowry and Dickson, *Trans. Chem. Soc.*, 1913, ciii. 1072.
[5] *Wied. Ann.*, 1898, lxiv. 349.
[6] Lowry, *Roy. Soc. Phil. Trans.*, 1912, A, ccxii. 261-297.

Drude was far from exact even over the narrow range from Li 0·6708 to Hg 0·4358, within which visual readings can be taken. A satisfactory agreement was, however, obtained by reintroducing one of Drude's infra-red terms as in the equation

$$a_3 = \frac{k}{\lambda^2} + \frac{k_1}{\lambda^2 - \lambda_1^2} + \frac{k_2}{\lambda^2 - \lambda_2^2},$$

where $\lambda_1^2 = 0{\cdot}010627,$

$\lambda_2^2 = 78{\cdot}22,$

$k_1 = 11{\cdot}6064,$

$k_2 = 13{\cdot}42,$

$k = -4{\cdot}3685.$

This formula, in the case of twenty-two out of twenty-four wave-lengths, gave an average deviation between the observed and calculated rotations of only 0·001° per mm. or 1 part in 25,000, and this deviation has since then been reduced to one-half of its former magnitude by introducing for the wave-lengths the more exact values deduced in recent years from measurements with the interferometer; but even this formula becomes inexact when applied to the most exact measurements in the ultra-violet region of the spectrum. These measurements, made by a photographic method, with a column of laevo-quartz nearly half a metre in length, include some 700 wave-lengths, and can be expressed by the formula

$$a_4 = k + \frac{k_1}{\lambda^2 - \lambda_1^2} + \frac{k_2}{\lambda^2 - \lambda_2^2},$$

where

$\lambda_1^2 = 0{\cdot}012742, \quad \lambda_2^2 = 0{\cdot}000974,$

$k_1 = 9{\cdot}5644, \quad k_2 = -2{\cdot}3114, \quad k = -0{\cdot}1915.$

In this formula it has been necessary to introduce two "ultra-violet" terms, with dispersion-constants, λ_1^2 and λ_2^2, deduced independently of the constant 0·010627 which Drude had derived from measurements of refractive dispersion, and which is perhaps a sort of "mean" of the two constants set out above. The increased importance which is thus attached to the more distant ultra-violet absorption-band is counterbalanced by a diminution in the influence assigned to the infra-red bands; this is so slight that it is a matter of indifference whether it is expressed by a term $k/(\lambda^2 - 78{\cdot}22)$ or by a mere constant as in the equation now adopted, where the infra-red terms contribute only −0·1915° per mm. to a rotation which ranges from 16·5359° per mm. at Li 0·6707846 μ to 41·5487° at Hg 0·4358342 μ, and 187·225° at Fe 0·2327468 μ. This formula represents the rotations in this range with an average error of 0·0007° per mm. (or about 0·003 per cent in visual readings) for twenty-three wave-lengths, and 0·003° per mm. (or about the same percentage as for the visual readings) for 700 wave-lengths read by the photographic method. The problem of redetermining the rotatory power of quartz in the infra-red region has not been undertaken seriously, but the formula given above shows an average deviation of about 0·05° per mm. in comparison with the first series of new infra-red readings.

The optical rotatory power of quartz for some important wave-lengths is set out in Table II.

Radiation, Application of Quantum Theory to. See "Quantum Theory," § (4).

RADIATION, DETERMINATION OF THE CONSTANTS AND VERIFICATION OF THE LAWS

I. Introductory Discussion

§ (1) Statement of the Laws of Radiation.—The derivation of the laws of radiation from a uniformly heated enclosure or so-called black body are given elsewhere in this Dictionary.[1] It is therefore sufficient to say that the law of total radiation, generally called the Stefan-Boltzmann (2) law, states that the total emission of thermal radiation R of all wave-lengths passing from a uniformly heated enclosure at temperature T_1 to another body at a temperature T_0 is proportional to the difference of the fourth powers of their absolute temperatures, or

$$R = \sigma(T_1^4 - T_0^4). \quad . \quad . \quad . \quad (1)$$

In this formula σ is the coefficient or constant of total radiation under discussion. The numerical value of this coefficient is of the order $\sigma = 5{\cdot}7 \times 10^{-5}$ erg per cm.^{2} per sec. per deg.^{4}. In this paper only the first three significant figures will be mentioned, *e.g.* $\sigma = 5{\cdot}72$.

That the total radiation from a properly constructed and uniformly heated cavity is proportional to the fourth power of the absolute temperature is amply demonstrated within the experimental errors of observation and the accuracy of the temperature scale.

The law of spectral radiation, which specifies the distribution of thermal emission intensities in the spectrum of the radiation emitted by a uniformly heated enclosure, or so-called black body, is best represented by Planck's (3) formula

$$E_\lambda = c_1\lambda^{-5}(e^{C_2/\lambda T} - 1)^{-1}. \quad . \quad . \quad (2)$$

In this formula the constant C_2 determines, to a great extent, the slope of the isothermal spectral energy curve. Suffice it to say that these laws are based on well-grounded theoretical foundations, and after almost two decades of discussion they remain unchanged.

The object of this paper is to examine into the various instruments and methods employed in the determination of these two constants, σ and C_2, and to give an estimate of the results therewith obtained.

At first glance the various determinations of these constants appear to cover a wide range of numerical values. This is especially true of the values of the coefficient of total radiation, σ, in the measurement of which all sorts of ill-considered methods have been used. Moreover, no corrections were made for atmospheric absorption of the thermal radiation in its passage from the radiator to the receiver. As will be shown presently, most of these older determinations are in remarkably close agreement with the newer ones, when obvious corrections for atmospheric absorption and for reflection of the incident radiation from the receiver are introduced.

While no doubt it is desirable to conform to strict specifications and methods of procedure, in the ultimate result compromises have to be made. For example, it is conceded to be desirable to use a black body receiver as well as radiator, but most of the receivers of this type, thus far used, were usually of great heat capacity, hence slow acting and subject to errors; whereas the question of speed is an important factor in making measurements. Each method has some defect, but in some cases this is negligible in comparison with the accidental errors of experimentation.

The evaluation of radiant energy in absolute measure is accomplished by substitution methods; and the fault to be found with the various methods thus far employed is that they are unsymmetrical in their application. What is needed is some sort of quick-acting calorimeter in which the energy recovered can be compared with the energy supplied. But one can hardly expect to make accurate measurements on a radiator heated to say 1000° C. with an instrument that is adapted to measure the solar constant.

It may be noted that in many of the experiments which will now be described the radiators were operated at temperatures which were too low to eliminate properly the correction for temperature (radiation) of the shutters, diaphragms, etc., and also for the losses by air conduction in the receiver. On the other hand, some experimentors used radiators operated at a high temperature,

[1] See "Quantum Theory," § (4); "Radiation Theory," § (6); "Pyrometry, Optical," § (1), Vol. I.

thus obviating these difficulties; but then the receiver was a sluggishly acting instrument which could not be properly calibrated. To Féry is due the credit for abandoning the idea of using a radiator heated to 100° C., and adopting a radiator heated to 1000° C. or higher. In this manner the radiation to be measured is far in excess of the small disturbing factors, such as radiation from shutters, diaphragms, etc.

§ (2) Discussion of Black Body Radiation and Radiators.—In order to arrive at an intelligent understanding of what has been accomplished in the determination of the constants of radiation, and in order to indicate the way to future progress in this subject, it is important to consider some of the conceptions, as well as some of the most recent instruments and methods used in the production and measurement of the radiation emanating from a uniformly heated enclosure or so-called black body.

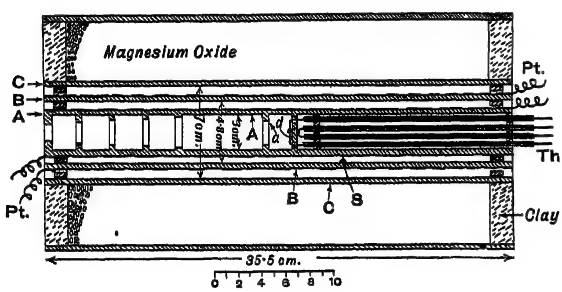

Fig. 1.

Every substance has a characteristic emission spectrum. On the other hand, the emission spectrum of a uniformly heated cavity is independent of the composition of the material forming the walls of the enclosure. It is a function only of the temperature.

The emission of thermal radiation from, and the absorption of thermal radiant energy of all wave-lengths entering into the cavity is complete. In a material substance this can occur only on the short wave-length side of a band of anomalous dispersion where the absorptivity is high but where the refractive index and hence the reflecting power is practically *nil*—for example in quartz (14), selenite and aluminium oxide, in the region of 7 μ to 10 μ (μ=0·001 mm.).

Modern conceptions of black body radiation are the result of slow development from such simple experiments as those of Draper[1] (4), who found that the interior of rifle barrel became luminous at a certain temperature; of Christiansen (6), who observed that the scratches and conical-shaped holes in an incandescent metal surface were brighter than the smooth surface; and of St. John (7), who found that the selective emission commonly observed in the rare oxides disappeared when these substances were heated to incandescence in a uniformly heated porcelain tube.

(i.) *Radiators.* — The modern uniformly heated cavity or so-called black body is the outcome of such observations and facts as those just mentioned. It is the invention of Wien and Lummer (8), and, for attaining high temperatures, it consists of a diaphragmed porcelain tube wound with a platinum ribbon which is electrically heated. In the modification used by Coblentz (15) this radiator consisted of three concentric porcelain tubes A, B, and C (*Fig.* 1). The inner tube A, of Marquardt porcelain, is wound uniformly with a platinum ribbon 0·02 mm. in thickness. This ribbon is 20 mm. wide in the centre, gently tapering to 10 mm. wide at the ends in order to provide extra heating at the ends so as to compensate for heat losses by radiation. The middle tube B is wound with a ribbon of platinum 10 mm. wide and 0·02 mm. in thickness. The ends are closely wound in order to provide extra heating and, in this manner, to compensate for the cooling of the ends by radiation. By properly regulating the current through these platinum strips the cavity can be heated uniformly throughout the greater part of its interior, as shown by Waidner and Burgess (16). The use of platinum ribbon instead of thick platinum wires eliminates local non-uniformity of temperature. The central 25 mm. length of the tube A was wound so that one turn of the platinum ribbon entirely covered what comprises the theoretical black body.

In radiators of this type the porcelain tubes sag on heating to 1200° C. To overcome this difficulty, in the determination of the radiation constants, to be described presently, Coblentz (15) placed a wedge-shaped fragment of porcelain with a sharp edge S (*Fig.* 1), about 2 mm. long, about 25 to 30 mm. to the rear of the radiating diaphragm. This support causes no local cooling and it preserves the life of the radiator. Further improvements are made in completeness of the emission of the radiation by painting the walls and the front side of the radiating diaphragm with a mixture of chromium oxide and cobalt oxide. Since these oxides become electrically conducting at 1200°, the front thermocouple, Th, was completely enclosed in a porcelain insulating tube, as shown in *Fig.* 2, B. The short piece of

[1] The number (4) and other similar numbers refer to the Bibliography at the end of the article.

porcelain which lies across the radiating wall of the black body was covered with cobalt oxide. Since the cobalt oxide did not adhere well to the porcelain tube, the latter was first covered with a thin layer of iron oxide, obtained by wetting the porcelain tube with writing ink which was burned into the tube. The cobalt oxide paint was then applied and also burned upon the tube by means of a blast lamp. After replacing the thermo-

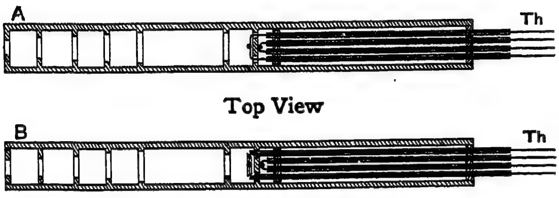

FIG. 2.

couple, enclosed in this short tube within the radiator, the whole interior was again painted with a mixture of cobalt and chromium oxides. In order to be able to insert the thermocouple including the short tube, and also to paint the interior of the radiator, the first diaphragm (which in the commercial porcelain tube has an opening of only 1 cm.) was removed (*Fig.* 2, B), and after making all the adjustments another porcelain diaphragm was put in its place.

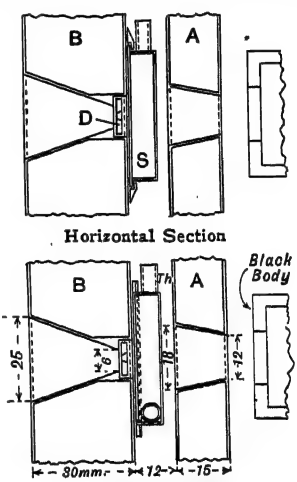
The cobalt oxide has a high temperature coefficient of absorption, so that it appears black on slight heating. Its emission spectrum (14) (*loc. cit.* p. 120) is continuous, so that there is less difficulty in producing a perfect radiator than when the radiating enclosure is of white porcelain (17, 18). However, porcelains having a low melting-point when heated above 1000° emit a far more continuous spectrum than the "Marquardt porcelain" from which are made the black bodies ordinarily used.

All these tubes, especially the painted ones, become electrically conducting when heated above 1300° C. Hence, at the highest temperatures the radiator should be heated by alternating current from a motor generator which is operated from a storage battery. By this means there is no more difficulty in maintaining a constant current than when heating the radiator directly by means of current from a storage battery. By means of a low-resistance rheostat at the observing table, the current can be regulated so that the temperature of the radiator can be kept to a few hundredths of a degree.

(ii.) *Water-cooled Shutters and Diaphragms.*—In discussing the relative merits of the various determinations of the radiation constants, and in particular the coefficient of total radiation, the writer will have occasion to refer frequently to the use, or misuse, of shields for preventing the receiver from being heated by the radiator, and of shutters for exposing the receiver to radiation. It is therefore important to consider briefly the functions of this apparatus.

The determination of the coefficient of total radiation usually consists in noting the heat interchange when the receiver is exposed to two radiators which are at widely differing temperatures, say 0° C. and 100° C., *i.e.* ice and boiling water. The radiator at the lower temperature may be and usually is used as a shutter. If the temperature of the shutter is lower than that of the receiver the latter radiates to the shutter. Hence it is important to have the receiver face a large (say water-cooled) diaphragm, maintained at a constant temperature, at the back of which is placed the shutter and the radiator. In this manner the surrounding conditions, facing the receiver, are not changed when the shutter is moved in order to expose the receiver to radiation.

There is no doubt that some of the unusual results obtained in the determination of the



Vertical Section

FIG. 3.

radiation constants are owing to the fact that the receiver did not face uniform conditions when the shutter was opened and closed in making the measurements.

Experience shows that the arrangement of the shutter should be similar to that illustrated in *Fig.* 3, which particular design of apparatus was used by Coblentz in the determination of the coefficient of total radiation described on a subsequent page.

The water-cooled shield employed consisted of a tank A, 25 cm. in diameter and 1·5 cm. in thickness, the radiator, and a tank B which faced the radiometer. The water-cooled shutter S (*Figs.* 3 and 6), consisting of a thin metal box 3·5 by 3·5 by 0·8 cm., was operated in vertical ways between these two shields. A mercurial thermometer was inserted at Th. Its bulb was in the water flowing through this shutter and was used to measure the temperature T used in equation (1). A more detailed illustration of a similar shutter is given elsewhere (15), and some of the parts are shown in *Fig.* 3. The side of the shutter facing the radiometer was smoked in a sperm candle, and in connection with the conical-shaped opening (painted black and smoked) in the water-cooled diaphragm B it formed a miniature black body the temperature of which remained constant throughout a series of measurements. The temperature of the shutter was easily kept constant to within 0·5° C. The opening in the diaphragm B, which must be accurately known, was defined by means of a series of small perforated discs of brass 8 mm. in diameter and 1·5 mm. in thickness, which were mounted in a recess provided for the purpose. These brass discs were provided with accurately cut, knife-edged holes which varied from 2 to 5·5 mm. in diameter. In this manner one could easily change the size of the opening which admits radiation upon the receiver and thus study the effect upon the radiation constant.

II. The Coefficient of Total Radiation

It has been shown by Stefan (1), Schneebeli (10), Wilson (11), Lummer and Pringsheim (9), Valentiner (12), and others (20), that the total radiation emitted from a uniformly heated cavity is proportional to the fourth power [1] of the absolute temperature. The measurements extend over a temperature range of about 1500° C. They verify the fourth power law within the accuracy of the temperature scale and the general errors of observation; these are small owing to the fact that the measurements are relative.

The evaluation of the coefficient of thermal radiation in absolute measure is an extremely difficult task which has been attempted by numerous experimenters whose data will now be considered.

The early determinations of the coefficient of emission of a substance (*e.g.* blackened plates, balls of glass or copper) by Lehnebach (19), Christiansen (21), and others are of great historical interest, but they cannot be considered in connection with present-day determinations of the coefficient of total radiation of a uniformly heated enclosure.

[1] See "Pyrometry, Total Radiation," Vol. I.

§ (3) Bolometric Methods of Electric Compensation. (i.) *Observations of Kurlbaum* (22).—The first determination of the constant of total radiation in absolute value, by a method which is free from the gross experimental errors that are inherent in the work, was made by Kurlbaum.

The principle of the method is as follows: Three branches of a Wheatstone bridge (bolometer) consist of thick manganin wires, which are not affected by a change in current through the bridge. The fourth branch consists of thin strips of platinum, the resistance of which is affected by a change in current in the bridge.

Starting with the bridge balanced, the bolometer branch of thin platinum, at a distance of 18 to 20 cm., was exposed to the radiation from a black body at 100° C., and the change in resistance (or galvanometer deflection) was noted. With the bolometer branch shielded from radiation, the bridge current was varied until the change in resistance in the bolometer branch was equal to that attained when exposed to radiation. In other words, the bridge current was increased by a sufficient amount to produce the same galvanometer deflection as was caused by radiation falling on the bolometer strip. From a knowledge of the change in the bridge current, the bolometer resistance, etc., Kurlbaum was able to compute the energy input. He used two very different surface bolometers and found very concordant values. He found a value of $\sigma = 5{\cdot}32$. In a subsequent communication (23) he made a correction of 2·5 per cent for loss by reflection from the platinum black surfaces of the bolometer. This gives a value of $\sigma = 5{\cdot}45$. Coblentz (24) determined the reflecting power of platinum black, and found that, using the blackest obtainable deposits, the reflecting power is almost 2 per cent for wave-lengths at 8 to 9 μ. An examination of six surface bolometers (12 branches or 24 surfaces of about 3 by 4 cm. area), purchased abroad, showed that all of them had microscopically small bright patches of bare platinum. These bright areas would increase the loss by reflection. From this it appears that Kurlbaum's correction to his work is none too large.

(ii.) *Observations of Valentiner* (12).—The method of measuring the coefficient of total radiation by means of a large surface bolometer was continued by Valentiner, who found quite different values, depending upon the blackness (kind) of radiators employed, which were heated as high as 1450° C. For the two blackest radiators (the steam-heated radiator "W.S.K." and the electrically heated unblackened porcelain tube radiator "G.S.K.") he found a value of $\sigma = 5{\cdot}36$.

In a subsequent paper (25) he made a correc-

tion of about 4 per cent for various causes (*e.g.* 1 per cent for lack of blackness of the radiator, 2·5 per cent for reflection from the bolometer, etc.) giving a value of $\sigma=5{\cdot}58$. No correction was made for atmospheric absorption.

The numerical values of the various determinations made by Valentiner, upon any one radiator, vary by about 3 per cent, which is greater than the effect of atmospheric absorption in a space of 30 to 50 cm. However, when using a larger porcelain tube radiator (12), "G.S.K.," the distances were longer than usual (being respectively 89 and 125 cm.) and the effect of absorption seems unmistakable. The value of the radiation constant is about 2 per cent smaller for the greater distance, *i.e.* an increase of 35 cm. in optical path introduced an absorption of about 2 per cent.

A conservative estimate of the correction to Valentiner's data for absorption by atmospheric water vapour and carbon dioxide is 2 to 3 per cent. This increases Valentiner's value to $\sigma=5{\cdot}68$ with a possibility of the value being as high as $\sigma=5{\cdot}75$, which is in remarkably close agreement with the various determinations made by other methods. That a correction of not less than 1 per cent is to be applied to these data is indicated in Gerlach's (33) recent work on atmospheric absorption of black body radiation.

The surface bolometers used by Kurlbaum and by Valentiner consisted of two grids of thin platinum foil, placed one back of the other, with the edges overlapping. In this manner a continuous surface is formed, but part of the rear bolometer strips are shielded from the radiation incident on the front strips. The operation of the receiver is unsymmetrical. Gerlach (28) has discussed the effect of this overlapping, and has shown that in some cases it might lower the value of the observed radiation constant by a very considerable amount. Coblentz (27) has found that using one bolometer strip back of the other, 50 per cent of the energy, incident upon the first receiver, is re-radiated to the rear one. In the reverse process, of heating the strip electrically, this effect would enter symmetrically and a low value would result.

It was found by Kurlbaum and by Valentiner that the rate of temperature rise was different when heating the bolometer by absorption of radiation and by electrical heating. The low values of the radiation constant obtained by Valentiner are explained (28) in part as the result of reading the galvanometer deflection before temperature equilibrium was fully attained.

Callendar (30) has described surface bolometers which would overcome some of the defects of conduction, etc. However, using radiators at 600° to 1000° C., there is no need to employ such large receivers with the unavoidable defects just noted.

(iii.) *Observations of Gerlach* (31).—The following method is not exactly bolometric in principle, but it may be considered at this point since its virtues have been under discussion in connection with the results obtained by the bolometric methods just mentioned. Gerlach determined the constant of total radiation, σ, by a modification of Ångström's electric compensation pyrheliometer.[1] In the original pyrheliometer of Ångström (32) the receivers are two thin narrow sheets of manganin to each of which is attached one junction of a thermo-element which is joined through a galvanometer. One of these manganin strips is exposed to solar radiation. Through the other manganin strip is passed an electric current of such strength that it is heated to the same temperature as is the receiver which is exposed to solar radiation. The equality of temperature is indicated when there is no current flowing through the galvanometer.

In the instrument as used by Gerlach (31) the receiver consists of but one strip of manganin. At the back of this manganin strip and close to it is a thermopile of 45 elements (joined through a galvanometer) which is heated by radiation from the strip, thus differing from Ångström's device, in which a single thermo-junction is heated by conduction from the manganin strip. The object of using many thermo-junctions is to integrate the radiation from the whole strip, thus eliminating any irregular heating caused by inequalities in the thickness of the receiver, which was blackened electrolytically with platinum black. The manganin strip is heated electrically to the same temperature as that attained by the strip when exposed to the radiation from a black body, which was heated by steam. From a knowledge of the resistance of the strip and the electric current the energy input, and hence the value of the radiation constant, is determined.

Gerlach experienced some difficulty in determining when he had exact compensation when heating the receiver electrically and radiometrically. Covering the sides of the receiver with knife-edged slits had no effect upon the radiation constant; but shielding the ends of the manganin strip from radiation caused the value to increase from $\sigma=5{\cdot}83$ for the unshielded ends to a constant value of $\sigma=6{\cdot}14$, when the shields covered 1·5 mm. or more of the ends of the strips. This is caused by heat conduction from the receiver to the heavy copper electrodes. In practice he exposed the whole length of the receiver to radiation, claiming that the heat conducted from the ends is the

[1] For an account of this and some others of the instruments referred to see Vol. III., "Radiant Heat, Instruments for Measurement of."

same when the metal strip is heated radiometrically and electrically. This appears to be the weak point in the device. In the instrument used by Coblentz (20, 29) this difficulty was eliminated by placing the potential terminals on the receiver, and at some distance from the heavy electrodes. This seems to be the logical way to use such a receiver.

The work of Gerlach aroused considerable discussion among experimenters previously engaged on this same problem. This brought forth a very considerable amount of laborious experimental work by Gerlach (35), in which he showed that his apparatus gave the same values when operated by Kurlbaum's (22) bolometric method as when operated by his method.

In subsequent investigations Gerlach determined the effect of atmospheric absorption (33) and of blackening the receivers (36) upon the radiation constant. He operated the radiator at higher temperatures (to 450° C.), but the radiometric apparatus remained the same as in the earlier work. With this outfit his new value (37) of the coefficient of radiation, uncorrected for reflection of radiation from the receiver and for atmospheric absorption, is decidedly lower than that which he had previously obtained under similar conditions, being of the order $\sigma = 5{\cdot}6$ to $5{\cdot}7$. Applying a correction of about 1·7 per cent for reflection of platinum black as observed by Coblentz (24) and depending upon the temperature of the radiator, a correction of 0·2 to 1·2 per cent for absorption of CO_2, the mean value of 52 independent sets of measurements is $\sigma = 5{\cdot}85$. In a recent discussion of his data Gerlach (102) places his value at $\sigma = 5{\cdot}80$.

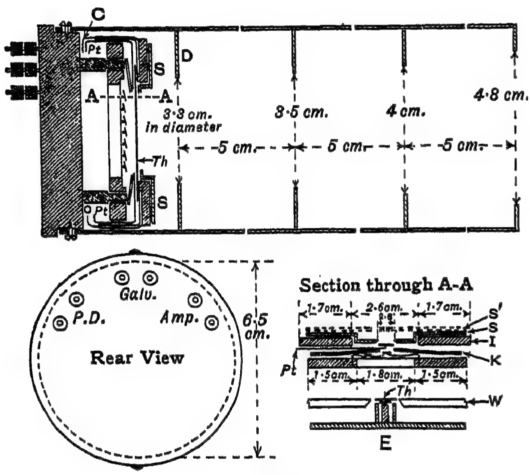


FIG. 4.

Gerlach's determination is one of several, which should be a convincing demonstration that the extreme values of $\sigma = 5{\cdot}3$ to $6{\cdot}5$ are subject to correction, in so far as the corrections can be determined.

(iv.) *Observations of Coblentz* (20, 29, 39).—This research was undertaken after a study of the instruments and methods used in the earlier determinations, and an effort was made to embody the good features and eliminate the defective ones previously employed. It is therefore proper to discuss the work in considerable detail.

In designing the apparatus an attempt was made to embody black body conditions in the radiator, *Fig.* 1 (including the shutter, *Fig.* 3), and the receiver.

The lack of blackness of the radiator has been discussed by Wien and Lummer (8), who give a method for computing the correction for the opening in the radiator, on the assumption that the enclosure is spherical and diffusely reflecting. The amount of energy that can escape by diffuse reflection through the opening is determined practically by the size of the opening as compared with the total area of the interior of the radiator. In the porcelain tube radiator used here the interior is uniformly heated over a length of 8 to 10 cm. However, for the purpose of the present computation, a length of only 2·5 cm., which is defined by the first diaphragm, is considered. The area of the enclosure is 37·6 cm.^{2} and that of the opening is 3·1 cm.^{2}. On the basis that the reflecting power of the interior of the painted radiator is 7 per cent (*loc. cit.* (20), p. 523, Table 3) the loss of energy by diffuse reflection through the inner diaphragm is 0·63 per cent. Using an unpainted Marquardt porcelain radiator the coefficient of total radiation is decreased by about 1 per cent (*loc. cit.* (29) p. 571), showing that the question of lack of blackness of the radiator is important.

For a receiver (40) it was decided to use a modified Ångström pyrheliometer (32) embodying novel features which had not yet been tried by others. In order to reduce the heat capacity of the manganin receiver Th, *Fig.* 4, and provide better insulation, the thermopile of bismuth and silver, having a continuous receiving surface, was placed a short distance back of the receiver as shown in E, *Fig.* 4. The apparatus used by Gerlach embodied this same idea.

The crucial and novel part of the apparatus was a receiver R, *Fig.* 5, with potential ter-

minals PP attached thereto, at a sufficient distance from the ends to avoid the question of heat conduction to the electrodes. These potential wires, which were from 0·003 to 0·025 mm. in diameter, accurately defined the length of the central part of the receiver which was utilised in the measurements. By

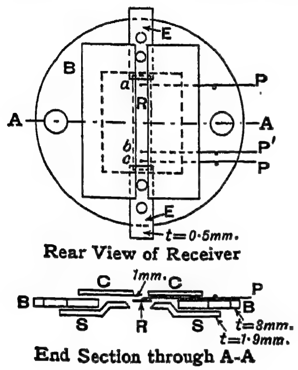

Fig. 5.

exposing the whole length of the receiver to radiation, conduction losses from its end do not enter the problem.

The effect of the presence of the potential terminals was determined (20) (by using a third terminal P′) and found negligible, viz. 0·3 per cent. The method of finding the difference of potential between two terminals attached to the receiver seems more certain than to find the difference of potential between two heavy electrodes as used by Gerlach (31).

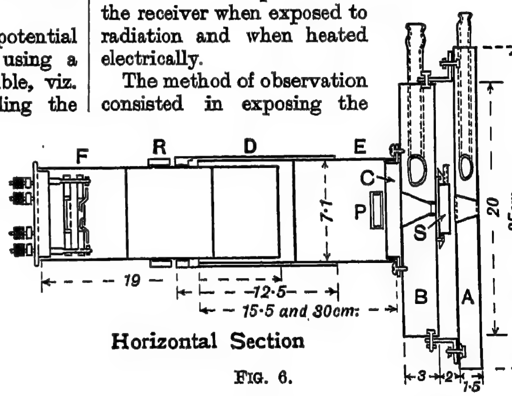
The operation of this type of radiometer, with a hemispherical mirror placed in front of the receiver (20, 24, 38), may introduce errors when the receiver is heated by electrical means. Hence, after conferring with specialists in geometrical optics who were in agreement with the writer's opinion that a reflecting enclosure is likely to introduce errors, the receiver was used without the hemispherical mirror. Subsequently this mirror was employed in a separate experiment to determine the diffuse reflection (24) from lampblack and platinum black, and finally in determining the loss by reflection from some of the receivers actually used in the observations. Hence, the loss of radiation incident upon the receivers was probably accounted for as accurately as it would have been by employing a "blackening" device in front of the receiver.

In order to test the question of the accuracy of the corrections used for eliminating the loss by reflection, a series of observations was made on one receiver. In this test the slits in front of the receiver, and all other conditions remained unchanged. The only variation was in smoking the platinum black receiver with a sperm candle after making the first set of observations. The reflecting power of platinum black is taken to be 1·7 per cent (39) and that of lamp-black 1·2 per cent. The respective determinations, after correcting for energy lost by reflection, were $\sigma = 5{\cdot}822$ and $\sigma = 5{\cdot}814$. They differ by only about 0·1 per cent, which is very satisfactory, and shows that the reflection factors were well determined.

The assembled apparatus is shown in *Fig.* 6, in which A and B are the water-cooled diaphragms, S the shutter (see *Fig.* 3), F the radiometer, and D the telescoping diaphragmed tubes enclosing the optical path from which the moisture was removed by means of phosphorus pentoxide P. Subsequent tests showed that in this outfit the effect of atmospheric absorption was less than 0·1 per cent (20), which conclusion is substantiated by recent measurements made by Gerlach (33).

The thermopile was connected with an unusually well shielded iron-clad Thomson galvanometer of special design (38, 41), which served merely as a null instrument to indicate the rise in temperature of the receiver when exposed to radiation and when heated electrically.

The method of observation consisted in exposing the receiver to radiation and noting the galvanometer deflection; then in heating the strip electrically to give, within 1 per cent, the same deflection. The measurements of the electric power put into the strip were made with the same potentiometer used in measuring the temperature of the radiator. No difficulty was experienced in determining temperature equilibrium on heating the receiver by radiation and by electrical means.



Horizontal Section

Fig. 6.

The exact amount of energy necessary to cause the same deflection as that produced by absorbing radiant energy is obtained by multiplying the observed energy input by the ratio of the galvanometer deflections. This gives the "constant" of each receiver. In order to reduce all the measurements to a common

basis, and at the same time obtain a value of the coefficient, or the so-called Stefan-Bolzmann constant, of total radiation, the custom of previous experimenters was followed in reducing the data. For this purpose it is necessary to know the area A_1 of the water-cooled diaphragm, the area A_2 of the receiver which is exposed to the radiation emanating from A_1, the distance D between these two surfaces, the absolute temperature T_1 of the shutter, and the absolute temperature T_2 of the radiator. The electrical energy input necessary to produce the same (galvanometer deflection) rise in temperature as was produced by exposing the receiver to the radiator is EI, both of which quantities are measured with the potentiometer as already described. Under these conditions the energy consumed by the electrical stimulus may be equated to the energy emanating from the radiator, or

$$EI=\frac{\sigma}{\pi}(T_2^4-T_1^4)\frac{A_1A_2}{D_2}, \quad . \quad . \quad (3)$$

where σ is the coefficient of total radiation, E is the voltage, and I is the current.

Usually the distance between the two surfaces A_1 and A_2 is so close that experimenters have had to apply a second term correction (42). In Gerlach's (31) work the correction applied was

$$\frac{A_1A_2}{D^2}\left(1-\frac{1}{6}\frac{a^2+b^2+a_1^2+b_1^2}{D^2}\right), \quad . \quad . \quad (4)$$

where the sides of the openings in the rectangular diaphragms were a, b, a_1, b_1. A shorter correction factor is

$$\frac{A_1A_2}{D^2}\left(1-\frac{1}{4}\frac{a^2+b^2}{D^2}\right), \quad . \quad . \quad . \quad (5)$$

which results from neglecting the effect of the first diaphragm, which was very small in this work. In either case this second term correction is quite negligible in the present investigation, since it usually amounts to less than 2 parts in 1000.

The radiator was operated at a temperature of 800° to 1100° C., within which range the temperature scale is quite well determined.

To the data obtained with 10 receivers, a correction of 1·2 per cent, for losses by reflection, was applied to measurements made with receivers covered with lamp-black (soot) and a correction of 1·7 per cent to measurements made with receivers covered with platinum black. The reflection from a receiver covered with platinum black, then smoked, is 1·2 per cent. As just mentioned, these corrections were determined by direct measurements upon some of the receivers used in this investigation and by comparison of the surfaces of the other receivers with samples of lamp-black whose reflection losses had been determined in a previous investigation (24).

The value obtained for the coefficient of total radiation, after applying the corrections just mentioned, is

$$\sigma=(5{\cdot}722\pm0{\cdot}012)\times10^{-12}\text{ watt cm.}^{-2}\text{ deg.}^{-4}.$$

No correction was made for absorption by atmospheric carbon dioxide, which was found to be less than 0·1 per cent. According to Gerlach's (33) measurements this might perhaps amount to 0·1 or 0·2 per cent, thus increasing the value to $\sigma=5{\cdot}73$.

The method of operation is unsymmetrical in that, when the receiver is exposed to radiation, the heating is produced in the lamp-black surface, while in passing an electric current through the strip the heat is generated within the receiver. However, from the data obtained with receivers differing 10 times in thickness, and covered with different kinds and thicknesses of absorbing material, it appears that the manner of heating the receiver has but little effect upon the final result.

For any one receiver, operated under different conditions, the precision attained is usually much better than 1 per cent. For the different receivers the maximum range in the value of σ is of the order of 1·5 to 2 per cent. This seems to be independent of the length and width of the receiver, and of the kind of slits used. The accuracy attained with this method of evaluating energy in absolute measure, as estimated by the departure of individual determinations from the mean value, appears to be of the order of 1 per cent. To this extent one can consider the present device a primary instrument for evaluating radiant energy in absolute measure.

(v) *Observations of Kahanowicz* (44).—The apparatus used by Kahanowicz is essentially a modification of the Ångström pyrheliometer (32).

The receiver was placed at the centre of a spherical mirror with an opening in one side to admit radiation. In this manner the correction for reflection was eliminated. The shutter was close to the receiver. If its temperature was different from that of the water-cooled diaphragm, which was before the radiator, errors in the radiation measurements would occur. As mentioned elsewhere in this paper, the shutter should be placed between the water-cooled diaphragm and the radiator, to avoid a change in the surroundings facing the receiver when the shutter is raised for making the radiation measurements.

The temperature range was from 260° to 530° C. The distance from the radiator to the receiver was 35 to 55 cm. A series of 28 measurements gave an average value of $\sigma=5{\cdot}61$. Of this number 11 gave a value of $\sigma=5{\cdot}7$. Out of a series of 4 measurements made in December 1916 (lower humidity), with the distance $\sigma=56$ cm., 3 gave a value of $\sigma=5{\cdot}7$.

A recent determination, using temperatures ranging from 256° to 1076° C., gave a value of $\sigma=5\cdot61$.

No corrections were made for atmospheric absorption, which for the temperatures used is not negligible. In a previous paper (*loc. cit.* (20), p. 576) it was shown that on removing the moisture (vapour pressure of 10 to 12 mm.) from a column of air 52 cm. in length, the radiation constant was increased from $\sigma=5\cdot41$ to $5\cdot55$, or about 2·6 per cent. The vapour pressure at Naples is considerably higher than at Washington. From these (39), as well as Gerlach's (33) data, it appears that the corrections for atmospheric absorption should be at least 1 per cent. For the temperatures at which the radiator was operated, a conservative estimate of the correction to the radiation data obtained by Kahanowicz is 1·5 to 2 per cent, resulting in a value of $\sigma=5\cdot69$ to 5·72. In other words, the Naples value of the coefficient of total radiation is comparable with other recent determinations which indicate a value of $\sigma=5\cdot7$.

(vi.) *Observations of Puccianti* (43).—The method of operation is just the opposite of that usually employed, and in view of the small radiant energy exchanges involved in comparison with the transfer of energy by heat conduction and by convection, this may perhaps be the weak point in this method.

Puccianti constructed a bolometer in the form of a black body, which is kept at room temperature. This black body is really the radiator. The other black body (which is really the receiver), instead of being at a higher temperature, as usually is the case, is at the temperature of carbon dioxide, snow, or of liquid air. He measured the electric power which had to be supplied to the first black body to keep the temperature constant in order to compensate for the energy lost by radiation to the second black body. He very ingeniously constructed two black-body bolometer branches exactly alike, the one to be exposed to the cold receiver and the other to be protected from it. Each of these bolometer branches consisted of a vessel of 0·1 mm. sheet copper having the form of a cone and a frustum of a cone united at the bases as shown in B_1 and B_2, *Fig.* 7. The lengths were 12 cm.; the maximum internal diameter was 4 cm. The internal surface was smoked. The external surface was polished, and upon it was wound two thin insulated wires. One of these wires, of iron, formed the bolometric branch, and the other wire, of manganin, was used as a heating resistance. The other two branches of the bolometer bridge were formed of resistance coils and the whole was connected with a galvanometer and storage battery as in any ordinary bolometer. The two sensitive black-body branches of the bolometer were in an evacuated vessel C_1 which was kept in a tank of water.

The receiver was a blackened glass bulb N_1 immersed in liquid air, and the bolometer was allowed to radiate to this receiver. The constant K of the instrument was determined from the diameters of the diaphragms D_1 and D_2. A correction was made for the energy interchange between these two openings (42).

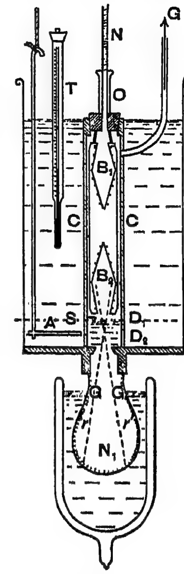


FIG. 7.

Puccianti assumed that the shutter and the bolometer branch B_2 were at the temperature T of the water bath. The resistance R of the manganin heating coil surrounding the bolometer branch B_2 was determined. In the course of the test Puccianti measured the voltage E, which was necessary for compensation to prevent the bridge from being unbalanced when the branch B_2 was exposed to the receiver N_1 at the temperature T_0. He obtained a value of $\sigma=5\cdot96$.

The method is an ingenious variation from the usual procedure. The apparatus should have been constructed so that both bolometer branches could have been used as radiators. From the illustrations it appears that radiation from one branch could fall upon the other, which would introduce errors. Another uncertainty is the temperature and the manner of operation of the shutter. Tests might have been made to determine whether the bolometer remained balanced when a heating current was applied to both branches, without allowing one branch to radiate to the receiver. Furthermore, to repeat the herein oft-mentioned device, a heating coil should have been inserted temporarily within the radiator to determine the energy input as compared with the energy input required in the outer heating coils in order to maintain a balance. The device, as used, is unsymmetrical in that the heating coil is not in the proper place to operate most efficiently. From this it appears that the constant should be smaller than that indicated by his measurements.

§ (4) THERMOMETRIC METHODS WITH "BLACK" RECEIVERS. (i.) *Observations of Féry* (45).—In order to eliminate the question of reflection from the surface Féry (45) made

a series of determinations of the radiant constant σ, by means of a thermojunction, formed into a long conical-shaped metal receiver which was blackened on the inside. On the outside of the cone, and insulated from it, was wound a heating coil of known resistance for calibrating the receiver. This was done by noting the temperature rise (galvanometer deflections) with the energy input, in watts. The receiver was then exposed to an electric furnace which was heated to various temperatures from 500° to 1200° C., and the corresponding galvanometer deflections were observed. He obtained a value of $\sigma=6{\cdot}30$.

(ii.) *Observations of Féry and Drecq* (46).—The work was undertaken anew by Féry and Drecq (46), the receiver being a cone of brass, having an aperture of 30°, placed within a large sphere of brass which was surmounted by a glass tube with a capillary 1 mm. in diameter. The large brass sphere was filled with alcohol, the whole forming a thermometer in which 1 mm. rise in height of the column in the capillary indicated a rise in temperature of 0·005°. Surrounding the outside of the brass case was a coil of wire through which an electric current was passed and the energy input noted which caused the same temperature as that produced by exposing the opening of the cone to the radiator. They found a mean value of $\sigma=6{\cdot}51$, which is the highest value yet obtained. The relative values obtained with the instrument show a fair constancy over the whole temperature range, which extended to the melting-point of gold. However, the same is true of Valentiner's values determined by the bolometric method. It indicates that there is some constant factor which is not eliminated and which causes a high or low value.

Various suggestions have been made as to the cause of their excessively large values. It appears that part of the difficulty lies in the unsymmetrical way in which the instrument is operated. It is calibrated by a heating coil which is in connection with the alcohol (or air, in the first case) and can warm the latter by conduction and by absorption of radiant energy. On the other hand, the incoming radiation must be transformed by absorption in the cone and then reaches the alcohol principally by conduction. As a result of this type of calibration, the apparent value of the radiation constant is higher than the true value. The weak point lies in not having the heating coil within the receiver, which should be so constructed that but little, if any, of the entering radiation, or the energy radiated from the heating coil, can escape through the opening in the receiver. This might easily have been done by forming the receiver into a double-coned receiver, such as was used by Puccianti. However, even with all these precautions, this type of receiver does not appear satisfactory.

Another determination of this constant was made by Féry and Drecq (47) in which the radiations from an electric furnace fell upon a strip of platinum (area 36 by 55 mm. and 0·03 mm. in thickness), blackened electrolytically with platinum black. The radiation measurements were made by sighting upon the front and the rear surfaces of the platinum strip by means of a Féry pyrometer, the angle of incidence being 48°. Their new value of the radiation constant was $\sigma=6{\cdot}2$. The measurements upon the posterior surface resulted in a value of $\sigma=5{\cdot}57$, which is said to correspond with the measurements on the anterior surface made with plane receivers. If we correct the latter value by (the round number) 2 per cent for reflection (24), we obtain the value $\sigma=5{\cdot}68$, which is of the same magnitude as observed by the writer. This new determination of σ by Féry and Drecq appears to have been made defective by their reduction of the original observations; for example, they claim that the coefficient of absorption of the receiver was only 0·82 to 0·84, which seems impossible from numerous and diverse experiments on the diffuse reflecting power of platinum black made by others. Attention has been called to this fact by Bauer (48), who placed their value of σ between 5·1 and 5·8, and, by making a correction of 2 per cent for reflection, deduced a value of $\sigma=5{\cdot}68$.

In all of the foregoing methods the data are meagre as to elimination of the various errors which may occur. For example, a source of error may arise in determining the power put into the platinum strip used in the last method. Another important source of error lies in the manner of operation of the water-cooled shutter, which should be placed between the water-cooled diaphragm and the radiator.

(iii.) *Observations of Bauer and Moulin* (49).—In order to obviate the difficulties encountered by Féry and Drecq (47) in calibrating their conical-shaped receivers, Bauer and Moulin calibrated their receiver (which was a Féry pyrometer) by sighting it upon a strip of platinum, heated to different temperatures by an electric current. In order to determine the amount of radiant energy falling upon the receiver it was necessary to eliminate the losses from the strip by conduction and convection. For this purpose the platinum strip was heated in air and in a vacuum, the power consumed being determined for a definite length of platinum, defined by potential terminals welded to the strip. Having calibrated the pyrometer by noting the galvanometer deflections for the various amounts of energy (in watts) put into the platinum strip, they sighted the pyrometer upon a black body heated to various temperatures and noted the

galvanometer deflections. Their first announced value was $\sigma=6\cdot0$. However, as in numerous other cases herein cited, errors were introduced in the final reduction of their data. They had observed the radiation emitted from the platinum strip at an angle of 13° from the normal and applied a correction (50) of about 12 per cent, which reduced their value to $\sigma=5\cdot3$. This correction is recognised to be much too large (48), so that their value of the radiation constant lies between $\sigma=5\cdot3$ and $6\cdot0$. They made no correction for atmospheric absorption, which would increase their value from $\sigma=5\cdot3$ to $\sigma=5\cdot6$ or $5\cdot7$. In an earlier communication on the solar constant, Bauer and Moulin (*loc. cit.* (50), p. 1658), using an Ångström pyrheliometer, found the value $\sigma=5\cdot7$.

(iv.) *Observations of Puccianti* (51).—In a continuation of his investigations, Puccianti gives a determination in absolute measure of the radiation of a black body in which the temperature change is measured by means of a toluene thermometer, the bulb of which is formed into a hollow cone that is allowed to radiate to a black-body receiver, which is at the temperature of liquid air. The measurement is made by compensating the heat lost by the thermometer by the application of an electric current.

The apparatus not being differential in construction, the temperature of the water bath had to be kept rigorously constant in order to have the meniscus of the thermometer move slowly and regularly. The response of the apparatus was, of course, slow and sluggish, which is a common property of this type of receiver (radiator), so that it required from four to eight minutes to obtain a measurement.

The same criticisms apply to this instrument that have been mentioned in the cruder form of thermometer used by Féry and Drecq (46). The energy for compensation is supplied by a heating coil which is in contact with the liquid (a good scheme in so far as it applies to heating the liquid) and on the side of the wall of the receiver opposite to that upon which the incoming radiations impinge. The arrangement is therefore unsymmetrical. The heat of compensation should have been supplied by a coil inserted within the receiver, provision being made that little or none could escape by reflection and by direct radiation through the opening. In this manner the condition of symmetrical heat interchanges would have been the most closely fulfilled. In the instrument as used the opportunity for escape of energy seems greater, so that in compensation there is a tendency to produce a value which is higher than the true value for radiation unaccompanied by conduction. By placing the heating coil within the receiver and using a high temperature radiator, Puccianti's device should be applied in the manner recently used by Keene (52).

Puccianti considered the precision of this method as high as that of the bolometric apparatus, but the sensitivity of the thermometric apparatus was very much inferior to that of the bolometer. Nevertheless, he seems to prefer the thermometric method in spite of its small sensitivity. He assigned a value of $6\cdot00<\sigma<6\cdot3$, and his intermediate value is $\sigma=6\cdot15$.

(v.) *Observations of Keene* (52).—The most recent determination of the constant σ is by Keene. The radiator consisted of an electric furnace which could be heated to 1000° C. The receiver consisted of a hollow spherical double-walled thermometer bulb provided with a small aperture in its side to admit the radiation to be measured, as shown in *Fig.* 8. The space between the walls is filled with aniline, which served as thermometric substance, its expansion being observed in a capillary tube in the usual way, 1 mm. division $=0\cdot0005°$ C.

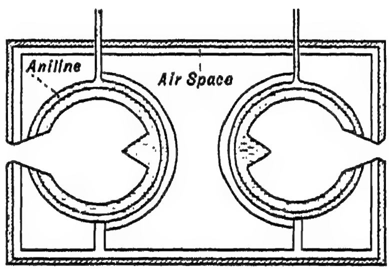

FIG. 8.

In order to eliminate the effect of the variation of room temperature, two such thermometers were used differentially, radiation being admitted into one of them, the differential effect giving a measure of the energy supplied. The interior of the bulb receiving the radiation was provided with an electric heating coil for the purpose of calibration. His paper contains the derivation of an exact expression for the energy interchange between two radiating coaxial circular openings; for he found that the approximate formula which is ordinarily used when the distance between the openings is large was not accurate enough for the work.

His value of the radiation constant is $\sigma=5\cdot89$.

The receiver and the radiator being close together, and the time for attaining temperature equilibrium being rather long, there is a possibility of diffusion of hot gases into the receiver when the shutter is raised for observa-

tions. This would tend to give a high value. It would have been interesting to determine if it would have required less electric power in the heating coil, provided the opening in the receiver had been closed with a reflecting cover to prevent escape of heated gases, while calibrating the device.

§ (5) INDIRECT AND SUBSTITUTION METHODS. (i.) *Observations of Shakespear* (53).—His value of the constant σ is obtained by a method which is based upon the principle that a heated body in air, in surroundings at a lower temperature, loses heat (*a*) by conduction, (*b*) by convection, and (*c*) by radiation. If the rate of loss by a body be observed in two cases, the only difference being that the emissivity of the radiating surface varies, other conditions remaining the same, it is quite correct to assume that the losses (*a*) and (*b*) will be the same and that the difference between the observed rate of loss of energy in the two cases is due only to the difference in the losses by radiation. If, now, these two different surfaces, at the temperature of boiling water, be exposed in turn to a radiomicrometer at room temperature, we obtain the ratio of the rates of the energy radiated by the two surfaces.

In the experiments, a plate of metal with a silvered surface was heated electrically to 100° C. and close to it was another plate, blackened with soot, which was cooled with water. Between the plates was air at atmospheric pressure. Shakespear measured the energy input in order to maintain the plate at 100° when (1) the surface of the plate was highly polished, and (2) when it was blackened. He measured also the ratio of the emissivities of the plate under these two conditions, using a radiomicrometer for the purpose. From this he obtained a value σ' in absolute units. He then compared the emissivity of the lamp-black surface at 100° with that of a black body at the same temperature by means of a radiomicrometer. From this latter comparison combined with the value of σ' he found a value of $\sigma = 5{\cdot}67$.

From this description it may be noticed that the essential parts of the method differ from that of Westphal (55) in that the radiator was a flat metal plate used in air instead of a vacuum, and that the black body, with which the emissivity of the plate had to be measured, was separate from it; while in Westphal's instrument the black body was self-contained within the metal (in the form of a cylinder) of which the emissivity of the surface had to be measured.

(ii. *Observations of Todd* (54).—In his experiments on the thermal conductivity of gases, Todd used a thin layer of air enclosed between two horizontal, parallel, good-conducting plates, which were maintained at different temperatures. The colder plate, of course, receives heat by radiation and by conduction through the air from the hotter plate, which is above it. Communication from the surrounding air is shut off by an insulating ring, and the two plates being close together, in comparison with their linear dimensions, the convection currents are eliminated. He determined the energy lost by radiation by varying the distance x between the two plates and noting the corresponding variation in the quantity Q of heat passing from the upper to the lower plate. These values of x and Q when plotted from a rectangular hyperbola and the horizontal asymptote give the value R of the radiation. The energy input was determined by a calorimetric method. In order to determine the constant σ he had simply to find the ratio of emissivities of the blackened plate to that of a black body at the same temperature, for which purpose a radiomicrometer was employed. The value of this ratio and the constants obtained in the main part of his experiment enabled him to compute the radiation constant, which he found to be $\sigma = 5{\cdot}48$.

This, like the preceding method, is likely to give a low value of the coefficient of radiation owing to uncertainty of the exact temperature of the radiating surface of lamp-black. A thin layer of soot is fairly efficient in its emission and absorption. But a thick layer of soot is quite non-conducting of heat, as was found in the measurements of diffuse reflection (34).

(iii.) *Observations by Westphal* (55).—An important determination of the coefficient of total radiation was made by Westphal (55). The experiment consisted in comparing the emissivity of a cylindrical block of copper, when it was highly polished and when it was blackened, with the emissivity of a black body at the same temperature. The novelty involved in the method is in having the black body contained within the cylinder as shown in *Fig.* 9. The copper cylinder was heated electrically, and to reduce the energy losses by gaseous heat conduction this copper cylinder was suspended in a glass flask from which the air could be exhausted to 1 mm. pressure. The outer surface of the cylinder was either highly polished to give it a low emissivity E_2 or painted with lamp-black to give it a high emissivity E_1. The end surfaces remained unchanged. The heat losses by conduction and convection were therefore the same throughout the experiment, and the difference in energy input, when the surface of the cylinder had a high emissivity and when it had a low emissivity, was a measure of the energy lost by radiation.

If the temperature of the glass flask is kept constant T_0, and the blackened cylinder is heated

electrically to the (absolute) temperature T, then the energy input W which is required in order to maintain a stationary temperature is

$$W_1 = O\sigma E_1(T^4 - T_0^4) + f(T,T_0). \quad . \quad . \quad (6)$$

In this equation, O is the surface of the cylinder and (T,T_0) is an unknown function which represents the

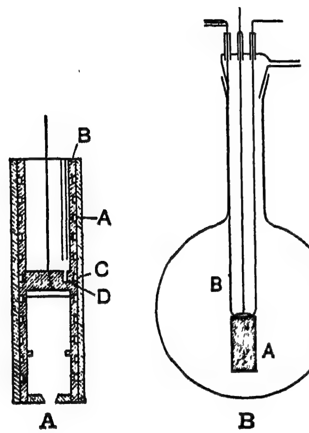

FIG. 9.

energy lost by conduction through the air and lead wires, and by radiation from the ends of the cylinder.

If now the surface of the cylinder is polished and thus given the emissivity E_2, and if the cylinder is heated to the temperature T, while other conditions remain unchanged, the energy lost from the cylinder is

$$W_2 = O\sigma E_2(T^4 - T_0^4) + f(T,T_0) \quad . \quad . \quad (7)$$

and the constant sought is

$$\sigma = \frac{W_1 - W_2}{O(E_1 - E_2)(T^4 - T_0^4)}. \quad . \quad . \quad (8)$$

Using the surface of the cylindrical body when highly polished, Westphal proceeded to find the curve of watt-input W_2 of the body between the temperatures 350° and 425° absolute as a function of the temperature. Then the surface of the body was brought to a high emissivity by applying in succession different blackening materials, and the energy W_1 input was measured at different temperatures.

The emissivities of the surface and of the interior of the copper cylinder were compared by means of a thermopile. The numerous details need not be discussed. Suffice it to say that the work appears to have been thoroughly done, and from the nature of the method it seems free from gross systematic errors. His mean value is $\sigma = 5{\cdot}54$.

He modified the apparatus and extended the observation over a wider range of temperature with a view to increasing the accuracy. The new value (56) agrees well with the earlier determination, being $\sigma = 5{\cdot}57$. Although nothing further seems to have been published subsequently, Westphal obtained further measurements which yielded the value $\sigma = 5{\cdot}67$ (58). This is in excellent agreement with Shakespear's results (53) showing that the coefficient of radiation as determined by reliable methods is of the order $\sigma = 5{\cdot}7$.

As already noted in discussing Todd's data, it is uncertain whether in all cases the surface of a layer of black soot has the temperature of the metal plate upon which it is deposited. Gerlach (36) performed experiments which led him to question whether Westphal's results were not slightly low owing to the use of lamp-black.

This and the preceding measurements of the coefficient of total radiation are excellent variations from the direct method. They are likely to give slightly low values, just as the thermometric methods, just described, give high values. Hence, these two methods serve the purpose of establishing upper and lower limits of the radiation constant.

(iv.) *Deductions of Lewis and Adams* (57).—In concluding the survey of what the writer considers the most reliable experimental determinations of the coefficient of total radiation, it is of interest to include in this paper a theoretical computation by Lewis and Adams (57) based upon data on the elementary electric charge e, the gas constant R, and the Faraday equivalent F. Their calculations lead to a value of $\sigma = 5{\cdot}7$.

The foregoing data are assembled in Table I., which gives also conservative corrections for atmospheric absorption, which is an important factor that in many cases was neglected by experimenters. By applying this obviously necessary correction it is interesting to find that these data, which were obtained by different methods, and which appear so discordant on first perusal of the original papers, can be brought into excellent agreement. They range about the number $\sigma = 5{\cdot}7$. In fact, two-thirds of the total number (12) of determinations recorded in Table I. are close to $\sigma = 5{\cdot}7$. The mean value of all these data which are free from question is $\sigma = 5{\cdot}72$ to $5{\cdot}73$.

If we neglected Todd's low value, determined from gas conduction experiments, and Puccianti's value, which is no doubt too high, the mean value remains unchanged. As we shall see presently, experimental evidence on ionisation potential, X-rays, and photoelectric work show that the value of the coefficient of total radiation is of the order $\sigma = 5{\cdot}7$.

TABLE I

OBSERVED VALUE AND THE MOST PROBABLE VALUE OF THE CONSTANT OF TOTAL RADIATION AFTER CORRECTING FOR REFLECTION, ATMOSPHERIC ABSORPTION, ETC.

Observer.	Date.	$\sigma \times 10^5$ erg.	Probable Value of $\sigma \times 10^5$.	Method.
Kurlbaum	1898	5·45	?	Bolometer
Féry	1909	6·3	?	Thermometer
Bauer and Moulin	1909	5·30	5·7	Thermopile

Mean value, $\sigma = 5{\cdot}72\text{-}5{\cdot}73 \times 10^{-5}$ erg cm.$^{-2}$ sec.$^{-1}$ deg.$^{-4}$.

III. THE CONSTANT OF SPECTRAL RADIATION

In order to appreciate fully the significance of the constant of spectral radiation, it is of interest to consider briefly the instruments and methods of observation.

§ (6) THE SPECTRORADIOMETER.—The determination of the constant, C_2, of spectral radiation requires very sensitive radiometric apparatus for measuring the intensities of the emission in different parts of the spectrum. In order to eliminate absorption, and especially the lack of achromatism which exists in lenses, the spectrometer is provided with mirrors as illustrated in *Fig.* 10, which shows the general arrangement of the apparatus required for such investigations. The radiations emanating from the black body A are focussed upon the spectrometer slit b by means of silvered mirrors placed in an air-tight box B. The spectrum is produced by means of a fluorite or quartz prism p (*Fig.* 10).

The radiometer for measuring the spectral intensities is shown at D, which in this case is a vacuum bolometer. The thermocouple for measuring the temperature of the furnace A is shown at Th. A sensitive ironclad Thomson galvanometer is used in connection with the spectrobolometer or thermopile.

The prism is calibrated by computing the minimum deviation settings, using for this purpose the refractive indices of fluorite (67) or quartz and the angle of the prism. As a fiducial mark or "zero" of the spectrometer circle the yellow helium line (15) is a convenient standard reference line.

By means of apparatus of this type the distribution of energy is measured in different parts of the spectrum. Two types of measurements may be made, viz. "Isochromatics" and "Isothermals."

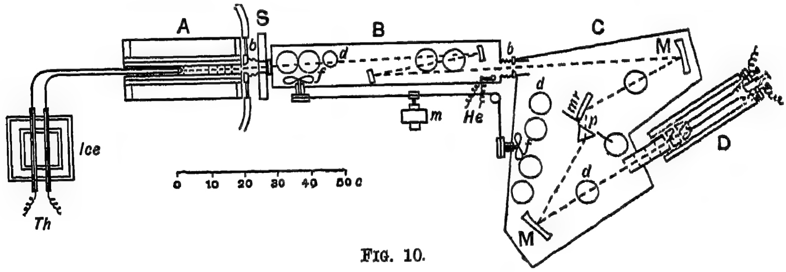

FIG. 10.

In making *isochromatic measurements* the spectrometer is set on a given wave-length, and the intensities are measured as the temperature of the radiator is varied.

In making *isothermal measurements* the temperature of the furnace is kept constant and the thermal radiation intensities are measured in different parts of the spectrum. This gives the prismatic spectral energy distribution[1] illustrated by the dotted curve (*Fig.* 11). On reducing these prismatic measurements to the standard normal spectrum (15) one obtains an energy distribution as illustrated in the continuous curve (*Fig.* 11). With rise in temperature the maximum of the emission curve shifts towards the short wave-lengths. This fact enters into spectral radiation formulas to be discussed presently.

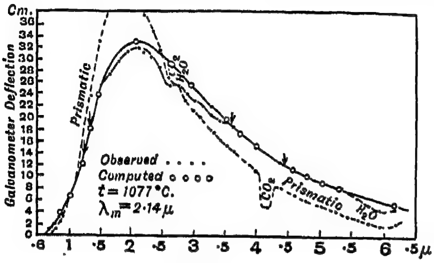

FIG. 11.

One of the difficulties encountered is the absorption by atmospheric water vapour and carbon dioxide, which produce depressions in the spectral energy curves as indicated in *Fig.* 11. However, by enclosing the spectrometer, by absorbing the moisture with phosphorus pentoxide, and by making the observations when the humidity is low, one can obtain trustworthy measurements over a wide region of the spectrum.

§ (7) FORMULAS FOR REDUCING SPECTRAL RADIATION DATA.—Planck's equation (2) is no doubt the closest representation yet formulated of the observed energy distribution in the spectrum of a black body. In *Fig.* 11 the circles represent the spectral energy distribution computed (66) by means of the Planck formula. In the spectral region, free from atmospheric absorption, to 6 μ, the observed and the computed curves agree to within the errors of observation, viz. 0·5 to 1 per cent.

Rubens and Kurlbaum (68) have made isochromatic observations, using the residual rays of fluorite in the spectral region of 24 μ and 52 μ. Their data also are in exact agreement with those computed by the Planck equation. From all of these data it appears that the Planck equation may be considered as representing, within the errors of observation, the energy distribution of a black body in the spectrum extending from 0·5 μ to 50 μ.

[1] See also "Radiation Theory," *Fig.* 1.

The Planck formula is based on theoretical considerations, and after almost two decades of discussion it remains unchanged. Recently, it is true, Nernst and Wulf (69) have arbitrarily modified the coefficient in the equation, changing C_1 to $C_1(1+\alpha)$, where α is a variable. Their whole procedure is based upon the assumption that the numerical value of the constant is $C_2=14300$ micron degrees, as observed from isochromatic observations, and that since the older values of C_2, obtained from isothermals, are somewhat higher, they must be reduced by a factor $(1-\alpha)$ depending upon the temperament of the radiator. They point out explicitly that the whole procedure depends upon the truth or falsity of the value of $C_2=14300$; or rather, as will be seen presently (see Table II.), upon the truth or falsity of the older values of $C_2=14400$ (about) obtained from isothermal measurements. Their deductions lead to a value of $\sigma=6{\cdot}04$, which, from a consideration of the whole subject on a subsequent page, appears to be much higher than the true value. Until we have more reliable experimental data from isothermal measurements, it does not appear necessary to consider their modification of Planck's equation.

(i.) *The Spectral Radiation Formulas—Isochromatic.*—After having made the spectral energy measurements, as indicated in the preceding pages, the next step is to compute the constant C_2 from the Planck formula (equation (2)). In view of the fact that some of the outstanding differences arise from methods of computing the constants from the experimental data it is important to consider the various reduction formulas which may be used in the computation.

For computing the constant C_2 from an *isochromatic* energy curve at any wave-length, λ, Planck's equation is used in the following form (15):

$$C_2=\frac{(\log E_2-\log E_1)\lambda T_1T_2}{\log e(T_2-T_1)}-\frac{(e^{-C_2/\lambda T_2}-e^{-C_2/\lambda T_1})\lambda T_1T_2}{T_2-T_1}, \quad (9)$$

where E_1 and E_2 refer to the emissivities corresponding to the absolute temperatures T_1 and T_2 respectively. In this equation the terms $\log(1-e^{-C_2/\lambda T_1})$, etc., which are similar to the terms in equation (13), are expanded in series, and only the first term of the expansion $(e^{-C_2/\lambda T_1}\log e)$ is used. An approximate value of $C_2=14300$ is used in applying the second term correction. For wave-lengths up to 1 μ this correction term

(to the Wien equation) is small, being only 2·1 and 4·3 for temperature intervals of $(T_2 - T_1)$ 363° and 623° respectively, when using $T_1 = 1450$. However, these corrections increase very rapidly with wave-length beyond 1 μ, so that at 2 μ with the same temperature intervals ($T_1 = 1450$; $T_2 = 1813$ and 2073°) the corrections to the values of C_2 amount to 168 and 227 respectively. This explains the rise in the value of C_2 with wave-length as found by Lummer and Pringsheim (61), who did not use the second term correction. Energy curves which coincide closely with the Wien equation give uniform values of C_2 with increase in wave-length when computed by using only the first term in equation as was found by Paschen. In their preliminary results Warburg (70) and his assistants, using a quartz prism, found that the value of C_2, obtained from isochromatics, is independent of the wave-length. On the other hand, they found an increase in C_2 with wave-length when using fluorite prisms.

(ii.) *Isothermal.*—Using an *isothermal* spectral energy curve, the constant of spectral radiation, C_2 (equation (2)), may be derived from the value of the wave-length of maximum emission, λ_m, by means of the equation

$$C_2 = a\lambda_m T, \quad . \quad . \qquad (10)$$

in which the value of a is 4·9651. The equation makes use of the Wien displacement law, which is the mathematical expression for the shifting of the wave-length of the maximum emission toward the shorter wave-lengths, with rise in temperature, viz.

$$\lambda_m T = A \text{ (a constant).} \qquad (11)$$

The value of the constant is close to $A = 2885$ micron degrees.

Experimenters are therefore concerned with the proper method of computing the position of the wave-length of maximum emission λ_m from the isothermal spectral energy curve, such as illustrated in *Fig.* 11.

In case one cannot observe the complete energy curve, as, for example, when using a quartz prism which absorbs strongly beyond 2·2 μ, it is possible to compute the value of λ_m from Planck's equation by reducing the observed energy curve to the normal spectrum, and taking from the energy curve the values of E_1 at λ_1 and E_m. The proper equation is

$$\frac{E}{E_m} = \left(\frac{\lambda_m}{\lambda}\right)^5 \cdot \frac{(e^{4 \cdot 9651} - 1)}{(e^{4 \cdot 9651\lambda_m/\lambda} - 1)}. \quad . \qquad (12)$$

This equation, which has been used extensively by Warburg (80) and his collaborators, appears to be well adapted for reducing the observations obtained with a quartz prism; but the temperatures must be sufficiently high so that the E_m does not fall in the region beyond 2·2 μ, where, as already mentioned, quartz begins to absorb strongly. This equation is not well adapted for reducing measurements made with a fluorite prism, owing to the small dispersion of the prism and hence the steepness of the energy curve on the short wave-length side, where one would want to use it, and also owing to the fact that, at the temperatures usually employed, the maximum emission E_m falls in the region of atmospheric absorption bands or in the region of 1·6 μ, where the dispersion curve of fluorite has a point of inflection. The latter point makes it quite difficult to determine accurately the factors for reducing the observations from the prismatic to the normal spectrum.

Another method of determining the values of λ_m from an isothermal spectral energy curve is by the "method of equal ordinates." For this purpose the normal spectral energy curve is drawn on accurately ruled co-ordinate paper, as illustrated in *Fig.* 11. Then, as indicated by the arrows, at two points where the intensities (the galvanometer deflections) are equal, $E_1 = E_2$, the corresponding wave-lengths λ_1 and λ_2 are read from the curve. The value of λ_m is easily derived (15) from equation (2) by equating $E_{\lambda_1} = E_{\lambda_2}$, and for the complete solution it is

$$\lambda_m = \frac{5(\log\lambda_2 - \log\lambda_1)\lambda_1\lambda_2}{a'(\lambda_2 - \lambda_1)\log e}$$

$$- \frac{\lambda_1\lambda_2[\log(1 - e^{-C_2/\lambda_1 T}) - \log(1 - e^{-C_2/\lambda_2 T})]}{a'(\lambda_2 - \lambda_1)\log e}. \qquad (13)$$

The second term in this equation can usually be abbreviated, since terms involving λ_1 are usually negligible. For values of λ_2 which are less than 4 μ the term $\log(1 - e^{-C_2/\lambda_2 T})$ may be expanded into a series and (by dropping all terms but the first) may be used in the form $-e^{-C_2/\lambda_2 T} \log e$. In this equation $a' = 4 \cdot 9651$. It may be noted that an approximate value of C_2 is necessary in order to obtain a solution for the second term factors in equation (13). This may be obtained by solving for λ_m by using only the first term in equation (13), which is the solution of the Wien equation as used by Paschen (59). It is sufficiently accurate (15) to use $C_2 = 14300$ in making this computation. A decrease of 100 units in C_2 (say $C_2 = 14200$) decreases the mean value of λ_m by 0·0012 μ.

The method of equal ordinates has been extensively used by Paschen (59) and by Coblentz (15, 66). It has several commendable features, because it is possible to utilise values of λ_1 and λ_2 which correspond with values of E_{λ_1} and E_{λ_2}, which are closely the same in magnitude as originally observed,

and hence contain the same errors of observation; also the slit widths are closely the same. This method does not require the most accurate wave-lengths and refractive indices (at least not for values of λ_2 greater than 4·5 μ), and it permits the selection of parts of the spectral energy curves which are free from atmospheric absorption bands. At a temperature of 1000° C. and at $\lambda_2 = 4·5\ \mu$ to 6 μ an error of $\lambda_2 = 0·05\ \mu$ changes λ_m by 0·007 μ to 0·008 μ. This amounts to 0·7 per cent in the value of C_2, and is much greater than would occur in practice.

The method of equal ordinates necessitates reducing the prismatic spectral energy measurements to a normal spectrum, plotting the data upon co-ordinate paper, and drawing in a smooth curve from which the values of λ_1 and λ_2 are read, corresponding with the equal ordinates $E_{\lambda_1} = E_{\lambda_2}$. Although it requires but little additional time to plot the data, after having made the observations, if one is certain that the observations lie close to the curve, the obviously logical procedure is to compute the spectral radiation constants from any two observed points E_{λ_1} and E_{λ_2}. This, however, does not shorten the observational work, for it will be necessary to make observations at three adjacent spectrometer settings (separated by the width of the radiometer receiver) in order to determine the spectral purity factor which is required in order to reduce the data to a normal spectrum. After spending months in obtaining the data, the question of saving time in their reduction is of minor importance. Furthermore, it is desirable to draw the complete curve and preserve it for future reference. If the observations do not lie close to the smooth curve, then this method is slightly arbitrary as to the manner of combining the observations so as to obtain an integration of the whole curve without making more computations than would be used in the "method of equal ordinates."

The appropriate formula for computing the radiation constants from any two observed points, E_{λ_1} and E_{λ_2}, on an isothermal spectral energy curve is easily deduced from Planck's equation, and in its complete form, as shown by Dellinger (71), is

$$C_2 = \frac{\lambda_1\lambda_2 T}{(\lambda_2 - \lambda_1)\log e}\left[\log\frac{E_{\lambda_2}}{E_{\lambda_1}} + 5\log\frac{\lambda_2}{\lambda_1} - \log\left(\frac{1 - e^{-C_2/\lambda_1 T}}{1 - e^{-C_2/\lambda_2 T}}\right)\right]. \quad (14)$$

The term $\log(1 - e^{-C_2/\lambda T})$ may be expanded into a series, and usually all the factors can be neglected, except one which is $\log e \,.\, e^{-C_2/\lambda_2 T}$. It is therefore necessary to know the approximate value of C_2, as is required in the method of computation used by Coblentz (15, 66).

In concluding this discussion we may notice a calculation of the constant C_2 by an extension of the theory of least squares, by Roeser (72). Using the data illustrated in *Fig.* 11, his calculation gave a value of $C_2 = 14342$, as compared with $C_2 = 14339$ computed by Coblentz (66) (*loc. cit.* p. 462), by the method of equal ordinates.

(iii.) *Spectrophotometric.*—A spectrophotometric method may also be used in determining the constant C_2. It consists in determining the ratio of brightness of a black body at, say, the melting-point of gold (1063° C.) and at some higher temperature, say the melting-point of palladium (about 1556° C.). This requires a knowledge of the wave-length ($\lambda = 0·65\ \mu$ is usually taken) of the light photometered and the absolute temperatures T_1 and T_2 of the radiator. The appropriate formula is

$$\log\frac{E_2}{E_1} = C_2 \log e\left(\frac{1}{T_1} - \frac{1}{T_2}\right). \quad (15)$$

The intensities E_1 and E_2 are usually measured with an optical pyrometer. If the constant C_2 is known the temperature T_2 (say 2000° C.) may be computed. Conversely, using known temperatures T_1 and T_2 the constant may be determined. As a matter of fact the method has never been used very successfully in a quantitative manner because, as will be noticed presently, the higher temperature T_2, at some fixed temperature point (say the melting-point of palladium), is not accurately known. Recent experimenters are therefore proceeding in the reverse order, and assume that if the constant $C_2 = 14300$, then the melting-point of palladium is 1557° C., or if $C_2 = 14350$, then the melting-point of palladium is 1550° C. The task before us is therefore to obtain an estimate of the probable value of the constant C_2.

§ (8) Determinations of Constant of Spectral Radiation.—In spite of all that has been published on the partition of energy in the spectrum of a black body there are but few experimental data at hand which are more than qualitative in value.

To the writer it seems that all these early data should be considered from the standpoint of historical interest, since it seems impossible to give them much weight in connection with the results obtainable at the present day.

(i.) *Observations of Paschen* (59, 60).—The pioneering work in spectral radiation measurements and constants was inaugurated by Paschen (59), who observed an extensive series of spectral energy curves at temperatures ranging from 100° to 450° C., using six different kinds of bolometers covered with different kinds of absorbing material, *e.g.* lamp black and platinum black or copper oxide; also having

the bolometers in the focus of a hemispherical mirror. The radiators were heated by means of boiling water, aniline, sulphur, etc. The mean value of all his observations, which are in close agreement, was $A=2891$ and $C_2=14352$. He continued the work at temperatures ranging from 400° to 1050° C., using a large porcelain radiator. He used also metal cups of copper or platinum, blackened with oxides of copper or iron, which were heated within this porcelain radiator; making in all about a dozen different arrangements of the radiators. The bolometer was covered with platinum black and was situated in the focus of a hemispherical mirror to "blacken" it. The mean of the new series was $A=2907$, with a probable error of ± 16.

In a further investigation Paschen (60) undertook the work anew, after redetermining the reflecting power of silver and the refractive indices of fluorite. He used a porcelain tube radiator, also three other radiators, which he blackened as in the preceding research. He took the wise precaution to project an image of the radiating wall of the black body upon the spectrometer slit (see *Fig.* 10), in order to avoid possible radiations from the side walls and diaphragms falling upon the prism and bolometer. He made complete corrections for the selective reflection from the prism. He then found that his observations fitted neither the Wien nor the Planck equation, the values on the long wave-length side of the energy curves falling between the two theoretical curves. He found that if (for reasons he himself could not explain, *loc. cit.* p. 295) he multiplied his observations by factors varying from 1·02 at 3·91 μ to 1·195 at 8·25 μ, etc., the observed energy curve would fit the Planck equation and fulfil better the condition of congruence. Upon this basis, and presumably by computing the λ_m by using the first part of equation (13), he obtained a value of $A=2921$ for his newest data. He then applied similar factors to some of his previous data, thus making them agree better with the Planck equation, and the value of A was increased from 2891 to 2915, or about 0·87 per cent. From this it appears that, if he had not multiplied his observations by these arbitrary factors, his latest results would have been about 0·87 per cent lower or $A=2894$, which is practically the same as the value previously obtained.

Coblentz (15, 66) obtained a plausible estimate of the correction to Paschen's values by applying the values of the second term which result from computing λ_m by equation (13). This is admissible, because Paschen's observed curves are said to fit the Planck equation to about 4 μ. The conclusion arrived at (*loc. cit.* (66), p. 468) is that Paschen's recent determination is of the order $A=2894$. This is close to the earlier determination $A=2891$, which is probably more reliable as regards the temperature scale. In other words, Paschen's original data fall within the range of the recent and more accurately determined values, being of the order $C_2=14360$ micron degrees.

(ii.) *Observations of Lummer and Pringsheim* (61, 63, 74).—Their spectral radiation measurements were made on porcelain tube radiators, illustrated in *Fig.* 1. The radiator was placed directly in front of the spectrometer slit. This reduces the length of air-path, and hence the absorption; but there is uncertainty in keeping the alignment, especially since in their designs no attempt was made to prevent the tube from sagging.

As is true of all the older measurements on radiation, operated above 1200° C., the temperature scale is defective (too high), giving values of C_2 which are too high.

The values of the constants published by Lummer and Pringsheim (61) require a treatment similar to that just given to Paschen's data. They used the earlier indices of refraction of fluorite, published by Paschen (73) in 1894, which are in error in wave-length by 0·02 μ for the region of 1 μ to 2·5 μ. Fortunately most of their values of λ_m are greater than 2·5 μ and no correction is required. But little information is at hand as to how they calculated their values of λ_m. In their earlier work (61) they say that, after bridging over the absorption bands by means of a smooth line, the values of λ_m and E_m may be read directly from the spectral energy curve. This would permit the determination of only one reading of λ_m, whereas the method of equal ordinates permits the calculation of a number of values of λ_m.

In their first investigation a series of four spectral energy curves, observed at temperatures of 837° to 1416° abs., gave a value of $A=2879$.

For a second series of measurements they enclosed the spectrometer in order to dry the air. A series of five spectral energy curves, observed between the temperatures of 814° and 1426° abs., gave a value of $A=2876$. These two values are in close agreement with Paschen's determinations made at that time. Since they observed the value of λ_m at E_m, instead of by the method of equal ordinates, the second term correction of equation (13) does not enter into the calculation. They found that their data did not fit the Wien equation, and this no doubt gave impetus to the formulation of the Planck equation. Suffice it to say that their data, obtained up to this time, if reduced on the basis of the Planck factor $\alpha=4·9651$, lead to a value of $C_2=14290$. In a subsequent investigation (63) the radiator was heated to a much higher

temperature — to 1646° abs. A series of 8 isothermal spectral energy curves gave a value of $A=2940$ and $C_2=14590$. In view of the fact that a correction of about 0·02 μ must be made for the calibration at 1 μ to 2·5 μ, this would reduce the value of λ_m and of C_2 by 2 per cent, or $C_2=14300$. Although the apparatus was enclosed, in order to remove the CO_2 and water vapour, the energy curves are appreciably affected by atmospheric absorption.

As in previous work, their temperature scale above 1000° C. was obtained by extrapolation. Just how much the thermocouple calibration may be in error is not recorded. In a subsequent paper (75) they revised the temperature scale used in the previous test (9) of the Stefan-Boltzmann 4th-power law. The revised temperatures are 10 to 12° lower, and, at the highest temperatures, they are 20 to 25° lower than previously used. Hence the value of A (see equation (11)) would be lowered. Whether any temperature correction of this magnitude must be made to the spectral radiation data is not stated; though the researches on the gas thermometer by Holborn and Day (76) were then in progress. Suffice it to say that although their later value of $A=2940$ is the one frequently quoted in books, none of the subsequent investigators have found a value of A which is within 15 per cent as high as is this one.

From the foregoing consideration of the data obtained by Lummer and Pringsheim it appears conservative to place their value at $C_2=14300$ micron degrees.

(iii.) *Observations of Warburg and Collaborators* (80 to 90).—During the past twenty years the determination of the constants of radiation and their application to the temperature scale has been relentlessly pursued by the Phys. Tech. Reichsanstalt (75) at Berlin.

During the past ten years these investigations have been carried out by Warburg and his collaborators. They used fluorite and quartz prisms and vacuum radiators. The sodium line was used as a zero setting of the spectrometer.

The radiometer was a vacuum bolometer, operated by a null method. In this manner the galvanometer acted merely as an indicator. The temperature fixed points were the melting-point of gold and some higher temperature, *e.g.* melting-point of palladium.

In their first communication (80, 81) they reported a value of $C_2=14570$ on the basis that the melting-point of palladium is 1549° C. On the other hand, if the higher temperature point was determined radiometrically, by extrapolation from the gold point, using the Stefan-Boltzmann law, then the value of C_2 was found to be the smaller. Hence they questioned the gas thermometer temperature scale and proceeded to make their investigations at high temperatures by using the radiation laws to establish their scale of temperatures. In this manner they avoided the temperature scale as transferred from the gas thermometer by means of thermocouples. They retained only one temperature fixed point, viz. gold at 1064° C. (later 1063°). The higher temperatures (1400° C.) were determined radiometrically. For this purpose they observed the position, E_m, of the isothermal spectral energy curve reducing the data by means of formulas (12) and (10).

Using Paschen's refractive indices of refraction of fluorite and Carvallo's (93) indices of quartz, in their next communication (82) they report values which varied from $C_2=14200$ to 14600.

Using improved methods for adjusting the sodium lines on the bolometer, and making further provision so that only radiation emanating from the central diaphragm of the radiator was incident upon the bolometer, in their next report (83) the fluorite prism gave values ranging from $C_2=14300$ to 14600, and it was discarded. A quartz prism gave a value of $C_2=14360$ micron degrees.

In a very complete investigation (84, 85) they repeated the previous work. Using a quartz prism the values obtained are $C_2=14370\pm40$ and $A=2894\pm8$ for the temperature interval of 1337° and 2238° abs.

Their next step was to cut a prism out of a block of quartz of which the absorptivity had been determined previously. With this and other improvements, including different radiators, a value of $C_2=14250$ was obtained (87, 88), from the temperature scale based on the Stefan-Boltzmann law of total radiation; and a value of $C_2=14300$ or 14400 was obtained by using the Wien displacement law (*e.g.* 11) to establish the temperature. The uncertainty in the value of $C_2=14300$ or 14400 is owing to the uncertainty in their calibration curve (refractive indices) of the quartz prism.

The present position of their work has led them to the adoption (89) of the value of $C_2=14300$ and the melting-point of palladium $=1557°$ C. Subsequent investigations (90) appear to be made on this basis.

There is an uncertainty of perhaps 1° in the temperature scale at the melting-point of palladium (92). In view of the great variations in the various determinations of C_2, it was perhaps a wise decision for Warburg to adopt the round number $C_2=14300$ micron degrees for the spectral radiation constant; though, as we shall see presently, theory and other experimental data would place the value somewhat higher.

(iv.) *Observations of Coblentz* (15, 39, 66).—In this investigation the spectrum was produced by means of a mirror spectrometer and a fluorite prism, as illustrated in *Fig.* 10. In the first work an air bolometer, and later a vacuum

bolometer, was used for measuring the partition of energy in the spectrum. The radiator (*Fig.* 1) was a porcelain tube, wound with platinum ribbon, through which electric current was passed.

It was operated at temperatures ranging from 450° C. to 1500° C. Various incidental questions, such as the adjustments of the optical parts of the apparatus, the temperature uniformity and temperature control of radiator, the water-cooled shutters, the temperature scale, the method of reduction of the observations to the normal spectrum, the proper formulæ for computing the numerical constants, etc., were investigated.

The first paper (15) contains also data on various subsidiary problems such as (1) the variation of the reflecting power of silver with angle of incidence and with wave-length, (2) the variation of reflecting power of fluorite with angle of incidence and with wave-length (refractive index), and (3) data for reducing the observations from prismatic to normal spectrum.

As already explained in the discussion of the methods of reducing the observations, it was decided to observe isothermal spectral energy curves as illustrated in *Fig.* 11, and compute the position of λ_m by the method of equal ordinates, using equation (13).

From the very beginning of this investigation on black body radiation it was found that the Wien equation did not fit the spectral energy curves. The assumption was therefore tentatively made that the observed curves fit the Planck equation; and at the completion of the investigation this was found to be true for about 75 per cent of all the observed curves. This conclusion was based upon the uniformity of the values of λ_m which resulted from computation (by the method of equal ordinates $E_{\lambda_1}=E_{\lambda_2}$) of values of λ_1 and λ_2 which were taken far apart, and also close together, on the observed isothermal spectral energy curve.

The observations were made in the winter when the humidity was low, and the investigation extended over four winter seasons. An attempt was made to obtain a great many isothermal spectral energy curves, so as to avoid the personal bias which can enter the working over of a few curves. This was probably a mistake; for no attempt could be made to correct the observations for small changes in temperature and bolometer sensitivity.

In the meantime, owing to impairment of eyesight, the reduction of data had to be entrusted to others who were not familiar with the work. The first calculation of the data gave a value of about $C_2=14350$. But doubts arose concerning the calibration curve of the prism. A new calibration curve was worked out and the data recalculated and published as being $C_2=14456$.

Data were obtained also with a fluorite prism which was full of cleavage planes. This produced much scattered radiation which distorted the energy curves at 4 μ to 5 μ. These data were therefore not used in the calculations.

In the meantime Paschen (67) published further data on the dispersion of fluorite which indicated that the calibration curve, and hence the value of $C_2=14456$, was wrong.

In the earlier work the temperature scale was also in doubt. The last series (1912) was not observed at temperatures much above 1200° C., and hence is quite free from doubts about the temperature scale, which was 1° lower than previously used.

The second paper (66) on this subject dealt with a recalculation of these data, using a revised calibration curve. The mean value of the spectral radiation constant based on 93 spectral energy curves (series of 1912) is $C_2=14353$.

If the corrections to the temperature scale (mentioned in the previous paper (15)) are applied, the value is $C_2=14362$. A further correction $(=+7)$ is necessary because the second term in equation (13) was computed, using $C_2=14300$ instead of $C_2=14350$. Hence the final corrected value, as published in the second paper, is $C_2=14369$ micron degrees and $A=2894$ micron degrees.

In order to obtain a check on the method of calculation of the constant a least square reduction of the first isothermal curve of the series of 1912 was undertaken by Roeser (72). He obtained a value of $C_2=14342$, which is in agreement with the value computed by the method of equal ordinates, viz. $C_2=14339$.

Recently a further examination (39) was made of the accuracy of the factors used in converting the previously observed (15) prismatic spectral energy data into the normal energy distribution. The graphical methods previously employed were checked and similar factors were obtained by computation, using the first differential of the dispersion formula, which best represents the observed refractive indices of fluorite. These refractive indices were obtained from consideration of all the available data, which, in the region of 1 μ to 2 μ, are represented by the curve published by Langley and Abbot (94). The best dispersion formula is that of Paschen (97). However, owing to incompleteness of the formula, the graphical method was found to be just as accurate as was the method of computation.

The conclusion (39) arrived at was that the spectral radiation constant $C_2=14353$ micron degrees, determined some years ago (66), remains unchanged. However, at that date there was some doubt as to whether some of the corrections then applied should have been made, giving a value of $C_2=14369$—*i.e.* the value might be $C_2=14366$.

Rather curiously and unfortunately in all

these inquiries into the small errors that eight years ago were considered negligible the one concerning the zero setting has remained unconsidered until now. The calculation of the calibration curve was based on the sodium lines, $\lambda = 0{\cdot}5893\ \mu$, for a reference point. Subsequently Coblentz adopted the then novel procedure of using the yellow helium line, $\lambda = 0{\cdot}5876\ \mu$, instead of the sodium lines for adjusting the zero setting of the bolometer. For this purpose the refractive index $n = 1{\cdot}43390$ was adopted. Subsequently Paschen (67) published the value of $n = 1{\cdot}433907$ ($17{\cdot}5°$ C.) for the refractive index of the helium line, and $n = 1{\cdot}433866$ for the sodium lines. He observed a difference of 12″ in the minimum deviation settings of the sodium and the helium lines.

On the basis of Paschen's value of the refractive index of fluorite for the yellow helium line, $n = 1{\cdot}433877$ (at 20° C.), there is a difference of 6″ between the computed and the observed zero setting of the spectrometer circle. As a result, the average values of λ_m, in terms of the spectrometer circle, must be reduced by 6″. Since the wave-lengths λ_m occur between 2 μ and 3 μ (and the majority at about $2{\cdot}2\ \mu$), the 6″ are equivalent to $0{\cdot}003\ \mu$ to $0{\cdot}004\ \mu$ in this part of the spectrum. From equation (11) it may be noticed that this amounts to a reduction of the previously published value of the constant $C_2 = 14369$ by 0·3 to 0·4 per cent. This gives a value of $C_2 = 14311$ to 14326 micron degrees.

As already stated, the second paper (66) was the result primarily of a revision of the calibration curve of the fluorite prism used; and it is unfortunate that at that time the above application of the temperature coefficient of the refractive index of the helium line was overlooked.

The citations of the foregoing researches suffice to show some of the difficulties under which experimenters are labouring. One set is concerned with the temperature scale; another is determining the optical constants of the prism material; and a third group, using both the temperature scale and the optical constants, is engaged on the radiation constants. In turn, the first set of experimenters must apply the results of those working on the radiation constant in order to verify and extrapolate the temperature scale. In the meantime the second experimenter improves his measurements of the optical constants (refractive indices) of the prism material, while a fourth enters the field and adds refinements by determining the temperature coefficient of the refractive indices. Then the unpleasant task arises to recalculate the prism calibration and the numerical value of the spectral radiation constants. Added to these difficulties is the constant change in personnel, as is apparent from perusal of the title-pages of the published papers.

Fortunately the observations are in terms of the spectrometer circle scale, and, if the necessity arises, as it did in the case just discussed, one can revise the corresponding wave-lengths and recalculate the constants.

The various determinations of the constant of spectral radiation C_2 are assembled in Table II. The sixth column gives the probable value as determined from consideration of the data in the text. The mean value is $C_2 = 14320$ micron degrees. The latest and most reliable determinations of the national laboratories are close to this value. Unfortunately, perhaps, the average value is so close to the theoretical value, arrived at from consideration of photo-electrical and similarly related phenomena, that experimenters may be led to consider their task finished instead of just begun.

§ (9) Optical Pyrometer Measurements.—Various attempts have been made to determine the constant C_2 by means of an optical pyrometer, using equation (15). There are many difficulties to be overcome before one can conclude that the data so obtained are trustworthy. One of the uncertainties is the effective wave-length of the red glass used in the eyepiece of the pyrometer. Other difficulties are encountered when using a spectral pyrometer. Also the temperature scale is in doubt. Hence recent experimenters have not attempted to determine C_2, but reverse the process and, working on the assumption that C_2 is a certain value, say $C_2 = 14350$, determine the melting-point of palladium. This seems to be the preferable procedure.

(i.) *Observations of Holborn and Valentiner* (64, 65).—In 1906 Holborn and Valentiner (64) obtained a value of $C_2 = 14200$ as a result of a series of spectrophotometric measurements using formula (16). This is now admittedly in error, owing to an erroneous temperature scale in which the melting-point of palladium was taken to be 1575° instead of about 1556°, which would give a higher value of C_2. Recently Valentiner (65) corrected this value for lack of blackness of the radiator, etc., raising it to $C_2 = 14350$. This is one of the difficulties and uncertainties experienced by experimenters who have attempted to determine the constant C_2 by methods requiring a temperature scale which is higher than about 1200° C.

(ii.) *Observations of Mendenhall* (78).—One of the few recent direct determinations of C_2 by optical pyrometer methods was made by Mendenhall (78). In establishing a temperature scale he took the Day and Sosman value

of the melting-point of palladium, viz. 1549° C. From the ratio of brightness of the black body at the melting-point of gold and palladium he obtained the value of C_2 = 14413, as a check on his measurements. Correcting for the low temperature scale, which amounts to 3·6 to 5° C. on the basis that the melting-point of Pd is 1555° to 1557°, the value of C_2 is decreased by 0·23 per cent to 0·31 per cent or C_2 = 14368 to 14380.

It is difficult to obtain high accuracy in optical pyrometer measurements on a radiator to be open to question. Just why the temperature T_1 was not similarly determined radiometrically is not clear. The temperature T_1 = 1604° abs. (1331° C.) seems to be in doubt in view of the present-day belief that the melting-point of palladium is 1555° C. to 1557° C.

If the melting-point of Pd is 6° to 8° higher than the value used in this determination, then the value of C_2 is 0·22 to 0·3 per cent higher than his published value (C_2 = 14392) and is of the order of C_2 = 14425 to C_2 = 14435.

Table II

Observed Value and the Probable Value of the Constant C_2 of Spectral Radiation

at the melting-point of gold. In the main part of his research Mendenhall therefore established his lower fixed point T_1, as that having 14·91 times the intensity of radiation of a black body at the melting-point of gold, for the complex wave-lengths transmitted by a certain standard pyrometer glass.

Subsequently, by direct comparison with Day and Sosman's standard thermocouple, which was calibrated presumably on the basis that the melting-point of palladium is 1549° C., this temperature T_1 was found to be 1331° C.

The higher fixed point T_2 = 2705° abs. was determined radiometrically on the basis of the Stefan-Boltzmann law, and does not appear

(iii.) *Observations of Hoffman and Meissner* (79, 90).—These experimenters used an especially constructed black body in a bath of the molten metal. The ratio of the brightness of the black body at the melting-point of palladium is determined relative to the brightness of the same at the melting-point of gold. They found that if the melting-point of palladium is taken 1549° C. (scale of Day and Sosman), then C_2 = 14440 (79). In a further investigation (89) they found that if C_2 is 14300, and if the melting-point of gold is 1063°, then the melting-point of palladium is 1557° C. This is in agreement with the observations of Holst and Oosterhuis (91), who found a value of C_2 = 14465 if the melting-point of Pd is

1549°, and $C_2 = 14300$ if the melting-point is 1557° C.

(iv.) *Observations of Hyde and Forsythe* (92).—In their earlier experiments they found a value of $C_2 = 14460$ on the basis that palladium melts at 1549° C. The great inconsistencies in these and other data led them to use the value $C_2 = 14350$, which is commonly used by American experimenters.

Using a carefully constructed spectral pyrometer, and on the basis that the value of $C_2 = 14350$, their most recent measurements place the melting-point of palladium at 1555·5° C.

The outstanding question then is: What is the value of C_2? Is it $C_2 = 14300$ or 14350? If we accept 1556° C. as the melting-point of palladium, then Hoffmann and Meissner's data indicate a value of $C_2 = 14315$.

Both sets of experimentors (*i.e.* those interested in the radiation constants and those interested in the temperature scale) seem to realise the difficulty in attempting to define the value of the constant C_2 or the melting-point of palladium in terms of this constant. Hence as a compromise basis for future work and for future adjustments it seems appropriate to adopt the value of the spectral radiation constant $C_2 = 14320$ and the melting-point of palladium at 1556° C.

IV. Verification of the Laws of Radiation

In the foregoing pages an inquiry is made into the instruments and methods used in, and the numerical values of various determinations of, the constants of radiation.

The various methods are classified, and a brief description is given of each research. An attempt is made to indicate the good and the defective features in each research. This represents not only the writer's opinions but also those of other experimenters.

It is shown that the major part of the variation in the various determinations of the numerical values of the constants, especially the constant of total radiation, is owing to the fact that, in the original papers, no corrections were made for atmospheric absorption of radiation in its passage from the radiator to the receiver. Conservative corrections for atmospheric absorption are made to the various determinations in which such corrections had not been made. As a result, instead of having wide variations, there is a remarkably close agreement in the numerical values of the various determinations which are free from other obvious defects. Although it cannot be said that the true numerical values are exactly as here recorded, it is evident that the time is past when the value of the constants of radiation are swayed by a single and perhaps novel method of research. The best that an experimenter should expect is that his own little contribution to the subject may have sufficient merit to go into the melting pot with the other determinations.

§ (10) The Formula and the Coefficient of Total Radiation.—In the foregoing review the data are assembled and the evidence weighed *pro* and *con*. It is shown from various experiments that, beyond all reasonable doubt, the total radiation emitted from a uniformly heated enclosure is proportional to the 4th power of the absolute temperature—the so-called Stefan-Boltzmann law. Furthermore, the tabulated data show that the numerical values of the majority of the various determinations of the coefficient, σ, which enters into the mathematical formula of total radiation, range about the value given by the expression $\sigma = 5{\cdot}7 \times 10^{-5}$ erg cm.$^{-2}$ sec.$^{-1}$ deg.$^{-4}$. The average of 12 of the most reliable determinations is $\sigma = 5{\cdot}72$ to $5{\cdot}73 \times 10^{-5}$ erg cm.$^{-2}$ sec.$^{-1}$ deg.$^{-4}$.

§ (11) The Formula and the Constant of Spectral Radiation.—Experimental evidence is cited showing that throughout the spectrum from 0·5 μ to 50 μ Planck's formula fits the observed spectral energy distribution more closely than any other equation yet proposed. This formula is based upon theoretical principles, and after two decades of discussion it remains unchanged.

The constant C_2 which determines the slope of the spectral energy curve has been the subject of numerous investigations. The numerical value of C_2 has fluctuated considerably in the various determinations. In the foregoing pages it is shown that this is owing to experimental difficulties, such as, for example, lack of precise knowledge of the temperature scale, and of the refractive indices of the prisms used. The tabulated data show that the various determinations of the constant of spectral radiation are of the order of $C_2 = 14300$ to 14350, with a mean value of $C_2 = 14320$ micron degrees.

§ (12) Confirmatory Evidence.—One of the most interesting phases of the inquiry into the laws and constants of radiation is the confirmatory data which one obtains from a consideration of the inter-related phenomena of atomic structure, of X-rays, of ionisation and resonance potential, and of photo-electrical action. From these data, as well as from the foregoing data on the two constants of radiation, C_2 and σ, one can compute the value of Planck's element of action, h. This gives seven independent methods of determining the universal constant h. Or from any one of four of these methods one can calculate (99, 100, 101) the radiation constants; and it seems truly remarkable how close the calculated values agree with the observed values of the radiation constants.

For making these calculations from Planck's

radiation[1] theory (2) we have the following relations:

$$C_2 = chk^{-1} = 4{\cdot}9651\ \lambda_m T, \qquad (16)$$

$$\sigma = \frac{ac}{4} = \frac{12\pi \times 1{\cdot}0823k^4}{c^2h^3}, \qquad (17)$$

$$\lambda_m T = \frac{ch}{4{\cdot}9651k}, \qquad (18)$$

$$k = \frac{eR}{cF}, \qquad (19)$$

while the value of c_1 is $8\pi hc$.

In these equations the constants have the following values:

h (Planck's constant)	$=6{\cdot}55 \times 10^{-27}$ erg sec.
k (Boltzmann gas cons.)	$=1{\cdot}372 \times 10^{-16}$ erg deg.$^{-1}$.
c (Velocity of light)	$=2{\cdot}9986 \times 10^{10}$ cm. sec.$^{-1}$.
F (Faraday's constant)	$=96500$ coulombs.
R (Absolute gas constant)	$=831{\cdot}5$ erg deg.$^{-1}$.
e (Unit electric charge)	$=4{\cdot}774 \times 10^{-10}$ e.s.u.

From equation (19) it may be noted that a change in the value of e affects the value of C_2 directly, while the value of σ is affected by e^4.

The data computed from the above-mentioned constants and formulae are illustrated in *Fig.* 12, from which it is an easy matter

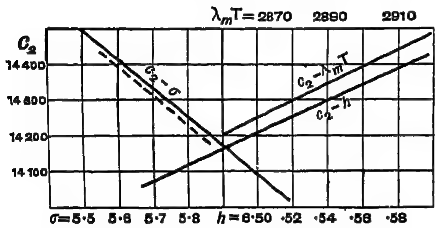

FIG. 12.

to compare experimental data (101). For example, Coblentz's (29) value of the coefficient of total radiation is $\sigma = (5{\cdot}72 \pm 0{\cdot}012) \times 10^{-5}$ erg cm.$^{-2}$ sec.$^{-1}$ deg.$^{-4}$. This indicates a value of $C_2 = 14321$ micron degrees (which is close to the average determination) and a value of $h = 6{\cdot}551 \times 10^{-27}$ erg sec. The value of h, determined by Blake and Duane (98), by X-rays, is $h = 6{\cdot}555 \times 10^{-27}$ erg sec.; or an indicated value of $C_2 = 14330$ micron degrees, which is close to the average of the direct experimental determinations of this constant.

Again, starting with Warburg's value of $C_2 = 14300$ the corresponding value of the coefficient of total radiation is $\sigma = 5{\cdot}74$, which is the higher estimated limit of the average of 12 different determinations of this constant. Hennig (99), on the basis of Sommerfeld's (102) theory, the measurement of spectral lines, and the value of the electron, obtains $C_2 = 14320$ and $\sigma = 5{\cdot}717$.

In summing up the evidence it is of interest to include Birge's (100) comprehensive and exact calculations of the constant h. In these calculations he, of course, assumes the truth of (1) Lewis and Adams' (57) theory of ultimate rational units; (2) of the relation between σ and h, as given by Planck's radiation formula; (3) of the quantum relation as applied to X-ray data (98); (4) of Einstein's photo-electric equation; (5) of Bohr's theory of atomic structure; and (6) of the quantum relation as applied to ionisation and resonance potentials.

In this manner he obtains seven separate calculations of Planck's constant of action h, the least square mean value of which, as shown in Table III., is $h = 6{\cdot}5543 \times 10^{-27}$ erg sec. This is close to the average of the value of h, which results from consideration of the two radiation constants.

TABLE III

BIRGE'S CALCULATION OF PLANCK'S UNIVERSAL CONSTANT h BY VARIOUS METHODS

Value of h.	Method.	Remarks.
$6{\cdot}551 + 0{\cdot}009$	$\sigma = 5{\cdot}72$	Total radiation
$6{\cdot}557 \pm 0{\cdot}013$	$C_2 = 14330$	Spectral radiation
$6{\cdot}542 \pm 0\ 011$	Rydberg constant	Bohr's theory of atomic structure
$6{\cdot}578 \pm 0{\cdot}026$	Photo-electric equations	Einstein's equation
$6{\cdot}555 \pm 0{\cdot}009$	X-rays	Quantum relation
$6{\cdot}560 \pm 0{\cdot}014$	Ultimate rational units	Theory of Lewis and Adams
$6{\cdot}579 \pm 0{\cdot}021$	Ionisation potential	..

Mean value, $h = (6{\cdot}5543 \pm 0{\cdot}0025)10^{-27}$ erg sec.

From this calculation and intercomparison by Birge (100) of the data on C_2, σ, and h, as determined by thermal radiometric, photo-electric, X-rays, and ionisation potential measurements, it appears that the value of h, computed from radiometric data, is in close agreement with that obtained by more direct measurement. In other words, it appears to prove the validity of laws of radiation and to establish the level of the numerical values of the constants entering therein.

The outstanding disagreement between all the observed and computed data appears to be of the order of 1 to 3 parts in 1000, whatever the method or experimentation. This is a very close agreement, considering the variety of the data and the difficulties involved in making the experiments. It seems to indicate

[1] See "Radiation Theory," § (6).

something more than a fortuitous relation between properties of matter.

In conclusion, it may be added that to a close degree of approximation we have the following constants:

Melting-point of palladium = 1556° C.

$C_2 = 14320$ micron degrees.

$\lambda_m T = 2885$ micron degrees.

$\sigma = 5{\cdot}72 \times 10^{-5}$ erg cm.$^{-2}$ sec.$^{-1}$ deg.$^{-4}$.

$h = 6{\cdot}55 \times 10^{-27}$ erg sec.

RADIATION THEORY

§ (1).—The behaviour of electromagnetic radiations can be regarded from two very different points of view. In optics the interest attaches to the study of the light waves themselves—their refraction, interference etc.—and little is said of the way in which the light arises. The present problem is the complement of this. It is concerned almost entirely with the emission and absorption of light, and makes use of optical properties only in so far as they help in the study of these. In consequence of this difference of aspect the mode of treatment is quite different. Physical optics is based on dynamics (including electromagnetic theory under the term), but the theory of radiation is founded on thermodynamics. As will be seen, pure thermodynamics can give a great deal of information about radiation, but is not capable of completely solving the problems that arise, just as it gives a great deal of information about the behaviour of a gas, but is not competent to give completely its equation of state. The subsequent problem is therefore to be solved by other methods. A direct application of the principles of mechanics leads to a definite and complete answer, but one which is entirely wrong; and to overcome this difficulty Planck introduced the quantum[1] principle, with the help of which the central problem of the theory is solved.

§ (2) Definitions.—It will be necessary to make certain definitions for the measure of radiation. These naturally take a very different form from those which are used in optics. There the starting-point is usually a train of monochromatic, polarised, plane, or spherical waves, and consequently the fundamental quantity is the amplitude of the waves. But in thermodynamics this is of no interest. The fundamental quantity is heat or energy, and the radiation measured as energy must be supposed to have a continuous distribution of frequencies and to be travelling in all directions.

The suitable definition is this. Take a small aperture $d\sigma$ and draw from its edges a cone of small solid angle $d\omega$; let the axis of the cone be at angle θ to the normal of $d\sigma$. Then a certain part of the radiation will pass through this aperture into the cone in time dt. If, as we suppose, the radiation is continuously distributed, the amount must be proportional to $d\sigma \cos\theta d\omega dt$ and the total energy entering the cone as radiation may be taken as $K d\sigma \cos\theta d\omega dt$. But a further analysis is necessary, for the pencil of rays may be supposed analysed into a spectrum. This spectrum will be continuous and so the definition will be concerned with the amount of energy between frequencies ν and $\nu + d\nu$. Finally, the radiation may be partly polarised, and this is represented by choosing two fixed directions and describing the energy corresponding to waves polarised in each. Thus the description of the radiation is fully given by an expression of the form

$$(K_\nu + K_\nu')d\nu d\sigma \cos\theta d\omega dt;$$

if the components of polarisation K_ν, K_ν' are known at every point and time the whole radiation field is fully described.

The connection between this definition and those of optical theory is not obvious. The definition is of course quite unsuited for the type of waves usually considered in theoretical optics, as these have been simplified by being taken monochromatic, plane, etc. (which is only approximately true), and the result of the present definition would be that K_ν would be infinite for one exact set of values and zero for all others. But if the electric and magnetic vectors are arbitrarily given at every point in a space, it is possible to deduce K_ν from them by means of rather complicated applications of Fourier integrals. The chief point of interest in the work lies in the spectral resolution into frequencies, which is done by virtue of a theorem of Lord Rayleigh's, whereby from a Fourier analysis of *amplitudes* it is possible to define a precise meaning for the *energy* in any range of frequencies.

In the treatment of radiation problems by thermodynamics it will be necessary to have idealised machinery for sorting out the radiation into its component parts. For example, the polarisation may be studied by means of Nicol prisms, but these have to be supposed capable of completely transmitting one component and completely reflecting the other. More important is the question of the spectral analysis. For this, advantage may be taken of the fact that many substances show a selective effect, transmitting light of some frequencies and reflecting the rest. If this is idealised it may be imagined that there exists a set of screens, each of which has the property of transmitting a certain range of frequencies perfectly while reflecting all others perfectly. The justification for the use of this idealised machinery here is much the same as in other branches of thermodynamics, as, for example, the use of ideal semi-permeable membranes in the study of mixtures of gases.

Next, consider the emission of radiation. This is defined in the same sort of way as above. A small volume dv of a body emits in time dt radiant energy $(\epsilon_\nu + \epsilon_\nu')d\nu d\omega dv dt$ into a solid angle $d\omega$. In the general case of an anisotropic body the two components of polarisation ϵ_ν and ϵ_ν' will both be functions of the direction of the element of solid angle. The emission from any substance in general

[1] See "Quantum Theory."

will depend on its past history (as in phosphorescence) or on the forces acting on it (as in tribo-luminescence and the light from discharge tubes). Now such effects as these are not steady state phenomena and so must be excluded from thermodynamic arguments. We shall exclude all such effects by the assumption that ϵ_ν and ϵ_ν' depend only on the nature of the matter composing dv, and on the temperature. Radiation which satisfies these conditions is called *temperature radiation*. The assumption includes what is known as Prevost's law of exchanges, viz., that a body emits an amount of radiant energy that depends only on its own temperature and not on that of its surroundings.

For absorption the type of definition is rather different. The absorption coefficient a_ν for any matter is defined by the fact that if a beam traverses a short length dl of it, then the beam's intensity is reduced by a fraction $a_\nu dl$ of itself, and the part which has disappeared from the radiation reappears as heat in the matter. For an anisotropic body a_ν will depend on the direction and polarisation of the beam. As a corollary, if a ray traverses a length l of matter its emergent intensity is a fraction $e^{-a_\nu l}$ of its incident.

§ (3) Radiation in the Steady State.—With these definitions it is possible to deduce many important consequences simply from the fact that a system left to itself tends to equalise in temperature and so arrive at a steady state. The proofs of these propositions are quite elementary and it will be unnecessary to give the chain of reasoning by which they are obtained.

(i.) The K_ν of a pencil of rays is invariant along its path in free space.

(ii.) K_ν is invariant for total reflection at any surface, plane or curved. (The concentration of light by a concave mirror is not due to any change in K_ν, but to an increase in the total solid angle through which the rays arrive at the focus.)

(iii.) In a non-homogeneous medium let the waves of frequency ν have refractive index μ_ν, varying from point to point. Then K_ν/μ_ν^2 is invariant along a pencil of rays.

These three results are really only matters of geometry.

(iv.) At a surface separating two media partial reflection occurs. Take an incident ray along the direction A, and suppose that a fraction ρ is reflected and a fraction $1-\rho$ refracted along B in the second medium; then the possibility of a steady state requires that the reverse ray coming along B should have a fraction ρ reflected and a fraction $1-\rho$ refracted into the first medium along A reversed.

A specially important case of this is that an ideal selective screen, which transmits light of one set of frequencies and reflects all others, must do so in exactly the same way from whichever side the light is coming. The same line of argument shows that it is impossible to combine the light from two sources by any optical device, so as to increase the K_ν of a pencil of rays. The results of (iv.) can be proved also on dynamical principles; the advantage of the present method is that it makes no reference to the mechanism of reflection and refraction.

(v.) Consider a vacuous space surrounded by perfectly reflecting insulating walls. In it are certain bodies of any character. By means of their radiations to one another they gradually set themselves to the same temperature. A test body placed anywhere in the space must also reach this temperature, and that through the action of radiation alone. By taking the test body as covered in turn with various types of selective screens, Nicol prisms, etc., it can be shown that the value of K_ν is the same at every point of the space and for every direction and polarisation of the rays. (If the refractive index differs from unity, K_ν must be replaced by K_ν/μ_ν^2.) This is the principal result of the argument—that in the steady state the radiation K_ν can depend only on ν and the temperature, and must be quite independent of the position, etc., of the ray examined. Such radiation is called *complete radiation*; also, for a reason that will appear later, *black radiation*. The determination of the form of K_ν as a function of ν and T is the cardinal problem of the radiation theory.

It is often convenient, in the general case where the radiation is not *complete*, to assign a meaning to the expression "temperature of a ray." This is defined as the temperature of the complete radiation which would give the same K_ν as the ray. The temperature of a ray can never be greater than that of the source from which it arose; this assumes that the radiation is temperature radiation. Conversely a body can never get hotter than the temperature of the hottest rays which strike it. To make a body as hot as possible by radiation it would be necessary to arrange some optical device whereby the hottest rays should strike it equally from all directions, while colder rays, of other frequencies, should be excluded by selective screens.

As the complete radiation is isotropic, it is convenient to use a quantity which makes no reference to the directions in which the rays are going. This is done by replacing the quantity K_ν by a derived quantity u_ν, where $u_\nu d\nu$ is the total energy in unit volume of frequencies between ν and $\nu+d\nu$. By summing the effects of all the rays passing through a small element of volume, it is easy to show that $u_\nu = 8\pi K_\nu/c$, where c is the velocity of light. The factor is 8π instead of the more usual 4π, because there are two components

of polarisation each with K_ν. u_ν will be the same at all points of the enclosure. (For the case with a refractive index the corresponding equation is $u_\nu = 8\pi K_\nu \mu_\nu / c$, and u_ν/μ_ν^3 will be the invariant.)

§ (4) KIRCHHOFF'S LAW.—In consequence of the universality of K_ν there must be a certain relation between the emission and absorption of every type of matter. Take a small body of volume v. A ray K_ν, in traversing it, loses an amount of energy $a_\nu K_\nu d\nu d\omega dtv$, by the definitions of § (2), and as the radiation must be the same on both sides of the body, this must be replaced by emission. The amount of the emission is $\epsilon_\nu d\nu d\omega dtv$. Therefore $\epsilon_\nu = a_\nu K_\nu$, and either $K_\nu = \epsilon_\nu / a_\nu$ or else both ϵ_ν and a_ν are zero. This result, Kirchhoff's law, may be stated as follows. The ratio of the coefficient of emission to the coefficient of absorption is the same for all substances whatever, and depends only on the temperature and the frequency of the rays examined. As long as only temperature radiation is considered this law admits of no exceptions. It is proved in the first place for bodies in an enclosure; its great utility lies in its extension to free space by virtue of Prevost's law of exchanges.

Kirchhoff's law makes it possible to deduce certain interesting and not very obvious consequences. For example, tourmaline polarises light by absorbing one component strongly, while transmitting the other. To the high absorption must correspond a high emission; so if a tourmaline crystal is heated, as it preserves the same characteristic when hot, it will emit polarised light, and the plane of polarisation will be perpendicular to that of the light which the crystal ordinarily transmits. Again, nebulae of a size thousands of times as large as the solar system emit light confined to a few lines in the spectrum. Therefore their matter is so rare and of such a peculiar character that a ray of light of any other frequency can go right through this enormous distance without experiencing any absorption whatever.

Next, suppose that we have a substance with the property that all radiation falling on its surface is completely absorbed. This is called a *black body*. Perfect blackness requires that there shall be no reflection at the surface, and this implies no change of refractive index there, and also that a_ν, the absorption coefficient, should be infinitesimal; the latter condition requires that the body should be of infinite depth. Such a surface has the property of emitting the complete radiation, whether enclosed in an envelope or in free space. For consider the radiation going into a small cone $d\omega$ at angle θ to the normal. One of the polarised components emitted by an element of volume $d\sigma dz$ at depth z below the surface is $\epsilon_\nu d\nu d\omega dt d\sigma dz$, and of this only a fraction $e^{-a_\nu z \sec\theta}$ gets through the surface. The beam outside is obtained by integrating this over all depths, and so is $(\epsilon_\nu/a_\nu) d\nu d\omega dt \cos\theta d\sigma$. Hence by Kirchhoff's law the K_ν outside is exactly the same as what it would be in an enclosed space at the same temperature as the black body; this explains why *complete radiation* is often called *black*.

In consequence of the presence of the factor $\cos\theta$ in the above formula a black surface will appear equally bright viewed from any angle. Any departure from the condition of blackness destroys this. For example, a change of refractive index at the surface involves partial reflection, and it is well known from optical theory that the oblique rays are more reflected than the perpendicular. Therefore such a surface will emit less light obliquely than perpendicularly.

The importance of the idea of the black body is that it makes it possible to get away from the highly idealised arguments about radiation in a completely enclosed space, and so to connect pure theory with the results of observation. To find the experimental values for the complete radiation it will be sufficient to determine the energy emitted (in various frequencies) from a black body of known temperature. In order to find its amount this energy must be completely absorbed. Thus both source and receiver must be black. The best form of source is a small hole in the wall of a furnace; for the absorption of such a hole is nearly perfect, since any ray that enters will undergo many reflections before coming to the hole again, and so will be practically completely absorbed, and therefore the emission of such a hole must also be nearly that of a black body. The same form is sometimes used for the receiving instrument; but in cases where there is little intensity of radiation it is necessary to concentrate the heat absorbed on as small an area as possible, so as to get the greatest temperature rise. It is therefore covered with platinum black or lamp black, and by subsidiary experiments an estimate is made of the imperfection of its blackness. For this part of the subject see "Radiation."

§ (5) STEFAN'S LAW AND WIEN'S LAW.—The theorems hitherto obtained were all based simply on the idea of equalisation of temperature. By the use of the second law of thermodynamics in the form that perpetual motion is impossible, two very important theorems can be proved—the law of Stefan and Boltzmann, and the displacement law of Wien. These are both concerned with complete radiation, and it will be convenient to replace the fundamental K_ν by the derived quantity u_ν, which depends on the energy per unit volume.

(i.) The total radiation of all frequencies in unit volume is denoted by $u=\int_0^\infty u_\nu d\nu$. It is a function of the absolute temperature T only and the Stefan-Boltzmann law [1] asserts that it is proportional to the fourth power of T.

First observe that the second law of thermodynamics requires that radiation should exert a pressure. Otherwise it would be possible to concentrate the radiation inside a perfectly reflecting cylinder by pushing in the piston, without doing any work; and the concentrated energy could be absorbed by a body hotter than that from which it was emitted. From the electromagnetic theory Maxwell showed that this pressure is equal to $\frac{1}{3}u$ for isotropic radiation and this leads to the result sought.

Consider a cylinder of volume V with perfectly reflecting walls. At one end in it is placed a small piece of matter to act as a vehicle for the transfer of heat from outside into radiant energy in the cylinder. The total energy of radiation is Vu. Now suppose that the volume is increased by an amount dV, while at the same time heat flows in from the outside and is partly converted into radiation by the piece of matter. The amount of heat absorbed will be

$$\mathrm{C}d\mathrm{T}+d(\mathrm{V}u)+\tfrac{1}{3}ud\mathrm{V},$$

or

$$\left(\mathrm{C}+\mathrm{V}\frac{\partial u}{\partial \mathrm{T}}\right)d\mathrm{T}+\tfrac{4}{3}ud\mathrm{V},$$

where C is the heat capacity of the matter. Now following the ordinary thermodynamic argument, if this is divided by T the result must be a perfect differential, and for this to be so

$$\frac{\partial}{\partial \mathrm{V}}\left(\frac{\mathrm{C}}{\mathrm{T}}+\frac{\mathrm{V}}{\mathrm{T}}\frac{\partial u}{\partial \mathrm{T}}\right)=\frac{\partial}{\partial \mathrm{T}}\left(\frac{4}{3}\frac{u}{\mathrm{T}}\right),$$

which leads to $\partial u/\partial \mathrm{T}=4(u/\mathrm{T})$. If this equation is integrated the result is $u=\sigma \mathrm{T}^4$, where σ is a constant. This is Stefan's law. A further consequence which will be required later is that in an adiabatic expansion VT^3 is constant.

The argument can be reversed so that the law of pressure may be deduced from Stefan's law. Thus, if the pressure is supposed to be the unknown f, an equation of the form $(\partial f/\partial \mathrm{T})-f/\mathrm{T}=u/\mathrm{T}$ must hold. Now if $u=\sigma \mathrm{T}^4$ is substituted and the equation integrated the result is $f=\frac{1}{3}u+a\mathrm{T}$, where a is an integration constant. So apart from this constant Stefan's law leads straight to Maxwell's law of radiation pressure. It is far the most accurate verification of the validity of that law, as the pressure itself is so exceedingly minute as to be barely perceptible to direct observation.

(ii.) The relation of Stefan and Boltzmann concerns only the total radiation, and has nothing to say as to the distribution in the various parts of the spectrum. If thermodynamics are to be made to give any information about this, it is necessary to have some mechanism whereby radiation of one frequency can be changed reversibly into another. The usual mechanism of conversion is by absorption and re-emission, but as long as the relation $\mathrm{K}_\nu=\epsilon_\nu/a_\nu$ is satisfied the thermodynamic conditions are fulfilled and so this method gives no help. But there exists another way of changing frequencies, namely, by the Doppler effect; that is, by reflection of the rays at a moving mirror. By the use of this idea it is possible to deduce a relation connecting u_ν, ν, and T. The argument falls into two parts—a thermodynamic and a mechanical. The former shows that, under certain conditions, if a reflecting enclosure is filled with *complete* radiation and then expanded adiabatically, the radiation will remain *complete*, without the intervention of matter. The second part consists in calculating the actual change in the radiation produced by the expansion.

(*a*) Consider the adiabatic compression of a cylinder with perfectly reflecting walls, supposing that some part of the walls reflects diffusely, so that the radiation certainly remains isotropic. At every stage the work done depends on the pressure, and this is given by the density of the total radiation. So whether the radiation remains *complete* or not, the energy density will be the same at every stage, and so will the work of compression. The relation VT^3=constant implies that when the volume is V the density of total radiation is the same as that of complete radiation of temperature T.

Now imagine that the effect of the adiabatic compression is to make the radiation no longer complete. Take V_1 as the initial volume, and suppose it filled with complete radiation of temperature T_1. Compress the cylinder slowly by a finite amount to volume V_2. Then if $\mathrm{V}_2\mathrm{T}_2^3=\mathrm{V}_1\mathrm{T}_1^3$, the density of total radiation will be the same as that of complete radiation of temperature T_2, but by hypothesis some spectral regions will be in excess and some in defect. Now introduce a small piece of matter of negligible heat capacity. This will readjust the radiation to completeness, but will not alter its total amount. The adjustment is an irreversible process and so involves an increase of entropy. Next, keeping the matter in the cylinder, slowly expand to the original volume. The work gained in the up-stroke is exactly equal to that done in the down-stroke, for they both depend only on the total radiation. If the matter is now withdrawn, the system will have returned to its original state, and no heat has been communicated from outside. The cycle could be repeated indefinitely and it would be possible to get a continual increase of entropy without any introduction of heat or performance of work; and this is contrary to thermodynamic principles. Therefore the adiabatic compression must conserve the completeness of radiation.

There is one small point in the proof worth mentioning. Reflection at a moving mirror not only changes the frequency, but also the direction of the light. If the walls are perfect cylinders with perpendicular ends, the compression will make the radiation anisotropic, and so of course not complete. This is the reason why it was necessary to specify that some part of the walls must reflect diffusely.

(*b*) It is now necessary to examine the effect on radiation when it is reflected at a moving mirror;

[1] See "Radiation," Part II.

in particular to count up the losses and gains for a small region $d\nu$ of the spectrum. If a beam inclined at angle θ falls on a mirror moving with small velocity v, it may be shown that the frequency of the reflected beam is $\nu'=\nu(1-2(v/c)\cos\theta)$ and that its direction is given by $\theta'=\theta+2(v/c)\sin\theta$. There is also a change in the intensity, since work is done on the mirror. It may be shown that the ray $u_\nu d\nu\,(\sin\theta d\theta d\phi/4\pi)$ (ϕ is the azimuthal angle) exerts a pressure

$$2\cos^2\theta\, u_\nu d\nu\,(\sin\theta d\theta d\phi/4\pi).$$

Now consider the gains and losses to the region $d\nu$. Of energy originally in this region and at this angle an amount

$$u_\nu d\nu\,(\sin\theta d\theta d\phi/4\pi)\,(c\cos\theta-v)dtd\sigma$$

strikes the mirror in time dt and in the element of area $d\sigma$. This energy is all lost. Summing over all angles the gross loss is

$$u_\nu d\nu\,\{(c/4)-(v/2)\}dtd\sigma.$$

There is a compensating gain from the light which has its frequency brought into $d\nu$. This comes from various regions. If one of them had frequency between ν_0 and $\nu_0+d\nu_0$ before reflection and inclination between θ_0 and $\theta_0+d\theta_0$, then $\nu_0=\nu\{1+2(v/c)\cos\theta\}$, and $\theta_0=\theta-2(v/c)\sin\theta$. The energy in this region gives after reflection an amount in $d\nu$ equal to

$$u_{\nu_0}d\nu_0\left(\frac{\sin\theta_0 d\theta_0 d\phi}{4\pi}\right)(c\cos\theta_0-v)dtd\sigma$$
$$-2\cos^2\theta u_\nu d\nu\left(\frac{\sin\theta d\theta d\phi}{4\pi}\right)vdtd\sigma,$$

the subtraction of the second term being due to the disappearance of energy in performing work. If $u_\nu+(\nu_0-\nu)(\partial u_\nu/\partial\nu)$ is written for u_{ν_0} and if the values of ν_0 and θ_0 are substituted and the result integrated over all angles, it gives as the gross gain

$$\left[u_\nu\left(\frac{c}{4}-\frac{v}{2}\right)+\frac{v}{3}\nu\frac{\partial u_\nu}{\partial\nu}\right]d\nu dtd\sigma.$$

The net gain is therefore

$$\tfrac{1}{3}\nu\frac{\partial u_\nu}{\partial\nu}d\nu vdtd\sigma,$$

and if this is summed over the whole mirror it becomes

$$\tfrac{1}{3}\nu\frac{\partial u_\nu}{\partial\nu}d\nu dV,$$

where dV is the total gain of volume in the time dt. Thus adiabatic expansion requires the equation

$$d(Vu_\nu)=\tfrac{1}{3}\nu\frac{\partial u_\nu}{\partial\nu}dV,$$

or written as a partial differential equation

$$\tfrac{1}{3}\nu\frac{\partial u_\nu}{\partial\nu}-V\frac{\partial u_\nu}{\partial V}=u_\nu.$$

The general solution of this equation is

$$u_\nu=\nu^3F(V\nu^3),$$

where F is an arbitrary function. But, since VT^3 remains constant in adiabatic expansion, $V=\text{constant}/T^3$, and this equation can be rewritten

$$u_\nu=\nu^3 f_1\left(\frac{\nu}{T}\right),$$

and this is Wien's displacement law.

The relation $u_\nu=\nu^3 f_1(\nu/T)$ makes it possible to deduce the radiation curve (that is, the curve connecting u_ν and ν) for any temperature once it is known for a single temperature. All purely thermodynamic conditions are now satisfied and the determination of the form of the function f_1 must invoke other principles. It is not surprising that it should not be possible completely to determine it; it is like the fact that no thermodynamic argument can completely determine the equation of state of a gas.

In connection with experimental work it is customary to use wave-length instead of frequency. This alters the form of the displacement law. Let

$$E_\lambda d\lambda=u_\nu d\nu,$$

so that E_λ is the density of isotropic energy per unit wave-length. If use is made of the relation $\lambda=c/\nu$ the law is given in the form

$$E_\lambda=\lambda^{-5}f(\lambda T).$$

§ (6) Planck's Radiation Formula.—The true radiation formula was found by Planck. Its theoretical deduction is given under "Quantum Theory."[1] The formula is

$$E_\lambda=\frac{8\pi hc}{\lambda^5(e^{hc/k T\lambda}-1)}.$$

Here c is the velocity of light—$2\cdot9986\times10^{10}$ cm. per sec.—and k and h are universal constants. k is the atomic gas constant; that is, $\frac{3}{2}kT$ is the mean kinetic energy of a molecule of a monatomic gas (supposed a perfect gas) at absolute temperature T. Its value is approximately $1\cdot372\times10^{-16}$ erg deg.$^{-1}$. h is the quantum, and its value is approximately $6\cdot55\times10^{-27}$ erg sec. Observe that the expression satisfies Wien's displacement law.

In *Fig.* 1 the firm line shows the curve for $T=1000°$ abs. The main characteristic of the curve is the rapid fall from the maximum on the side of short wave-lengths and the much more gradual fall on the other side. The unit for λ is 10^{-4} cm.—the visible spectrum would come about in the region between 0·4 and 0·8 of λ. E_λ is in C.G.S. units. Its significance will be made clearer by the statement that the energy in 1 c.c. in a spectral region of breadth 1 Å.U. (10^{-8} cm.) is $17\cdot38\times10^{-8}$ erg at the wave-length 28,850 Å.U. (the values are those at the maximum point).

The corresponding curve at a higher temperature T′ is obtained by shortening each λ in the ratio T/T′ and lengthening the corresponding E_λ in the ratio $(T'/T)^5$. The chain curve in *Fig.* 1 is that for the absolute temperature 1100°, and it may be seen what a large increase in the radiation is made by a

[1] See "Quantum Theory," § (4).

comparatively small change of temperature. Of two curves the hotter always lies entirely outside the colder.

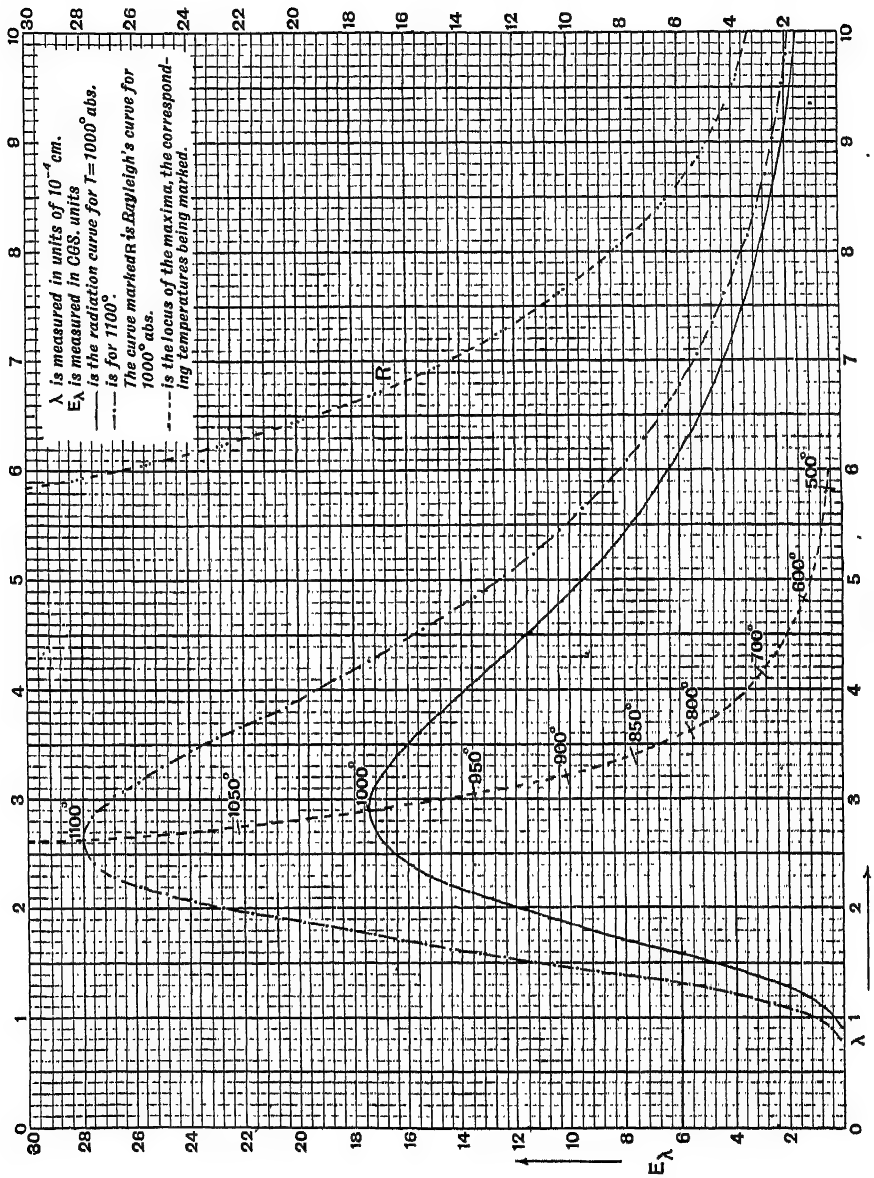

FIG. 1.

On the side of the short wave-lengths the curve is closely approximate to

$$E_\lambda = \frac{8\pi hc}{\lambda^5} e^{-hc/k T\lambda},$$

which is known as Wien's formula. The curve for this expression would lie very close to the corresponding curve of *Fig.* 1, except on the extreme right, where it would fall somewhat below it. Apart from the fact that it is a convenient approximation, the interest of Wien's expression is mainly historical, as it was the earliest radiation formula to be suggested.

On the side of the long wave-lengths, but

far beyond the region shown in the figure, Planck's formula becomes approximately

$$E_\lambda = \frac{8\pi k T}{\lambda^4}.$$

This is known as Rayleigh's formula.[1] The curve in *Fig.* 1 marked R is the Rayleigh curve corresponding to 1000°. Its importance lies in the fact that it is undoubtedly the expression which ought to be found if the classical system of mechanics were valid. For its derivation see "Quantum Theory," § (4). Planck found his formula by combining those of Wien and Rayleigh, so that each should be verified in its region of validity, and the formula then led him to his great discovery of the quantum.

The position of the maximum ordinate is given by

$$\lambda_m = \frac{hc}{kT}\frac{1}{\alpha},$$

where α is the solution of the equation

$$1 - e^{-\alpha} = \frac{\alpha}{5};$$

that is, $\alpha = 4{\cdot}9651.$

The height of the maximum is proportional to T^5. Its locus is shown in the broken curve of *Fig.* 1. It is of interest to observe the position of the maximum for a few temperatures. At ordinary room temperature it is about 10^{-3} cm. At 1000° abs., a dull red heat, it is still at a wave-length more than four times that of visible light. Even at 2000°, which is a dazzling white heat, it is still more than twice the wave-length of visible light. Again, from the fact that the sun's radiation has its maximum in the yellow, it may be deduced that its temperature is nearly 6000° abs.—a result confirmed by the application of Stefan's law to its total radiation.

Stefan's constant[2] σ may be deduced from Planck's formula by integrating over all values of λ. This leads to the result

$$\sigma = \frac{8\pi^5}{15}\frac{k^4}{h^3c^3} \text{ erg cm.}^{-3} \text{ deg.}^{-4}.$$

The determination of the constants k and h is usually done in the following two stages. One relation is found by measuring the total radiation. This gives σ. The second is got from the shape of the curve or the position of the maximum, which it may be seen determines hc/k. The universal constants k and h found in this way by the most refined experiments are given with about the same order of accuracy as by other methods.

Radiation theory is dealt with very clearly and thoroughly in Planck's *Die Theorie der Wärmestrahlung*, 4th edition (Barth, Leipzig). Many text-books of modern physics devote a chapter to the subject; for instance, Richardson's *The Electron Theory of Matter* (Camb. Univ. Press).

Radioactive Constant of a Radio-element: a term used in radioactivity to denote the fraction of the total amount of radioactive material changing in a unit of time, the unit of time being so chosen that the quantity of radioactive material at the end of it is sensibly the same as that at the beginning. See "Radioactivity," § (5).

Radioactive Substances, rays from, capable of exciting certain materials to emit visible light. See "Luminous Compounds," § (1).

RADIOACTIVITY

§ (1) General Properties of Radioactive Bodies.—The property of radioactivity was discovered by Henri Becquerel in 1896 for compounds of uranium, which he found to be spontaneously emitting radiations capable of affecting a photographic plate and of penetrating considerable thicknesses of matter. The radiations were also found to cause certain salts to fluoresce and to ionise air and other gases through which they passed. A fuller examination of the uranium salts showed that no variation could be detected in the intensity or in the character of the radiation with lapse of time. The intensity depended simply on the amount of uranium present, and was independent of the physical conditions to which the uranium was subjected. In 1898 Madame Curie and Schmidt independently showed that the property of radioactivity was also shared by thorium and minerals containing that element. The radiations from uranium and thorium are complex in character and consist of three distinct types which will be considered in detail later. These are known as the α, β, and γ radiations; the α rays consist of a stream of positively charged particles projected with great velocity, and are very easily absorbed by thin sheets of metal foil and by gases; the β rays are far more penetrating and are identical with the negatively charged particles constituting the cathode rays in a discharge tube; the γ rays are exceedingly penetrating and are identical in character with X-rays, the only difference between them being that the wave-length of the former is much shorter than that of the latter.

A substance which is capable of *spontane-*

ously emitting these penetrating radiations is said to be "radioactive." Of the 80 or more elements known in 1896 only uranium and thorium, the two heaviest elements, were found to be radioactive, and all the other radio-elements known to-day are derived from these two elements.

In addition to these radiations some of the radio-elements produce what are known as radioactive emanations which are gaseous. The emanations can be condensed at the temperature of liquid air, but even at ordinary temperatures they impart radioactivity to solid objects with which they come into contact.

In 1899 and 1900 the results of several investigations showed that some radioactive substances, unlike uranium, which showed no appreciable change of activity over a period of years, lost the greater part of their activity in the course of a few minutes or hours. For example, it was found that the emanation from thorium lost half its activity in less than one minute. Hence, in addition to the more permanent radioactive elements, there were others with only a transient existence.

§ (2) Uranium X.—Madame Curie had shown in her early experiments that the radioactivity of uranium was an atomic phenomenon. It is unaffected by chemical combination with other inactive elements. Crookes,[1] however, showed that by a single chemical operation, namely precipitating a solution of uranium with ammonium carbonate, the uranium could be obtained photographically inactive while the whole of the activity could be concentrated in a small residue free from uranium. This residue, which was called Uranium X, was many hundred times more active photographically weight for weight than the uranium from which it had been separated. A similar result was obtained by Becquerel, who found that barium could be made photographically very active by adding barium chloride to a uranium solution and precipitating the barium as sulphate. After a number of precipitations the uranium was rendered photographically inactive while the barium was strongly active. These results seemed to point to the fact that the activity of uranium was not due to the element itself but to some other substance which was associated with it.

The active barium and the inactive uranium in the last experiment were left for a year and again examined. It was now found that the uranium had completely regained its activity, while the activity of the barium sulphate had completely disappeared. The loss of activity of uranium was therefore only temporary in character.

§ (3) Thorium X.—Rutherford and Soddy[2] carried out similar experiments on thorium and were able in a single chemical operation to separate an intensely active constituent from thorium. This they called Thorium X. In a month's time the thorium X had lost all its activity whilst the thorium had completely regained it.

§ (4) Decay and Recovery of Uranium X.—The next step was to examine the time rate at which the processes of decay and recovery of activity took place. Uranium X emits only β rays, whilst uranium gives out only α rays. If all the measurements are made with β rays, the ionisation produced will depend on the quantity of uranium X present and not on the quantity of uranium—the uranium will be effective only in so far as it produces uranium X.

The uranium is left for some months so as to come into equilibrium with its product uranium X; they are then separated by one of the methods already mentioned. The β ray activity of the uranium will at first be zero, but it will gradually increase as uranium X is formed, whilst the activity of the uranium X falls off according to an exponential law. The two curves shown in *Fig.* 1 show the rates at

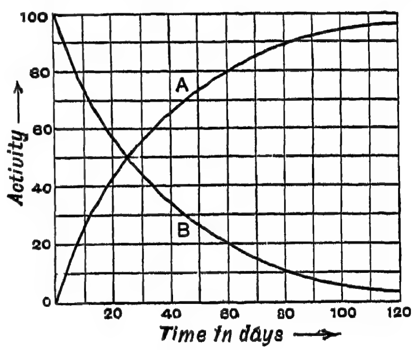

Fig. 1.

which the decay (curve B) and recovery (curve A) of uranium X take place. The sum of the β ray activities of the uranium and the uranium X is constant, showing that uranium X is being produced from uranium at exactly the same rate as it is decaying when separated from uranium. The curves show also that it decays to half value in 25 days.

Similar results have been obtained with other radioactive products separated from their parent elements, and the law that the rate of decay of activity of a given product is exactly equal to the rate of recovery of activity of the substance from which it has been separated, is universally true.

The decay curve in *Fig.* 1 shows that uranium X loses its activity according to an exponential law with the time. It will be seen later that

[1] Crookes, *Roy. Soc. Proc.*, 1900, A, lxvi. 409.
[2] Rutherford and Soddy, *Phil. Mag.*, 1902, iv. 370 and 569.

this is the general law of decay of activity in any type of radioactive matter, separated from its parent and from any secondary active products which it may itself produce. When this law is not fulfilled it can be shown that the activity is due to the superposition of two or more effects, each of which decays according to an exponential law with the time.

§ (5) THE RADIOACTIVE CONSTANT.—If N_0 is the number of atoms of any given product present at any time taken as zero, and N_t the number remaining after an interval of time t, then according to the above law of decay

$$N_t = N_0 e^{-\lambda t}, \quad . \quad . \quad . \quad (1)$$

where λ is a definite constant characteristic of the given product. The above equation may be written,

$$\frac{dN_t}{dt} = -\lambda N_t, \quad . \quad . \quad . \quad (2)$$

so that λ represents the fraction of the total amount of radioactive material changing in a unit of time, the unit of time being so chosen that the quantity of radioactive material at the end of it is sensibly the same as that at the beginning. It has different values for different types of radioactive material, but is invariable for any particular type of material. This constant λ is called the *radioactive* or *transformation constant* of the radio-element.

§ (6) THE HALF-VALUE PERIOD.—There is another constant which is extensively used in radioactivity. This is the *half-value period* or the *period of half change* of a radioactive substance. This is the time taken for the atoms present in a radio-element to decrease to half their number. Denoting this by T, equation (2) gives

$$T = 0 \cdot 6932 \, . \, \frac{1}{\lambda}. \quad . \quad . \quad . \quad (3)$$

The decay curve of uranium X given in *Fig.* 1 will be represented by equation (1) above, if the correct value is substituted for the radioactive constant λ. The equation for the recovery curve is at once obtained from the fact that at any time the sum of the quantity of uranium X in the portion separated from the uranium and the quantity produced by the uranium is a constant. It is

$$N_t = N_0(1 - e^{-\lambda t}), \quad . \quad . \quad . \quad (4)$$

where N_0 is the number of atoms of uranium X finally produced by the uranium.

The rate of decay of a radio-element is absolutely independent of any variation in physical and chemical conditions. For example, the decay of activity of any product takes place at the same rate when exposed to light as when it is kept in the dark, and at the same rate in a vacuum as in air or any other gas at atmospheric pressure. The activity is unaffected by intense heat or extreme
Electric discharges and strong magnetic f
are quite ineffective in producing a chan
the rate of decay.

factory way for all known facts of radioacti

The general law governing the rate of d
or, in other words, the rate of disintegrati
all radioactive substances (given by equ
(1)) states that the number of atoms brea
up per unit time is proportional to the nu
of atoms present. The number of a
breaking up in a given time is subjec
fluctuations round the average value of
magnitude to be expected from the ge
probability theory, so that λ, the radioa
constant, represents the *average* fraction o
number of atoms which break up per
time. The fraction of a product transfo
per second is independent of the age of
product and does not depend upon the
centration of the active matter itself.
found that radium emanation, for insta
more than three months old decays at ex
the same rate as emanation freshly prod
by radium; the chance of an atom brea
up in a given time is the same whether
produced a second before or has existed i
pendently for a long period of time. T
facts lead to the conclusion that radioacti
as far as the individual atom is concerne
an instantaneous phenomenon. There i
gradual loss of energy. Before and up to
actual moment of disintegration the atom
radio-element is in no way different fro
atom of an inactive element. Similarly
new atom produced after disintegratio
similar in all respects to an ordinary a
Hence any atom may exist unchanged fo
time from zero to infinity.

§ (8) THE PERIOD OF AVERAGE LIFE O
ATOM.—It is often convenient to speak o
average life of a large number of atoms.
be the number of atoms present at the t
then after an interval of time t the nu
which change in the time δt is equal to
(from equation (2) above) or $\lambda N_0 e^{-\lambda t} \delta t$.

[1] Rutherford and Soddy, *Phil. Mag.*, 1903, v.

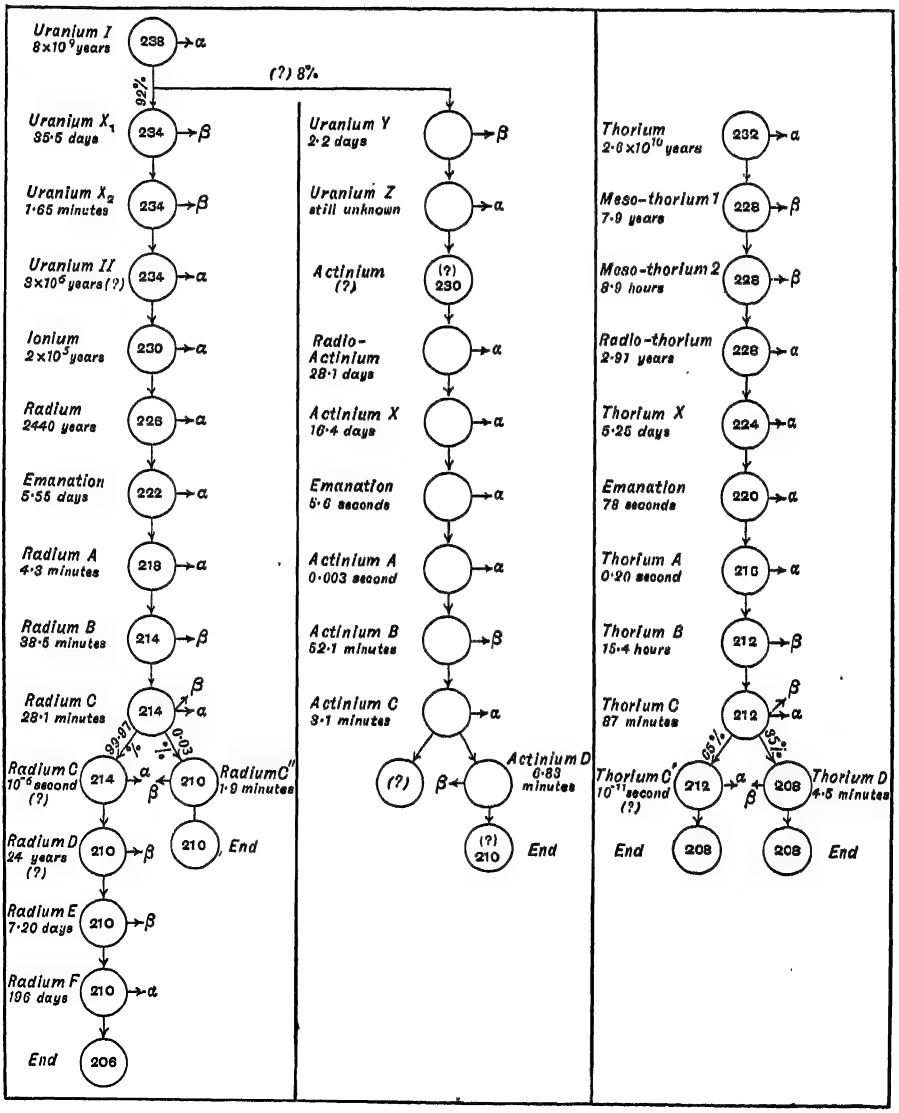
of these atoms has a life t, so that the average life of the total number is given by the expression

$$\int_0^\infty \lambda t e^{-\lambda t} \, . \, dt,$$

and this is equal to $1/\lambda$, that is, the period of average life of an atom is the reciprocal of the radioactive constant. The *period of average life of an atom* based on the above calculation may be defined as the sum of the separate periods of future existence of all the individual atoms divided by the number in existence at the starting-point, any time being taken as the starting-point. The constant relates, therefore, to the future life of the atom and is independent of the period the atom has already been in existence.

The period of average life of each of the atoms in the three disintegration series—radium, actinium, and thorium—is included in the following table, which also gives the atomic weight of the product together with the radiation emitted by it.

TABLE I



§ (9) Radioactive Equilibrium.—Each of the three disintegration series given in Table I. consists in a long succession of changes, P producing Q, Q producing R, and so on. The rate of change varies from product to product, but in each case it follows an exponential law. If a radioactive mineral is sealed up so that the products of transformation are allowed to accumulate, a stage is ultimately reached in which the amount of each product formed is equal to the amount transformed per unit time throughout the series. In this state there is a balance between the loss of activity of the matter already produced and the gain of activity due to the production of new active matter. Material which has reached this state is said to be in *radioactive equilibrium.*

It is evident that in the state of radioactive equilibrium the number of atoms disintegrating per unit time is the same for each product. So that if P, Q, R are the amounts of the successive members of the series present when radioactive equilibrium obtains, and λ_1, λ_2 and λ_3 their respective transformation constants, then

$$\lambda_1 P = \lambda_2 Q = \lambda_3 R. \quad . \quad . \quad . \quad (5)$$

The amount of each product present is therefore inversely proportional to its radioactive constant or directly proportional to its period of average life. According to the above relation there is a constant proportion between the quantities of successive members of a system in radioactive equilibrium. Thus in old uranium minerals the ratio of the amount of radium to uranium is always the same, there being about 3·2 tons of uranium for every gramme of radium. Now the period of average life of radium is known to be 2440 years, so that by the above relation the period of average life of uranium must be about 8×10^9 years. This relation may in this way be used to calculate the period of a long-lived product when its amount, relative to another whose period can be measured, is known. It is useful also to measure the quantity of a short-lived product when its period can be determined. Hence if the period and amount of a product in a given series are known and the period or amount of another product in the series can be measured, the remaining unknown quantity for this product can be calculated. In the radium series both the period and amount of emanation can be measured accurately with the result that the same information can be obtained by calculation for most of the other members of the series and for uranium itself.

The activity of a product is measured by means of effects produced by the radiations which it emits, and before proceeding further it would be advisable to consider the properties of these radiations in detail.

§ (10) Radiations of Radioactive Substances.—The first analysis of the complex radiations emitted by the radio-elements was made by Rutherford.[1] Two general methods were employed to distinguish between the types of radiations given out by the same body and to compare the radiations from different radio-elements. These were based on:

(i.) The deflection of the rays in a magnetic or in an electric field.

(ii.) The relative absorption of the rays in solids and gases.

Experiments carried out on these lines revealed three distinct types of radiation emitted by the radio-elements, which Rutherford called the α, β, and γ rays respectively. The difference between these radiations is brought out very clearly when a radioactive substance emitting the three kinds is placed in a strong magnetic field. Suppose a small quantity of radium in equilibrium with its products is placed at the bottom of the central hole in a lead cylinder L which rests on a photographic plate P. If a strong magnetic field be applied at right angles to the plane of the paper and directed towards the paper the three types are separated from one another in the manner shown diagrammatically in the figure. The γ rays proceed without deviation.

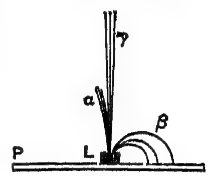


Fig. 2.

The α rays are deflected slightly to the left whilst the β rays move to the right, describing circular orbits whose radii vary within wide limits. The β rays are so much bent round that they strike the photographic plate, producing a diffuse impression upon it. The same relative effects are produced by the application of an electric field. It should be mentioned, however, that the deviation produced in the α ray beam is exceedingly small compared with that produced in the β ray beam. So small is the deviation produced in the case of the α rays that for some time they were thought to be non-deviable by a magnetic field until Rutherford[2] in 1903, by using a more active preparation of radium than had been previously employed, showed that they were deflected both by a magnetic and by an electric field. These experiments show that the α particles carry a charge opposite to that carried by the β particles. The latter were found by Giesel to be similar to the cathode particles in a discharge tube and therefore carried negative charges, whilst the former are similar to the canal rays in a discharge tube which had been shown by Wien to consist of positively charged particles travelling at great velocities.

[1] Rutherford, *Phil. Mag.*, 1899, xlvii. 116.
[2] *Ibid.*, 1903, v. 177.

§ (11) α Rays. (i.) *Range of α Rays.*—The α rays produce intense ionisation along their path in a gas, and, in consequence, they rapidly lose their kinetic energy until their velocity is reduced below the value at which they can ionise. Bragg and Kleeman [1] showed that the ionisation due to a homogeneous pencil of α rays ends after the rays have traversed a certain distance in air, this distance being called the range of the α particle in air. The range of an α particle from a simple product is a constant for a definite temperature and pressure of the gas traversed. It varies inversely as the pressure and directly as the absolute temperature, so that in specifying the range it is important to state the temperature and pressure as well as the nature of the gas. Different products emit α rays of different ranges, so that the range of the α particle is characteristic of the product from which it is emitted.

Geiger and Nuttall [2] employed the following method for determining the range, and it is applicable to every kind of radioactive matter provided the latter is not gaseous. The active material is placed in the form of a thin film on a small metal disc D in the centre of a metal bulb whose internal diameter is about 8 cm.

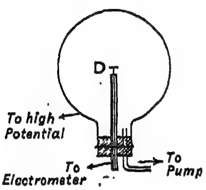

Fig. 3.

The disc, which is insulated from the bulb, is connected to one pair of quadrants of an electrometer, and the metal bulb is connected to a potential sufficiently high to produce the saturation current. Through the insulated stopper also passes a tube by means of which the bulb can be exhausted. The method of procedure was to measure the saturation current at different pressures. The results obtained are shown in *Fig.* 4. For low pressures the ionisation is very nearly proportional to the pressure, but when the pressure has reached a value such that all the α particles are completely absorbed in the gas, the ionisation current reaches a maximum value which remains constant with further increase of pressure, except in the case when two products in equilibrium were examined, in which case there are two abrupt breaks in the curve. The pressures at which the breaks in the curves occur correspond to the maximum ranges of the α particles in the gas at those pressures. The knowledge of this pressure enables the range in air at atmospheric pressure to be deduced, since the range is inversely proportional to the pressure.

[1] Bragg and Kleeman, *Phil. Mag.*, 1905, x. 318.
[2] Geiger and Nuttall, *ibid.*, 1911, xxii. 613; 1912, xxiii. 439; xxiv. 647.

Geiger [3] had previously found that the following relation existed between the range R of the α particle and its velocity V—

$$R = aV^3, \quad . \quad . \quad . \quad . \quad (6)$$

i.e. the range is proportional to the cube of the velocity. The results of Geiger and Nuttall showed that a definite relation existed also

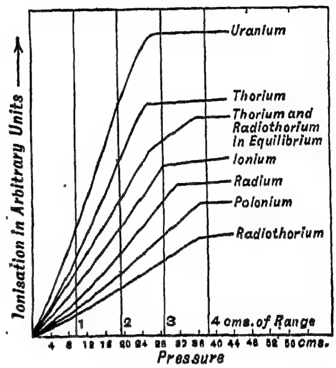

Fig. 4.

between the range and the radioactive constant of the substance emitting the radiation. This is shown graphically in *Fig.* 5.

If the range of the α particle of any product is known the period of this product can be deduced from this relationship. Thus the period of average life of uranium II should be about 3×10^6 years, and that of ionium 3×10^5

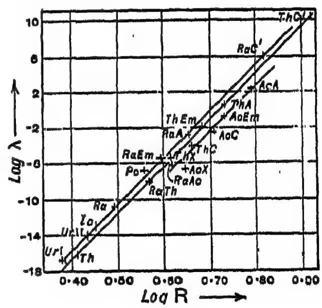

Fig. 5.

years, periods too long for direct determination. Similarly from the long range α particles emitted by radium C′ and thorium C′, the very short periods of these products can be deduced; these would be of the order of 10^{-6} and 10^{-10} seconds respectively.

The curves show that those products whose average life is long emit α rays whose range is small, and *vice versa*.

[3] Geiger, *Roy. Soc. Proc.*, 1910, A, lxxxiii. 5

(ii.) *The Stopping Power of Metal Foils.*—If a thin metal foil is inserted in the path of an α particle, the distance it will travel in air will be reduced. The difference between the range of the particle with and without the foil interposed is called the *stopping power* of the foil.

Stopping power is an atomic property. Bragg and Kleeman [1] found that for a single atom it is proportional to the square root of the mass of the atom, and for a molecule it is proportional to the sum of the square roots of the masses of the atoms composing that molecule. Two films will therefore have the same stopping power if the number of atoms contained per unit area is in the inverse ratio of the square root of their atomic masses.

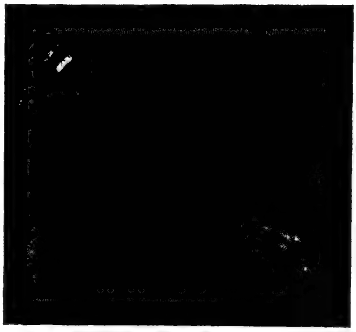

FIG. 6A.

The stopping power of an atom depends upon the speed of the particles. It is, however, almost independent of the speed in the case of substances of about the same atomic weight [2] as air, but it decreases with diminishing speed of the α particle for heavier molecules.

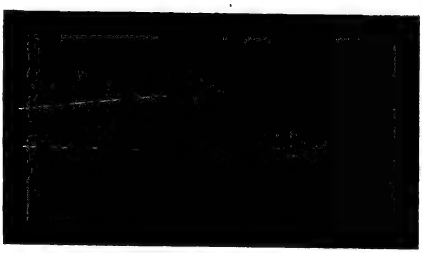

FIG. 6B.

When a stream of particles falls on a sheet of metal foil, some of the particles will come into direct collision with the atoms composing the foil. The particles travel with a velocity of the order of 10^9 cm. per sec., but however fast they travel we should expect that in a direct collision they would be stopped. This, however, was not found to be the case by Bragg and his colleagues. From their researches they concluded that each α particle pursued a rectilinear course, no matter what it encountered; it passed through all the atoms it met, whether they formed part of a solid or a gas, suffering little or no deflection on account of any encounter until very near the end of its course. A thin metal plate placed in a stream of particles robbed every particle of some of its energy, but the number of particles in the stream before and after traversing the thin sheet remained the same. Hence an α particle appeared to pass clean through atoms of matter in its path as if they were not there, in which case two atoms of matter occupy the same space at the same time. In passing through the atom some of the energy of the particle is absorbed and its velocity therefore diminishes as it pursues its course. Further, the slower it moves the more easily is it deviated from its course or scattered.

(iii.) *Visible Tracks of α Particles.*—C. T. R. Wilson [3] succeeded in making visible the tracks of α particles as they pass through a gas. The method consists in suddenly expanding moist air in a closed space, during which operation the moisture condenses on the ions formed by the particle along its path. By suitably illuminating the expansion chamber, the tracks of the particles can be made visible and actually photographed. The tracks of α particles from radium are shown in *Fig.* 6. It will be observed that the tracks are almost all perfectly straight, but there are a few which show abrupt large deflections, especially towards the end of the path (see *Fig.* 6B, which is an enlarged portion of *Fig.* 6A). The chance of a "single" scattering through a large angle increases rapidly with decrease of velocity of the particle, and in consequence such scattering will be most in evidence near the end of the range of the particle.

(iv.) *Counting of α Particles.*—Two methods have been employed to count the number of α particles emitted by a radioactive body.

(*a*) *The Scintillation Method.*—This is based upon the fact that each α particle produces one scintillation when it strikes a screen of a substance such as zinc sulphide (see article on "Luminous Compounds"). The method of procedure is to fix the screen to the microscope at such a distance from the objective that it is perfectly in focus. The microscope

[1] Bragg and Kleeman, *Phil. Mag.*, 1905, x. 318 and 600.

[2] The atomic weight of the hypothetical atom of air may be taken as 14·4.

[3] Wilson, *Roy. Soc. Proc.*, 1912, A, lxxxvii. 277.

is mounted on a graduated stand along which it can slide and be placed at any desired distance from the α ray source. It is advisable to use a microscope with a low-power eyepiece combined with an objective of high light-collecting power, and the area of the field of view need not be larger than about one square millimetre. Also the counting is facilitated if the screen is very faintly illuminated so as to keep the eye the more easily focussed upon it. Measurements can be made most accurately with about 40 scintillations per minute. With more than about 80 or less than about 10, the counting becomes troublesome and uncertain. It is best to count for one or two minutes, afterwards resting the eye to count again for another one or two minutes, and so on. It is also essential to remain in the dark for about half an hour before starting to count, so as to get the eye quite accustomed to the dark.

(*b*) *Rutherford and Geiger's*[1] *Electrical Method.*—In this method the ionisation produced by each α particle is magnified by using the principle of the production of ions by collision. In this way the small ionisation current produced by a single α particle may be magnified several thousand times and thereby be

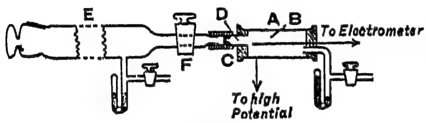

FIG. 7.

sufficiently strong to produce an easily measurable deflection of the needle of an ordinary electrometer. The apparatus employed is shown in *Fig.* 7. The detecting vessel consisted of a brass cylinder A, from 15 to 20 cm. in length and 1·77 cm. in diameter, with an insulated central electrode B connected to one pair of quadrants of an electrometer. The outside of the vessel was connected with the negative pole of a battery giving 1320 volts. The tube D fitting into the ebonite plug C had a circular opening 1·5 mm. in diameter at one end, the opening being covered with a very thin sheet of mica. The thickness of the mica sheet was equivalent in stopping power of the α particle to about 5 mm. of air at ordinary temperature and pressure. The glass vessel E, connected to the detecting vessel as shown, was about 450 cm. in length. The active matter was placed in this vessel in the form of a thin film of small surface area, and its distance from the aperture in D could be varied to any desired value. This vessel was exhausted to a low vacuum whilst the detecting vessel contained carbon dioxide at a pressure of about 4 cm. When the stopcock F was closed no α particles passed into the chamber, and the steadiness of the electrometer needle could thus be tested at intervals during the experiment. On opening the stopcock a small fraction of the total number of α particles emitted by the source passed through the aperture into the detecting vessel. The intensity of the source and its distance from the aperture were adjusted so that three to five α particles entered the chamber per minute. A ballistic throw of the electrometer marked the entrance of an α particle into the chamber.

If Q be the number of α particles expelled per second from the source at a distance r from the aperture of area A, then, since α particles are on the average projected equally in all directions, the number (n) of α particles entering the detecting vessel per second is given by $n = QA/4\pi r^2$. This expression holds so long as each portion of the active source can fire particles through the aperture.

By this method Rutherford and Geiger found that $3{\cdot}57 \times 10^{10}$ α particles were expelled per second from one gramme of radium itself. It is also known that the same number of α particles is emitted per second from one gramme of radium itself and from each of the next three α-ray products in equilibrium with it. So that the number of α particles expelled per second from one gramme of radium in equilibrium with its products is $14{\cdot}3 \times 10^{10}$.

The above method was modified later by the use of a string electrometer, the movements of whose quartz fibre could be photographically recorded on a moving film. In this way it was possible to detect with certainty the effect of each α particle even when 1000 particles

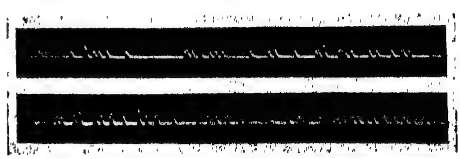

FIG. 8.

entered the detecting chamber per minute. The first method was not accurate when more than ten particles entered the chamber per minute. The records obtained in this way are shown in *Fig.* 8.

Kovarik[2] has devised a method by which the α particles are recorded by a pen on a moving strip of paper. The ionisation current produced by the α particle is magnified by a three-valve audion amplifier. The magnified current is used to operate a very sensitive relay, which in turn operates a local battery circuit accentuating the pen on a chronograph.

[1] Rutherford and Geiger, *Roy. Soc. Proc.*, 1908, A, lxxxi. 141.

[2] Kovarik, *Phys. Rev.*, 1919, xiii. 272.

The sensitive relay operates on a fraction of a milliampere. The method is also applicable to β, γ, and X rays.

(v.) *Ratio of the Charge to the Mass of the a Particle.*—The ratio of the charge to the mass of the α particle can be determined by measuring the deflections produced respectively in a magnetic and in an electric field. It can be shown that the path of a particle of mass m moving with velocity v and carrying a charge e will have a curvature ρ given by the relation

$$H\rho=\frac{mv}{e}, \quad . \quad . \quad . \quad . \quad (7)$$

where H is the strength of the magnetic field. Similarly, when it moves through an electrostatic field produced between two parallel plates whose difference of potential is V,

$$\frac{1}{2V}=\frac{e}{mv^2}. \quad . \quad . \quad . \quad . \quad (8)$$

These two equations enable the values of e/m and v to be determined. Rutherford [1] found by this method that the value of e/m for the α particle was 5070. From theoretical considerations it can be deduced that the value of the ratio of the charge to the mass of the hydrogen atom should be 9647, which is approximately twice that for the α particle. These results may be explained if we assume either that the α particle is a hydrogen molecule or an atom of weight 2 carrying a unit positive charge, or that it is a helium atom (atomic weight 4) carrying two positive charges. To decide between these two alternatives Rutherford and Geiger undertook an accurate measurement of the charge carried by the α particle.

(vi.) *Charge carried by a Particle.*—From the knowledge of the number of α particles emitted by a given product and the total charge carried by these particles, it is possible to deduce the charge carried by a single α particle. The measurement of the charge is, however, made more difficult on account of the fact discovered by J. J. Thomson, that emission of α particles is accompanied by the emission of negatively charged particles, which he termed δ rays. These particles are always emitted when α particles fall on any object. To determine the charge of the α particle the delta rays had to be removed, and this was done by Rutherford and Geiger [2] by placing the radioactive material in a strong magnetic field. The delta particles, which move at low velocities, are thus bent round and return back to the surface which emits them. In this way it was found that the charge carried by the α particle was $9{\cdot}3\times10^{-10}$ e.s.u. The value of the ionic charge had previously been found to be about half this value (the value of the ionic charge at present accepted is $4{\cdot}77\times10^{-10}$ e.s.u.), so that the α particle carried two unit positive charges.

[1] Rutherford, *Phil. Mag.*, 1906, xii. 348.
[2] Rutherford and Geiger, *Roy. Soc. Proc.*, 1908, A, lxxxi. 162.

(vii.) *Nature of the a Particle.*—Evidence so far accumulated pointed to the conclusion that the α particle was a helium atom carrying two unit positive charges. The following experiment carried out by Rutherford and Royds [3] confirmed this.

A quantity of emanation was compressed into a thin-walled glass tube A which was surrounded by a vacuum jacket T (*Fig.* 9). The thickness of the wall was less than 0·01 mm. This was strong enough to withstand atmospheric pressure, and the α particles readily passed through it, as was shown by the scintillations on a zinc sulphide screen held near the tube. The gases in the tube T could be compressed into the spectrum tube S by means of the mercury column H; the colour of the discharge through this tube was then examined spectroscopically. Two days after the emanation was introduced into the tube, the spectrum showed the yellow line of helium, and in six days' time the whole helium spectrum was observed. To show that the helium was not derived by diffusion from the inner tube, the emanation was removed and helium substituted. No trace of helium could be detected in the outer tube after standing for several days, so that the helium in the first instance must have originated from the α particles which had passed through the glass wall of the emanation tube.

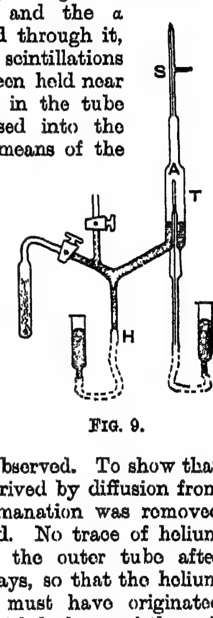

FIG. 9.

There is therefore no doubt that the α particle is a helium atom carrying two positive charges or, in other words, it is a helium atom which has lost two electrons. When its charge is neutralised the α particle becomes a normal helium atom.

§ (12) HYDROGEN PARTICLES.—Before leaving the α particle a brief reference will be made to the recent work of Rutherford, who has made a close quantitative study of the effect on an α particle of its passage through atoms of matter. Bragg had shown that the α particles pass straight through the atoms of matter in their path; this is undoubtedly the case with the majority of the α particles in the stream; but there are exceptions, in which cases the α particle suffers large deflections. This "occasional large-angle

[3] Rutherford and Royds, *Phil. Mag.*, 1909, xvii. 281.

scattering" is to be distinguished from the very slight deviations in different directions according to the laws of probability which later more detailed examination has shown to happen to the α particle as it traverses matter. These facts point to the conclusion that the central nucleus of the atom is very small, but however small it is an occasional α particle is certain to strike it absolutely "head on." It is these occasional close encounters that have been examined by Rutherford.[1] When such a collision takes place between the α particle and the nucleus of a heavy atom, the former will either be violently swung out of its path if the collision is not absolutely "head on," or repelled the way it came almost at its original velocity if it is "head on."

When, however, a "head-on" collision takes place between the α particle and the nucleus of a lighter atom—for example, atoms of hydrogen—then, in this case, the hydrogen atom would be propelled in the same direction as that of the α particle with a velocity far greater than the velocity of the original particle, and it would consequently travel a greater distance in hydrogen gas than the α particle before it is stopped. This was actually found to be the case in hydrogen. These high-velocity atoms were, for the sake of clearness, termed by Rutherford H-particles. The same phenomenon was observed also in the case of oxygen and nitrogen. In the case of nitrogen, however, there were observed in addition to the N-particle, whose range was only slightly longer than that of the α particle itself, particles of long range and other characteristics exactly similar to the H-particles produced in hydrogen gas, one H-particle being observed for every twelve N-particles produced, which suggests that the nucleus of the nitrogen atom struck by an α particle is occasionally shattered by the collision and that hydrogen atoms are produced from it. Later experiments carried out on these particles by subjecting them to the action of electric and magnetic fields proved that the H-particles generated in hydrogen and also in nitrogen consisted of hydrogen atoms, each carrying a single positive charge. The "N-particles" and "O-particles" were, however, not singly charged atoms of nitrogen and oxygen respectively, but were found to be identically the same and consisted of an entirely new particle of mass 3 carrying two positive charges.

Hence a nitrogen atom coming into close nuclear collision with an α particle is shattered, yielding in some cases atoms of hydrogen of mass 1 carrying a single positive charge, and in others atoms of a new kind of mass 3 carrying a double positive charge. In the case of oxygen only atoms of the new kind of mass 3 are produced.

§ (13) β Rays. (i.) *General Properties.*—The general properties of the β rays are identical with those of the cathode rays in a discharge tube. They are negatively charged particles or "electrons" projected at high velocities; the velocity of a β particle is far higher than that of the fastest known cathode ray, in some cases the velocity is almost indistinguishable from that of light. It is probable that the β ray has its origin in the central positively charged nucleus of the atom and, as in the case of the α particle, each disintegrating atom emits one β particle only.[2]

The character of the β rays is brought out very clearly in Strutt's[3] radium clock. A small quantity of radium salt is enclosed in the tube A, whose walls are thick enough to absorb the α rays (*Fig.* 10). This is suspended in an outer tube and insulated from it. A pair of gold leaves are attached to the bottom of the tube A and are in metallic connection with the radium. If the outer tube is highly exhausted, the radium becomes positively charged owing to the loss of β particles and the leaves diverge. If the vacuum is high several hundred volts may be reached before the loss of charge through the insulator and gas balances the rate of supply. In one form of the instrument, two plate electrodes B and C are sealed into the glass bulb, one on either side of the leaves and both connected to earth. These serve to discharge the leaves after a certain divergence has been reached. The charging and discharging of the leaves will in this way go on indefinitely.

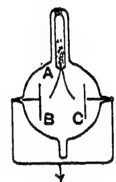

Fig. 10.

(ii.) *Magnetic Spectrum.*—β rays are readily bent by comparatively weak magnetic fields, and, since they carry a negative charge, the deflection is in the opposite direction to that produced in the case of the α rays. If all the β rays in a beam emitted by a radioactive body were travelling at the same velocity, the deflection produced by the magnetic field would be the same for each ray; this, however, is never found to be the case, so that the β particles are not expelled from the radioactive body all with the same velocity. In some cases the magnetic spectrum is continuous, in other cases there are distinct lines in the spectrum showing that there are present in the beam groups of rays of definite velocity.

An example of the spectrum of the β particles emitted by the active deposit of

[1] Rutherford, *Phil. Mag.*, 1919, xxxvii. 537; *Roy. Soc. Proc.*, 1920, A, xcvii. 374.

[2] Moseley, *Roy. Soc. Proc.*, 1912, A, lxxxvii. 230.
[3] Strutt, *Phil. Mag.*, 1903, vi. 588.

radium, photographed by Rutherford, is shown in *Fig.* 11. The rays, after passing through a narrow slit, fell on a photographic plate placed at an angle of about 45° with the horizontal. The central line is due mainly to the α rays; the β rays show on both sides of this line because the magnetic field was reversed during the experiment. The lines in some cases are very numerous; for instance, 48 lines for radium C have been observed with velocities ranging up to 0·986 of the velocity of light. It is possible, however, that the initial energy of each α particle from a single radio-element is the same. The particle has its origin in the nucleus, and it has to pass through successive rings of electrons surrounding the nucleus before it leaves the atom. In this process energy may be lost in quanta, and there is evidence to show that this is actually the case. The energy lost in this way reappears again as γ ray energy.

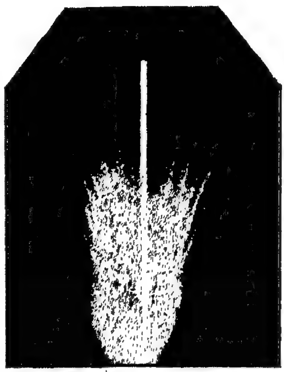

FIG. 11.

(iii.) *Absorption of β Rays by Matter.*—The absorption of β rays is investigated by placing thin sheets of the absorbing material in the path of the rays and measuring the activity through different thicknesses. It is found that the absorption of the rays follows an exponential law, that is, if I_0 is the activity when no absorbing material is interposed and I the activity when the rays pass through a thickness d, then

$$I = I_0 e^{-\mu d}, \quad . \quad . \quad (9)$$

where μ is known as the coefficient of absorption of the β rays in the absorbing material. The absorption coefficients of the β rays from uranium X in aluminium, copper, and lead are 14 cm.$^{-1}$, 66 cm.$^{-1}$, and 103 cm.$^{-1}$ respectively.

Since the rays are absorbed according to an exponential law, then each equal successive thickness of material interposed produces the same percentage reduction in the radiation remaining after traversing the previous layers. It was initially thought that this exponential law of absorption was a proof that all the rays travelled with the same velocity—that is, that the beam was homogeneous. Wilson [1] showed, however, that this was no test for homogeneity of the rays. The experiments of Von Baeyer, Hahn, and Meitner [2] also showed that β rays which obey the exponential law of absorption were divided into groups of different velocities when subjected to a magnetic field. When the differences of velocities of the groups are large, then the law of absorption is no longer exponential.

To obtain the true value of the absorption coefficient of β rays it is necessary to work with preparations, such as active deposits, that can be obtained free from other matter, in the form of very thin films in which the absorption of the β rays is negligible. The β rays starting from the surface of a layer of uranium oxide, for instance, will have a higher velocity than those that come from beneath the surface. The effect on the emission of β particles from different thicknesses of uranium oxide is shown in *Fig.* 12. The ionisation is proportional to the thickness for thin layers, but as the thickness becomes greater it increases less rapidly, ultimately reaching a steady value, in which case the radiation from the lower layers is completely absorbed by the active material in the upper layers. The curve gives sufficient data to calculate the absorption coefficient of the β rays in the uranium oxide itself. Considering a thin layer of thickness dx at a distance x below the surface of the active material, we have

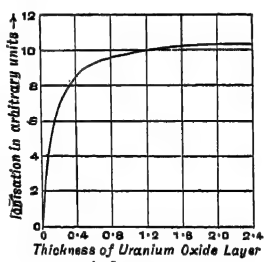

FIG. 12.

$$dI = I_0 e^{-\mu x} dx, \quad . \quad (10)$$

where dI is the amount of radiation entering the measuring vessel from the layer dx of active material. Hence the total amount of radiation emitted by a layer of finite thickness d is given by the expression

$$I_d = I_0 \int_0^d e^{-\mu x} dx = \frac{I_0}{\mu}(1 - e^{-\mu d}). \quad . \quad (11)$$

As the thickness of the layer increases, this tends to the value I_0/μ, which is a constant, I_0 being the intensity of the radiation emitted by a very thin layer of the active material, in which case there would be no absorption, and μ is the absorption coefficient of the radiation

in the material. Indicating the steady value of the intensity by I_∞, then

$$I_d = I_\infty(1 - e^{-\mu d}). \quad . \quad . \quad (12)$$

The value of the coefficient of absorption of the uranium oxide for the β rays can be calculated from this expression by substituting the values of I_d and I_∞ obtained from the curve.

(iv.) *Scattered β Rays.*—When β rays fall on a layer of matter, part of the radiation is absorbed and part is scattered. This scattered radiation is identical in type with the primary β rays, but is always of less average penetrating power than the latter. Its amount increases as the atomic weight of the radiator increases. Kovarik and Wilson [1] have also shown that the amount of scattered radiation from different materials increases with the velocity of the β rays up to a certain point and afterwards decreases. The above results apply to thick layers of material in which a considerable amount of absorption takes place. In order to be able to compare experimental results with any theory of scattering, it is desirable to do away with appreciable absorption and consequently to use very thin layers of scattering material. Two theories of scattering have been put forward, the one by J. J. Thomson [2] and the other by Rutherford.[3] On the former theory the scattering is supposed to be due to the chance combination of a multitude of successive minute deflections. The β particle as it encounters one atom after another in its passage through matter is deflected in different directions, but the average value of this deflection over a very large number of encounters will be a finite quantity. If θ is the average deflection due to each encounter with an atom, it can be shown that the mean deflection after n encounters is $\theta\sqrt{n}$. Hence, if the rays pass through a plate of thickness t containing N atoms of radius b per unit volume, the average deflection which they experience is $\theta\sqrt{N\pi b^2 t}$.

Rutherford, on the other hand, assumes that a moving electrified particle can be deflected through a large angle by a single atomic encounter, and he attributes the main features of the scattering of particles when they pass through thin layers of matter to this single scattering. The two theories differ also as to the constitution of the atom—in the former the atom is supposed to be constituted of N_o electrons accompanied by an equal quantity of positive electricity, the latter being distributed with uniform volume density throughout a sphere whose volume is equal to that of the atom; whilst in the latter the atom is imagined to consist of a central positive nucleus carrying a charge $+N_o e$ surrounded by N_o electrons carrying altogether a negative charge equal to the positive charge on the nucleus.

When the layer of scattering material is so thin that there is no absorption of the radiation, both theories lead to constant values for the fractions $\phi/\sqrt{t_o}$ and $mu^2/\sqrt{t_o}$, where ϕ is any particular mean deflection, t_o the thickness of material required to cut the radiation down to half value, and $\frac{1}{2}mu^2$ the energy of the β particle. The actual values of the constants are different, however, on the two theories, and consequently the values of the number of electrons in the atom which can be deduced from the value of $\phi/\sqrt{t_o}$ will differ in the two cases.

The experiments of Crowther [4] on the scattering of β rays by very thin sheets of different materials showed that the fractions $\phi/\sqrt{t_o}$ and $mu^2/\sqrt{t_o}$ were both constant in accordance with theory. Calculating the number of electrons in atoms of the metals Al, Cu, Ag, and Pt, which were employed in the investigation, the results based on Rutherford's theory agree more closely with the number of electrons per atom as determined by X rays than do those based on Thomson's theory.

§ (14) γ Rays. (i.) *General Properties.*—One of the chief characteristics of these rays is their great penetrative power. It is possible by means of the electroscope to detect the γ radiation emitted by 30 milligrammes of radium after it has passed through 30 cm. of iron. The γ rays are always found associated with β rays, and they are emitted in large amounts only from those radioactive bodies that emit penetrating β rays. A beam of β radiation falling on any substance gives rise to γ radiation in the same way that a beam of cathode rays produces X rays. Just as X rays liberate corpuscular radiation when they fall on a substance, so γ radiation liberates β particles, the only difference being in the velocity of the particle liberated.

(ii.) *Absorption of γ Rays from Radium.*—To measure the absorption of γ rays in any substance it is necessary to eliminate the effect due to the β rays. The latter may be removed either by deflecting them from the measuring apparatus by means of a magnetic field or by absorbing them in a layer of matter of sufficient thickness. The latter method is the one usually adopted, a screen of lead 3 mm. thick being sufficient to absorb almost completely the β rays emitted by radium and its products.

[1] Kovarik and Wilson, *Phil. Mag.*, 1910, xx. 866.
[2] J. J. Thomson, *Camb. Phil. Soc. Proc.*, 1910, xv. 465.
[3] Rutherford, *Phil. Mag.*, 1911, xxi. 669.
[4] Crowther, *Roy. Soc. Proc.*, 1910, A, lxxxiv. 226.

The absorption of the rays can be measured by means of an electroscope. Sheets of known thickness of the material investigated are placed in the beam, and from the knowledge of the deflection of the leaf with and without the absorbing material respectively in front of the electroscope the absorption coefficient of the material for the radiation can be calculated by means of the formula

$$I = I_0 e^{-\mu t}, \quad . \quad . \quad (13)$$

where I and I_0 are the intensities of the radiation entering the electroscope with and without the absorbing screen, t the thickness of the screen, and μ the coefficient of absorption.

It is important that the walls of the electroscope are sufficiently thick to absorb β radiation that may be excited by the radiation which falls on objects in the vicinity; also the windows through which the gold leaf is viewed should be well shielded. The values of the absorption coefficient depend somewhat on the arrangement of the apparatus. The following figures for the absorption of γ rays from radium in lead are due to Tuomikoski: [1]

Table II

Thickness of Lead in cm.	Ionisation Current.	Thickness of Lead in cm.	Ionisation Current.
0·3	100	7·0	2·57
1·0	61·6	8·0	1·62
2·0	33·1	9·0	1·00
3·0	19·9	10·0	0·63
4·0	11·7	11·0	0·39
5·0	7·07	12·0	0·30
6·0	4·26	..	..

The values of the absorption coefficients over the different thicknesses are given in the following table:

Table III

Thickness of Lead in cm.	μ cm.$^{-1}$.
0·4– 1·0	0·70
1·0– 2·2	0·58
2·2– 5·4	0·52
5·4–12·0	0·50

The absorption of γ rays in various substances shows that for substances whose densities lie between 2·6 and 8·8 the absorption is very approximately proportional to the density. The value of the mass absorption coefficient (μ/ρ) is therefore constant over this range of densities; for other substances the densities of which do not lie within the above limits the value of μ/ρ is greater.

γ rays from different radioactive products have different penetrating power. The relative values of the absorption coefficients are given in the following table: [2]

Table IV

Absorbing Screen.	γ Rays from			
	Radium C.	Thorium D.	Mesothorium 2.	Uranium X.
Lead . . .	1·0	0·924	1·24	1·45
Zinc	1·0	0·82	1·06	1·18
Paraffin wax .	1·0	0·78	1·26	1·08

The rays from thorium D are more penetrating, while the rays from mesothorium 2 and uranium X are slightly less penetrating than the rays from radium C.

(iii.) *Scattered γ Radiation.*—In addition to the production of β rays, γ rays in traversing matter give rise to a scattered radiation of the γ type. The amount of this scattered radiation appearing on the emergent side of a radiator is always much greater than that on the incident side. This asymmetry in the distribution of the radiation is also observed with X rays, but the effect is not so marked as with γ rays. Florance [3] found that the quality of the scattered radiation varied at different angles with the direction of the primary beam, the radiation scattered through a large angle being much more easily absorbed than the primary γ rays. The scattered radiation appearing on the side of incidence is also softer than that on the emergent side of the radiator.

(iv.) *Nature of γ Rays.*—There has been a good deal of controversy as to the nature of γ rays, but recent experiments on the diffraction of the rays have definitely proved that the rays are of the same nature as X rays, *i.e.* aetherial pulses, the only difference being that the wavelength of γ radiation is much shorter than that of X radiation.

Rutherford and Richardson [4] showed that radium C emits one and radium B two types of γ radiation, each of which is exponentially absorbed in aluminium. These radiations were carefully examined by Rutherford and Andrade [5] by reflecting them at a face of rock salt crystal. The source of radiation was a thin-walled α ray tube containing about 100 millicuries of emanation in equilibrium with its products A, B, and C. A diverging cone

[5] Rutherford and Andrade, *ibid.*, 1914, xxvii. 854; xxviii. 263.

of rays fell on the crystal face, and the distribution of the reflected radiation was examined by the impression produced on a photographic plate placed 10 cm. from the centre of the crystal.

The spectrum of the γ radiation from Ra B was found to consist of 21 lines having wave-lengths ranging from $0{\cdot}793 \times 10^{-9}$ cm. to $1{\cdot}365 \times 10^{-8}$ cm., the two strongest lines being reflected from the (100) face of rock salt at the angles 12°·05 and 10°·05, and therefore having wave-lengths $1{\cdot}176 \times 10^{-8}$ cm. and $0{\cdot}983 \times 10^{-8}$ cm.

The wave-lengths of the penetrating γ radiation from Radium C were found to range from $0{\cdot}71 \times 10^{-9}$ cm. to $1{\cdot}96 \times 10^{-9}$ cm.

§ (15) Various Effects produced by the Radiations.—It has already been pointed out that the radiations ionise gases through which they pass and, in consequence, make them temporarily conductors. This is effectively demonstrated by bringing a little radium near the secondary terminals of an induction coil. If the two terminals are so separated that a spark just does not pass between them when the coil is running, by bringing some radium near the gap the spark will readily pass. This property of the radiation from radium is made use of when it is desired, during the course of an investigation, to prevent electric charges accumulating on the surfaces of different parts of the apparatus.

The salts of radium are all luminous in the dark, and the radiations produce marked luminescence in certain salts (see article on "Radium"). Certain bodies after exposure to the radiations become luminous when they are heated to a temperature much below that required to produce incandescence. Fluor-spar and kunzite possess this property of thermo-luminescence to a marked degree. These substances are able to store the energy which they take up for a long period of time. The explanation suggested for this effect is that the rays cause chemical changes which are permanent until heat is applied which releases in the form of visible light the energy absorbed.

Glass exposed to the radiations for some time becomes coloured, soda glass is coloured a deep violet, and after a long period under the influence of the rays it becomes almost black. Other glasses are coloured yellow and brown under the action of the rays. This coloration is produced by all three types of radiation; that due to the α rays extends only a short distance corresponding to the range of the α particles in the glass, whilst that due to the β and γ rays extends throughout the whole of the glass. Mica plates acquire a brown or a black colour under the action of α rays. It had long been observed that certain kinds of mica contained small coloured areas whose sections were always circular and in whose centre there was usually a minute crystal of foreign matter. Under the action of polarised light these exhibited the property of pleochroism, and for this reason were called "pleochroic halos." Joly [1] found that the nucleus of these areas was radioactive and that the coloration was due to the α rays expelled from this nucleus. The halos exhibit a well-marked structure clearly shown in *Fig.* 13, which is a micro-photograph of a halo whose nucleus is a uranium mineral.[2] The central dark area is produced by the collective action of all the α particles emitted by the nucleus, and the boundary of it defines the range of the α particles from radium itself. The next dark edge corresponds to the range of the swifter α particles from radium A, and the edge of the outer ring to the range of the α particles from radium C. It is possible to find in the mica halos in various stages of development. In some may be found only the central "pupil," 0·013 mm. in radius corresponding to the range of the slower α particles from radium, but in more developed cases an outer ring always appears whose radius is 0·03 mm. corresponding to the range in mica of the α particles from radium C. Other halos have different diameters, and it is possible to decide from the diameter of the halo whether the nucleus contains uranium or thorium mineral. The fastest α particle emitted in the thorium series would travel a distance of 0·038 mm. in mica, and it was found on examination that halos of this dimension were obtained when the nucleus consisted of thorium mineral.

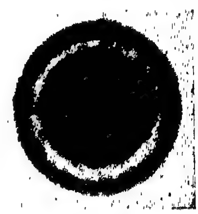

Fig. 13.

It has been estimated that the number of α particles emitted by the nuclei of these halos is of the order of 100 per year. The effect of this expulsion on the mica would be infinitesimal over a short period, so that it has probably taken several hundred million years to produce the actual halos that have been observed.

The action of α rays on photographic films examined by Kinoshita and Ikeuti [3] are of interest in this connection. A sewing needle carrying at its point a minute trace of radium active deposit was employed as a source of α rays. After the point of the needle had been in contact with the photographic plate for a short time, the plate was developed and a fine spot became visible to the naked eye. Under the microscope this spot was found to

[1] Joly, *Phil. Mag.*, 1907, xiii. 381.
[2] Joly and Fletcher, *ibid.*, 1910, xix. 630.
[3] Kinoshita and Ikeuti, *ibid.*, 1915, xxix. 420.

consist of a multitude of radial trails of silver grains around a circular dark nucleus. Halos were also observed and were shown to be produced by a process similar to that of the pleochroic halos.

Another important effect of the radiations is the decomposition of water. This is brought about by all three types, but the effect due to the α rays is much greater than that due to the β and γ rays. The effect is probably due to the ionisation of the water molecule, which is accompanied by the chemical dissociation of the molecule with the liberation of hydrogen and oxygen. Hence it is important, when sealing radium in tubes, to see that the salt is dry, otherwise in the course of time the pressure of the evolved gases inside the tube may become so great as to burst it.

§ (16) The Emanations. — Rutherford[1] found that thorium emitted, in addition to the radiations, a radioactive gas which he called the emanation. The amount given off is exceedingly small, but the ionisation produced by it is sufficiently large to be readily measured by means of an electroscope. The emanation can be carried away from the neighbourhood of the substance emitting it by a current of air, and its activity will not suffer appreciable loss when it is passed through a plug of cotton-wool or bubbled through solutions on its way to the measuring apparatus.

Shortly after the discovery of thorium emanation, both radium and actinium were found to give off emanations. The activity of each of the emanations decays according to an exponential law with time. Actinium and thorium emanations are short-lived, their half-value periods being 3·9 seconds and 54 seconds respectively, and on this account it is difficult to remove them quickly enough from solution before they disintegrate. Radium emanation, on the other hand, has a half-value period of 3·85 days, and practically the whole of it can be removed by passing a stream of gas through, by exhausting, or by boiling the solution.

Solid preparations differ enormously in the readiness with which they part with their emanation. In the case of thorium the best emanators are the hydroxide and the carbonate. After ignition to oxide the emanating power is greatly reduced. The higher the temperature of ignition the greater is this reduction, until after ignition at a white heat the emanating power may be reduced to a small fraction (a few per cent) of that of the unignited compound. The nitrate, oxalate and sulphate are all poor emanators. In the case of radium, the bromide is a better emanator than the chloride. From the sulphate and, to a less extent, the carbonate, very little emanation escapes in the solid. It has been found, however, that the same compounds may exhibit in this respect a marked variation in behaviour.

[1] Rutherford, *Phil. Mag.*, 1900, xlix. i.

Hence if the radioactive substance is required to retain its emanation in the open it is best in the case of radium to keep it as sulphate, and in the case of the other two radio-elements in the form of highly ignited oxides. If the emanation is required, the radioactive material is best kept in solution.

All the three emanations have distinct chemical and physical properties; they have characteristic bright line spectra, they are also chemically inert, and in consequence they are classed with the argon-helium group of the periodic table. They also all emit α particles and can be condensed at liquid air temperature.

§ (17) Radium Emanation.—If a solution of radium is kept in a sealed flask, the emanation steadily accumulates with time, reaching the equilibrium value in about a month's time. Oxygen and hydrogen are at the same time evolved owing to the decomposition of the water by the radium. On exploding the gases, a slight excess of hydrogen remains with the emanation. The hydrogen can be removed by passing the mixture into a bulb immersed in liquid air, where the emanation will be condensed and the hydrogen together with any helium produced by the emanation can then be pumped off. The liquid boils at about $-62°$ C. at ordinary atmospheric pressure and the solid melts at about $-71°$ C. The liquid emanation is colourless and transparent, whereas the solid is opaque and glows with great brilliancy and is of a steel-blue colour. As the temperature is still further lowered, the colour changes to yellow and becomes a brilliant orange red at the temperature of liquid air.

The volume of emanation at normal temperature and pressure, in equilibrium with 1 gram of radium, is found by experiment to be 0·62 cubic mm. This is also the value calculated on the assumption that the emanation molecule consists of single atoms, so that the agreement between theory and experiment directly proves the monatomic nature of the molecule. The atomic weight of radium emanation is 222·0, four units less than that of its parent, radium, which has lost an α particle in the process of disintegration.

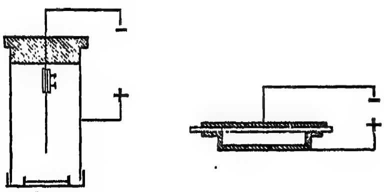
Radium emanation is soluble in water, the coefficient of solubility being about 0·3 at ordinary temperature and 0·12 at 80° C. It is more soluble in petroleum and toluene, the solubility coefficients being 9·5 and 11·7 respectively at ordinary temperature.

§ (18) Active Deposits.—Bodies which have been exposed for some time to the emanations from radium, thorium, and actinium acquire a temporary activity of their own, owing to the deposition of active matter on their surfaces. This "active deposit" consists of the dis-

integration products of the emanation which, in each case, are non-volatile at ordinary temperatures and have a relatively short period of life. When the emanations are allowed to decay in a strong electric field Rutherford found that the activity was confined entirely to the negative electrode, which indicates that the carriers of the active material must be positively charged. Owing to the fact that these products are produced from the emanation by the expulsion of α particles, it would be expected that the active deposit would be negatively charged. This apparent anomaly may be explained as follows. The atom emitting the α particle recoils and collides with the gas molecules in its path. During these collisions negative electrons are shaken out of the recoiling atom, which in consequence acquires a positive charge. Evidence in support of this view is the fact that α particles emitted by an active material are accompanied by a large number of δ particles which, as we have already seen, are slow speed negative electrons.

The active deposit may be concentrated and collected on a metal surface or a wire by making the latter the negative electrode inside a metal vessel containing the emanation, the vessel itself being connected to the positive pole of the source of potential. The potential gradient necessary to concentrate the whole of the active deposit on the negative electrode varies according to circumstances. It will, in general, be the same as that necessary to produce "saturation" of the ionisation current through the gas under the conditions of experiment. Higher potential gradients than 50 volts per centimetre are seldom necessary except in the case of intensely radioactive preparations or when the area of the surface to be covered with the deposit is very small.

To collect thorium and actinium active deposits the arrangements shown in *Fig.* 14 are



(a)

FIG. 14.

convenient for concentrating the deposits on a wire and on a plate respectively. The active material is placed in a shallow dish in each case, and the emanation escaping from it allowed to diffuse into the vessel. As it decays it produces active deposit which is driven by the electric field to the cathode, a wire in the one case and a plate in the other. To obtain the maximum activity the surfaces should be exposed for three hours in the case of actinium and three days in the case of thorium. It is, of course, advisable to use the salts that are the best emanators in each case. It is also an advantage to keep the salt slightly damp.

The above arrangements are not suitable in the case of radium on account of the long life of the emanation and its tendency to remain occluded in the radium salt. In this case the radium salt is dissolved in hydrochloric acid. The solution is placed in a stoppered bottle and kept positively charged by means of a wire which dips into it. The surface to be coated with active deposit is suspended above the solution in the bottle and is charged negatively. An exposure of three hours suffices to collect the maximum amount of active deposit.

In dealing with large quantities of radium the above method is unsuitable, because the stopper has to be removed when the surface to be coated is inserted into the bottle, with the result that an appreciable amount of emanation is lost. Also part of the emanation remains in solution and does not contribute to the activation of the surface. The following method, which diminishes the risk of any loss and makes the best use of the radium, is always employed when large quantities of radium are dealt with (*Fig.* 15).

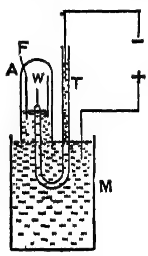


FIG. 15.

The emanation is first of all collected over mercury in the glass tube A. This is then introduced into the mercury reservoir M. The wire w which is to be coated with active deposit is sealed into the bent glass tube T and is connected to the negative pole of the battery. It is surrounded by an iron sheath F which fits the tube A and is in metallic contact with the mercury which is connected to the positive pole of the battery. It is advisable to use a high potential gradient in order to collect as much of the active material as possible—even 1000 volts per centimetre may be necessary in some cases. It is also preferable to use a platinum wire on which to collect the active deposit, as it is often necessary to dissolve the latter in strong acid or to volatilise it by exposure to a high temperature.

§ (19) RADIOACTIVE RECOIL.—Since the mass of the α particle is equal to that of a helium atom ($6{\cdot}56 \times 10^{-22}$ gm.), and it is expelled at a high velocity from the atom, it possesses considerable momentum. At the moment the α particle is expelled the residue

of the atom acquires an equal and opposite momentum and recoils at a considerable velocity. The recoiling atom is, therefore, able to penetrate a certain thickness of matter before it is brought to rest, and may even leave the surface upon which the radioactive product is deposited and be concentrated on another surface by the application of an electric field. It is possible in this way to separate certain disintegration products from the parent atoms.

Consider, for example, a surface made active by a short exposure to radium emanation. Immediately after removal from the emanation the activity is almost entirely due to radium A. An atom of radium A disintegrates with the expulsion of an α particle whose velocity is $1{\cdot}77 \times 10^9$ cm. per second. The atomic weight of radium B—the residual part of an atom of radium A after the expulsion of an α particle—is 214, so that by the principle of momentum its velocity of recoil will be $3{\cdot}27 \times 10^7$ cm. per second. An atom of radium B therefore leaves the active material with this velocity, but since its kinetic energy is small (compared with that of the α particle) it will be able to penetrate only a very small thickness of matter—it will be stopped by one-tenth of a millimetre of air at atmospheric pressure. A recoiling radium D atom from radium C has a "range" of 0·14 mm. in air at atmospheric pressure. Since the range of the recoil atoms is so short, it is necessary for successful separation by recoil to obtain the active material in the form of a thin uniform deposit on a carefully polished surface. This is supported in a good vacuum opposite to the surface on which it is desired to collect the recoil product, and connected to the positive pole of a battery. Almost all the recoil atoms moving away from the active plate, which is half the total number, may be separated in this way.

§ (20) Theory of Successive Transformations.—A full description of the theory of successive transformations of radioactive matter will not be attempted here. A few simple cases only will be considered which will illustrate the application of the theory to practice.[1]

(i.) *Decay of Thorium Active Deposit.*—The active deposit of thorium consists of the members of the thorium series included below thorium emanation in Table I., and of these only the first three need be taken into account when making α ray measurements. The products thorium A and thorium C emit α rays whilst thorium B emits soft β rays. Further the period of thorium A is only 0·2 second, so that the active deposit after removal from the emanation will behave as if it consisted only of two substances, namely thorium B and thorium C.

(a) *Short Exposure to Emanation.*—In this case the plate to be made active is exposed to the emanation for a few minutes and then removed. The plate is then transferred into an α-ray electroscope; in the course of this transference, unless it is carried out exceedingly rapidly, the thorium A is completely converted to thorium B. Assuming that the thorium A has all changed into thorium B by the time observations are commenced, the activity of the deposit at the beginning is due entirely to β rays from thorium B, and consequently is very feeble. As the thorium B disintegrates with the production of thorium C, an α-ray product, the activity rapidly rises and reaches a maximum value in about four hours (see curve ABC, *Fig.* 16). It then

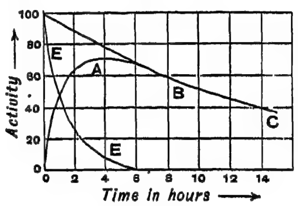

Fig. 16.

decreases and finally decays exponentially with the period of thorium B.

The rate at which the activity varies with time can be calculated if it be assumed that the influence of thorium A is negligible and that initially there is only thorium B present. This product disintegrates in accordance with Table I., thorium B into thorium C, and thorium C into thorium D.

Let P and Q be the number of atoms of the products B and C respectively present at a certain instant, then the rate of increase of thorium C will be given by the difference between the amount of thorium C produced by thorium B and the amount of thorium C disintegrating into thorium D, so that

$$\frac{dQ}{dt} = \lambda_1 P - \lambda_2 Q, \quad . \quad . \quad . \quad (14)$$

where λ_1 and λ_2 are the radioactive constants of B and C respectively, and P is given by the equation

$$P = P_0 e^{-\lambda_1 t}, \quad . \quad . \quad . \quad (15)$$

where P_0 is the initial number of atoms of thorium B present. The amount of thorium C present initially is zero, so that when $t=0$, $Q=0$, and the solution of equation (14) may be shown to be

$$Q = \frac{P_0 \lambda_1}{\lambda_2 - \lambda_1} \cdot [e^{-\lambda_1 t} - e^{-\lambda_2 t}] \quad . \quad (16)$$

[1] See Makower and Geiger, *Practical Measurements in Radioactivity*, p. 80.

This equation should give the same curve as ABC in *Fig.* 16, when the correct values of λ_1 and λ_2 are substituted in it.

The experimental curve shows a maximum, and the time at which this maximum occurs, obtained from (16), is given by

$$t_m=\frac{1}{\lambda_1-\lambda_2}\cdot\log\frac{\lambda_1}{\lambda_2}. \quad . \quad . \quad (17)$$

The values of the radioactive constants λ_1 and λ_2 may be deduced from the experimental curve ABC. The end portion BC of this curve follows a simple exponential law, the decay being governed by the period of the product of longer life. Hence the value of one of the transformation constants is immediately obtained. From equation (16) the curve is made up of two exponentials. Extrapolating the curve BC back to zero and subtracting the experimental curve from it, another exponential curve is obtained, represented in the figure by curve EE. This gives the value of the second transformation constant. To decide to which product each of the constants is to be assigned, it would be necessary to separate the two products and examine the rate of decay of activity for each separately.

The theory of a short exposure to actinium emanation is the same as that for thorium, but in this case the maximum occurs after nine minutes, and in consequence exposure to the emanation must not last for more than a fraction of a minute.

(*b*) *Long Exposure to Emanation.*—It will be assumed here that the exposure is so long that the products have had time to reach a state of radioactive equilibrium. If n_0 be the number of atoms of thorium A deposited per second from the source, then

$$n_0=\lambda_1P_0=\lambda_2Q_0=\lambda_3R_0, \quad . \quad . \quad (18)$$

where P_0, Q_0, and R_0 are the quantities of the products B, C, D present when equilibrium has been reached.

Combining equation (18) with equations (14) and (15) we obtain the equation

$$Q=\frac{\lambda_1P_0}{\lambda_2-\lambda_1}\left[e^{-\lambda_1t}-\frac{\lambda_1}{\lambda_2}\cdot e^{-\lambda_2t}\right], \quad . \quad (19)$$

which gives the number of atoms of thorium C present at any time after the termination of the exposure. This curve is again made up of two exponentials, and the values of λ_1 and λ_2 may be deduced in a similar manner to that described above.

It should be mentioned that the same activity curves would be obtained with thorium and actinium if the activity were measured by means of the β rays instead of the α rays as above.

(ii.) *Decay of the Active Deposit of Radium.*—It will be observed from Table I. that the period of radium A is comparable with the periods of the products which follow it, and on this account the case of the decay of the active deposit of radium presents more difficulty than that of thorium or actinium.

Supposing that there are P, Q, and R atoms of radium A, radium B, and radium C present at a certain time t, the amount of each will vary according to the following equations:

$$\left.\begin{aligned}\frac{dP}{dt}&=-\lambda_1P,\\ \frac{dQ}{dt}&=\lambda_1P-\lambda_1Q,\\ \frac{dR}{dt}&=\lambda_2Q-\lambda_3R.\end{aligned}\right\} \quad . \quad . \quad (20)$$

In the case of a *short exposure* to the emanation, when only radium A will have had time to be deposited, $Q_0=R_0=0$, when $t=0$, and the above equations become

$$\left.\begin{aligned}P&=P_0e^{-\lambda_1t},\\ Q&=\frac{\lambda_1P_0}{\lambda_2-\lambda_1}\cdot\left[e^{-\lambda_1t}-e^{-\lambda_2t}\right],\\ R&=\lambda_1\lambda_2P_0\left[\frac{e^{-\lambda_1t}}{(\lambda_2-\lambda_1)(\lambda_3-\lambda_1)}+\begin{matrix}\text{two similar}\\ \text{terms}\end{matrix}\right].\end{aligned}\right\}(21)$$

In the case of a *long exposure*, the initial conditions, when the deposit is removed from the emanation, are

$$\lambda_1P_0=\lambda_2Q_0=\lambda_3R_0, \quad . \quad . \quad (22)$$

whence

$$\left.\begin{aligned}P&=P_0e^{-\lambda_1t},\\ Q&=Q_0\left[\frac{\lambda_2}{\lambda_2-\lambda_1}\cdot e^{-\lambda_1t}+\frac{\lambda_1}{\lambda_1-\lambda_2}\cdot e^{-\lambda_2t}\right],\\ R&=R_0\left[\frac{\lambda_2\lambda_3e^{-\lambda_1t}}{(\lambda_2-\lambda_1)(\lambda_3-\lambda_1)}+\begin{matrix}\text{two similar}\\ \text{terms}\end{matrix}\right].\end{aligned}\right\}(23)$$

These equations enable the numbers of atoms of radium A, radium B, and radium C present at any time after a short or a long exposure to be calculated.

Radium A and radium C both emit α rays, whilst radium B and radium C emit β rays, and on this account the activity curves will be different according to whether the α rays or the β rays are employed for measuring the activity.

The α-ray activity M is given by the equation

$$M=\lambda_1P+k\lambda_3R, \quad . \quad . \quad . \quad (24)$$

where k is the ratio of the ionisation produced by an α particle from radium C to that produced by an α particle from radium A under similar conditions. The β-ray activity N is given by the equation

$$N=\lambda_2Q+l\lambda_3R, \quad . \quad . \quad . \quad (25)$$

where l is the ratio of the ionisation produced by a β particle from radium C to that produced

by a β particle from radium B. The theoretical curves calculated from these equations, when appropriate values are inserted for the ratios k and l, are shown in *Fig.* 17; curves

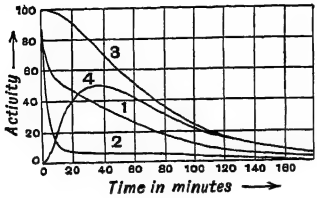

FIG. 17.

(1) and (2) show the variation of α-ray activity of radium active deposit after a long and a short exposure respectively to the active material; curves (3) and (4) the variation of the β-ray activity of radium C only after a long and a short exposure to the active material. The curves do not give the relative magnitudes of the ionisation currents produced by the α and the β rays respectively.

The above cases will suffice to show the usefulness of the theory to calculate the decay curves of radioactive products. A fuller account of the theory and its application will be found in Rutherford's *Radioactive Substances and their Radiations*.

§ (21) CHEMICAL CHARACTER OF THE RADIO-ELEMENTS.[1]—Each of the radio-elements appearing in Table I. has distinct chemical as well as radioactive characteristics, and although many of the products are exceedingly short-lived their complete chemical properties have been unravelled. In some instances the radioactive product may be prepared "chemically" pure, in which case its properties may be examined by chemical methods similar to those adopted in the case of ordinary elements —radium salts were prepared by Madame Curie sufficiently pure to carry out an investigation on the atomic weight of radium. In other cases a product may be obtained "radioactively" pure, in which case it is entirely free from other radioactive material, but is mixed with a certain amount of inactive matter. This may be the case when a radioactive substance is separated by precipitating it in the presence of an element resembling it in chemical properties. Lastly, a product may be prepared "radio-chemically" pure, in which the radio-element may be mixed with a certain amount of inactive matter, but is free from substances chemically analogous to itself. Such is the case with a product prepared by the method of recoil or as active deposit. The inactive material present in the last two cases will not interfere with the detection and measurement of the radioactive substance, but it will absorb the radiation emitted, a correction for which can be applied if necessary.

The results of the purely chemical study of the radio-elements has led to the division of the elements into two main classes:

(*a*) Those which possess distinct radioactive properties, but whose chemical characters are already completely known; and

(*b*) Those which, in addition to possessing a characteristic and distinct radioactivity, are new in chemical properties.

An instance of the first class is ionium. It resembles thorium more closely than any other member of Group III. of the Periodic Table and is found to be chemically identical in properties with it. The radioactivity of ionium is quite unique and different from any other radio-element, but in its chemical nature it is not new. All its chemical properties may be inferred from those of thorium, which can be obtained in large quantities, whereas ionium itself occurs in infinitesimal quantities, and even then it cannot be obtained "radio-chemically" pure, because thorium is present in all the minerals from which it may be obtained.

An instance of the second class is radium. It resembles barium very closely but not absolutely. In this case the chemical as well as the radioactive properties are unique, and we have a new type of chemical element.

§ (22) POSITION OF RADIO-ELEMENTS IN THE PERIODIC TABLE.—It was pointed out by Soddy that the expulsion of an α particle caused a change in the position of a radio-element in the periodic table by two places in the direction of diminishing mass. Fajans also drew attention to the fact that in a transformation involving the emission of β rays the resulting product is more electro-negative than the parent substance. Further knowledge of the chemical properties of the radio-elements has led to a complete generalisation as to the relation of the position of the radio-element in the periodic system and the nature of the change in which it is produced. The generalisation was independently arrived at by Russell,[2] Fajans,[3] and Soddy,[4] and may be stated thus:

In an α-ray transformation the product falls into a group two places lower than that to which the parent substance belongs, whereas in a β-ray transformation the product falls into a group one place higher than the parent substance.

The resultant grouping of the radio-elements is shown in Table V. It will be observed that the α-ray changes are far more numerous than the β-ray changes, and

[1] See Soddy, *The Chemistry of the Radio-elements*, p. 43.

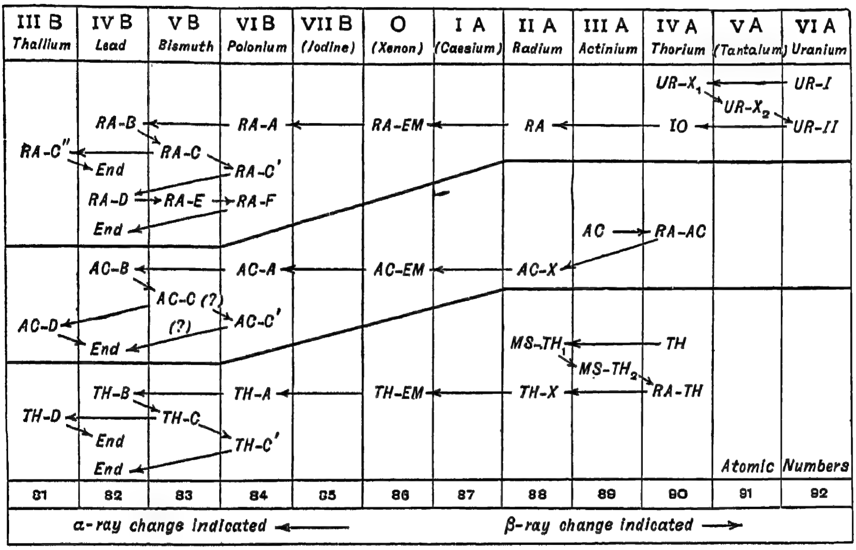
[3] Fajans, *Phys. Zeits.*, 1913, xiv. 131 and 136.
[4] Soddy, *Chem. News*, 1913, cvii. 97.

in consequence there is a movement from the right to the left extending over the last twelve places in the periodic table from uranium to thallium. The members in the vertical columns of the table are non-separable from one another and from the title element, except when this is enclosed within brackets. Thus uranium X_1, ionium, radio-thorium, and radio-actinium are all chemically identical with thorium; they belong to the first class mentioned above, all their chemical properties being known "by proxy." To the second class of radio-elements belong, for example, mesothorium 1, thorium X, and actinium X, which are all chemically identical those elements; such tests would only distinguish between elements in different columns of the table, and consequently, would only pick out ten kinds of radio-elements, whereas radioactivity tests would show the existence of thirty-four, so that separate places in the periodic table do not correspond with single elements necessarily, but with single chemical types of elements.

When uranium I loses an α particle with the production of uranium X_1, each atom of uranium X_1 is deficient of two positive charges. Uranium X_1 changes to uranium X_2, and uranium X_2 to uranium II, with the loss of a β particle in each case, which brings the charge

TABLE V



with radium. Elements of the first class are similar to one or other of the last five elements in the periodic table, namely, uranium, thorium, bismuth, lead, and thallium. The members of the second class, which are new types of chemical elements, are identical with one or other of five new elements, namely, radium, polonium, actinium, the emanations, and "eka-tantalum." The chemistry of radium and the radium-emanation is completely known, and consequently all the other elements in the same column in the table are definitely known. Hence, apart from actinium, polonium, and "eka-tantalum," the chemistry of the whole of the radio-elements is known.

§ (23) ISOTOPES.—Elements with identical chemical properties are called "Isotopes," thus radium B, radium D, thorium B, and actinium B are all isotopes of lead. Chemical tests would not be able to distinguish between on the atom to the same value as it had before any transformation took place. Uranium I and uranium II are identical in chemical character, and the net charge on the nucleus of each of the atoms is the same, but owing to the loss of an α particle in the transformation the masses of the atoms differ by four units. Hence it would appear that it is the net charge on the nucleus of the atom and not its mass that determines its chemical properties.

Since the expulsion of an α particle displaces the element two places in one direction and the expulsion of a β particle displaces it one place in the opposite direction, each of the successive places in the periodic table corresponds with unit difference in the net positive charge on the nucleus of the atom. The magnitude of the positive charge is now known to be exactly equal to the number of the element in the periodic table when the

elements are arranged in order of atomic weight. This number is called the "atomic number" of the element. Thus the atomic number of hydrogen is 1, helium 2, etc., up to that of the last and heaviest atom of uranium with atomic number 92.

Not only do the isotopic elements possess the same net nuclear positive charge and the same number of electrons in their external systems, and are chemically identical and inseparable; their common purely physical characteristics, such as spectrum and volatility, are also found to be identical.

It has recently been found that this property of isotopism of the elements occurs frequently amongst the elements. Aston[1] has found that neon, for instance, is a mixture of two isotopic gases of atomic weight 20·00 and 22·00. Similarly chlorine contains no atoms of atomic weight 35·46, but consists of four isotopes with atomic weights 35·00, 36·00, 37·00, and 38·00 respectively. Several other elements have been examined, the conclusion arrived at being that all the atomic weights, except that of hydrogen, are exact integers, and that the fractional values found for some of the elements are due to a mixture of two or more isotopes.

§ (24) THE END PRODUCT.—The ultimate products of all the disintegration series in all branches end in the same place in the periodic table, namely, the place occupied by lead. The atomic weight of ordinary lead is 207·2. According to theory, lead produced from uranium should have an atomic weight 206, and that from thorium an atomic weight 208. Hence lead prepared from uranium minerals should have a lower atomic weight than that prepared from thorium minerals. Experiment[2] has shown this to be the case; the atomic weight of radio-lead from uranium minerals has been found to be 206·05, and that of radio-lead from thorium 207·9. Probably ordinary lead is a mixture of these two isotopes. It has also been found by experiment that the densities of the different kinds of lead are different just in proportion to the differences in their atomic weight, hence their atomic volumes must be the same, which is to be expected if isotopic atoms have identical shells of electrons but nuclei of different masses.

RADIOLOGY

I. INTRODUCTORY

§ (1) THE NATURE OF X-RAYS.—The study of the X-rays[3] now occupies such a prominent position in physics and medicine, and has led to such momentous results in a variety of directions, that it is difficult to realise that it is only 25 years ago that the rays were discovered by Professor Röntgen, and that it was only just prior to the war that a long controversy as to their nature was stilled.

The problem had attracted many minds, for the ability of the rays to pass through opaque bodies was wholly unprecedented. The explanation of the anomaly was obviously bound up with the nature of the rays, but, despite shrewd guesses, the secret was withheld from us for nearly 20 years.

We now know that the X-rays are another manifestation of radiant energy, of which light and heat are familiar examples. Indeed, the X-rays resemble light rays in almost every particular, the chief difference being that the X-rays have wave-lengths about 5000 times shorter. It was this very minuteness of wave-length—a distance of the same order as the sizes of atoms—that defeated all our earlier attempts to direct and sort out the rays. All our highest quality polished surfaces are inconceivably rough for such a purpose, and it was not until Nature herself was found to have provided an instrument of the requisite delicacy—in the shape of crystals which can function as diffraction gratings—that we began to analyse and sort out X-ray beams with much the same ease as in the case of visible light.

There are further parallelisms between X-rays and light rays. For example, we know that the spectrum of a hot body consists under suitable conditions of white light (which is a mixture of all wave-lengths), superposed on which are certain spectrum lines whose wave-lengths are characteristic of the radiating material, *e.g.* the D lines of sodium, the H and K lines of calcium. In just the same way an element when caused to emit X-rays not only gives out general radiation (which is a continuous spectrum of wave-lengths) but under suitable conditions impresses its own characteristic lines—K, L, M—on the general

[3] See also "X-Rays," Vol. II.

radiation. It should be added, however, that the X-ray spectrum of an element is much simpler than its light spectrum.

Just about a single octave of light waves are visible to the eye. Their spectroscopic examination has been conducted mainly with the diffraction grating, the distance between the rulings of which is comparable with the wave-lengths to be measured. With the help of special gratings and vacuum spectrometers, Schumann, Lyman and Millikan have extended the measurements some 4 octaves onwards into the ultra-violet. Then comes a gap of 4 octaves of rays in a region not yet explored, and finally some 7 or 8 octaves of X- and gamma-rays, of which the radiologist uses about 3 octaves (*Fig.* 1).

It is interesting to note that the gap between X-rays and ultra-violet rays has in a sense been already bridged, for Millikan has recently found the characteristic X-ray lines of carbon in the extreme ultra-violet region.

wave is very high and we get a high-frequency or "hard" X-ray. If the change of speed is less, the frequency is less and we get a "softer" or less penetrating ray. With much slower electrons, light rays may be similarly produced. Always, however, we find that the frequency of the wave is proportional[1] to the energy change of the electron. There will be a proportion of encounters where the whole of the energy is transferred, and in these cases the frequency will reach an upper limit. Below this limit we find every variety of energy-content depending on the energy of the electron involved.

The reverse effect is equally true. If X-rays (or light rays) strike a substance they may give up all their energy to moving electrons, or they may give up only a part, the rest being transferred to a series of groups of rays, all characteristic of the atom of the material. The energy balance-sheet can be fully set out, the several items all being definite and specific. The relation is not quite so simple as the

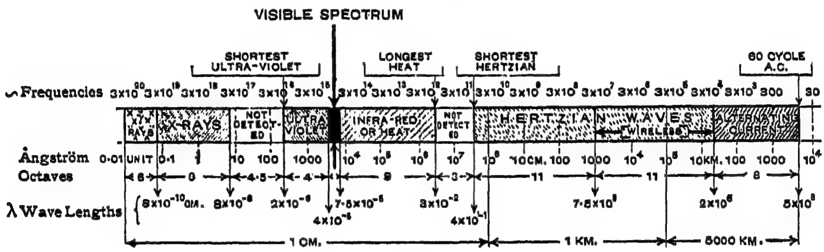

FIG. 1.

The study of this missing group of octaves bristles with interest and difficulties. It would seem as if a big absorption band were included; at either end of the gap the vacuum spectrometer is necessary. Moreover, it almost looks as if the grating method would fail us over this region. The wave-lengths are too small for our artificial gratings and too big for crystal gratings. We may have to wait for a new weapon of attack.

Following is a short table of some of the wave-lengths, in Ångström units, *i.e.* 10^{-8} cm.:

Visible light	7200–4000
Ultra-violet light	4000–200
X-rays	12 to 0·06
γ-rays	1·4 to 0·01

§ (2) X-RAYS AND ELECTRONS.—Experiment has shown the most intimate relationship between the X-ray and the electron—either is the manifestation of the other. The electron, the unit of negative electricity, is the active manifestation of the X-ray—innocuous in itself. Whenever an electron has its speed suddenly altered, an electromagnetic wave is produced. If the alteration of speed of the electron is very great the frequency of the

general case, but the exchange and partition of energy are equally precise.

The reversible process we have just described is of universal application in Nature. There is, for example, little doubt that the X-rays play a prominent part in atmospheric electricity. The earth is not an electrically neutral body, but its surface may be considered to be covered with a layer of negative electricity, and this gives rise to an electrical field in the atmosphere. The rate of alteration of potential is found to decrease with the altitude; the potential gradient being about 150 volts per metre on the ground and only about 2 volts per metre at a height of 9 kilometres—as we know by balloon tests. In other words, the atmospheric conductivity steadily increases the higher we go, and the rapidity of the increase suggests very large values at greater heights.

Some of this conductivity, we know, is due to radio-active emanations from the soil, but we are led to infer from the increase of conductivity with height that the majority is due to some agent external to our globe. Modern opinion favours the view that the effect is produced by very high-speed electrons

[1] See "Quantum Theory," § (3).

ejected from the sun with very nearly the speed of light itself. Some of these strike the atoms of the outer atmosphere, very penetrating X-rays are generated, and thus the whole depth of the atmosphere may be permeated by these electrons through the intermediary of their more penetrating alias the X-rays. Thus the earth's negative charge which is being continually dissipated by the action of the potential gradient in the atmosphere is as steadily replenished by a current of electrons passing downwards. It may be added that the conductivity of the air diminishes at night and during a solar eclipse.

One is tempted also to believe that in view of the temperature and gigantic electrical disturbances in the sun—as Hale's work has shown and Eddington's speculations would indicate—there may be an emission of X-rays from the sun itself.

One other source of X-rays in Nature may be referred to—the γ radiation of the radioactive elements. It will suffice to say that while some of the γ-rays can be exactly imitated, others are much more penetrating than any X-ray we have been able to generate artificially.

Although the electron is ubiquitous, it escaped detection until Crookes conducted his famous experiments in discharge tubes at low pressures, and so reduced the number of molecules present that instead of the electron being absorbed and suppressed within a mm. or so, as it would be at atmospheric pressure, it could now travel great distances without encountering more than say, 100 or so atoms, the majority of which it passed clean through without being deviated in any way. The high speed it received from the potential in the discharge tube gave it, so to speak, an innings.

We have anticipated matters somewhat, but it will now be convenient to review the main features of a discharge tube and their historical development.

§ (3) The Phenomena of a Discharge Tube.—When a high-potential discharge[1] is passed between two electrodes within a glass tube, the gas pressure in which is gradually reduced, the tube displays a succession of appearances which vary with the pressure. At atmospheric pressure the discharge takes the form of a spark which, as the pressure is lowered, loses its noisy character and is replaced by a bundle of irregular streamers, which, after a time, broaden out and fill the bulk of the tube with a pink glow, known as the positive column.

At a pressure of a few millimetres of mercury the cathode (the electrode by which the current leaves the tube) slowly becomes covered with a luminous glow—the negative glow—while between the positive column and negative glow comes a darker region, diffuse in outline, called the Faraday dark-space. All this time the rarefied air is increasing in conductivity, as evidenced by the shortening of the alternative spark gap.

As the exhaustion proceeds the positive column may break up into thin fluctuating striations, which presently widen and diminish in number. The negative glow proceeds to detach itself from the cathode, while a new film forms and spreads over the surface of the cathode. The two parts of the negative glow are separated by a dark region called the Crookes or cathode dark-space, the outline of which is sharply defined and runs parallel with that of the cathode. As the pressure is reduced the dark-space increases in size, its thickness often being used as a rough measure of the pressure.

At still higher rarefactions both positive and negative glows become darker and more indefinite, and the cathode dark-space grows until finally its boundaries touch the glass walls of the tube, which then begin to fluoresce.

Meanwhile the conductivity of the rarefied gas has been steadily lessening until, finally, it is possible to get the exhaustion so complete that no discharge can pass.

§ (4) Cathode Rays.—The study of the fluorescence of the glass wall was initiated by Plücker in 1859. He was followed in the 'seventies by Hittorf and Goldstein in Germany, Puluj in Austria, and Crookes in England. It was soon ascertained that the fluorescence was produced by some form of radiation (called Kathodenstrahlen by Goldstein) which sets off from the cathode and travels in straight lines. For nearly thirty years the English and German schools of physics disagreed as to the nature of the cathode rays, but Sir J. J. Thomson in 1897–98, in a series of classical experiments, was able to show that the cathode rays were bodies of sub-atomic size, moving with prodigious velocities, velocities which are comparable with the speed of light. Johnstone Stoney had previously suggested the name electron for the unit of electricity, and the suitability of the expression for the cathode rays was at once recognised. Thomson showed that each cathode ray had a mass about 1/1800 of that of the hydrogen atom and carried a negative electrical charge, agreeing in amount with that carried by the hydrogen ion in liquid electrolysis.

The bulk of the great energy of the cathode rays is dissipated as heat when the rays strike an obstacle. If the rays are concentrated by using a concave cathode or other focussing device, enormous heat can be generated with heavy discharges. Cathode-ray furnaces, working on this principle, have been con-

[1] See also "Electrons and the Discharge Tube," Vol. II.

structed, in which any known metal can be melted or vaporised.

By reason of their electric charge cathode rays are readily bent under the action of electric or magnetic force, and this property of the rays has found practical application in Braun tubes and other forms of oscillograph. The cathode rays, having no inertia, are able to follow the most rapid vagaries of an electric or magnetic field.

§ (5) Positive Rays.—In 1886, Goldstein, using a perforated cathode, noticed that a stream of rays emerged from the tube in a direction opposite to that of the cathode rays. Wien later observed that these "Kanalstrahlen" carried a positive charge. The deflection in electric and magnetic fields showed that the positive rays[1] (as they were called later by Sir J. J. Thomson) were molecular in size. J. J. Thomson and Aston have done extended work on the subject and derived highly important results. Positive rays play an important part in gas X-ray tubes, as we shall see presently.

§ (6) Discovery of X-rays — Röntgen Rays.—It was in the autumn of 1895 that Professor W. K. Röntgen at Würzburg, Bavaria, discovered the rays which now bear his name. During the course of a research on invisible light rays, he had enclosed a discharge tube within a screen of stout black paper. On passing the discharge he noticed that a fluorescent screen, lying on a table some distance away, shone out brightly. By interposing obstacles Röntgen traced back the unknown or "X" rays to their source, which proved to be the region of impact of the cathode rays on the walls of the tube. The feature of the new rays was their uncanny ability to penetrate many substances quite opaque to light. The degree of penetration was found to depend roughly on the density. For example, flesh is more transparent than bone, and accordingly the bones stand out dark in the shadow caused on a fluorescent screen. Röntgen saw at once the immense importance of his discovery to surgery, and communicated his results to the Physico-Medical Society of Würzburg in November 1895.

The main features of the rays were soon discovered by an army of workers. It was found, for example, that X-rays travel in straight lines, cannot apparently be refracted or reflected, do not carry an electric charge, and possess the property of ionising or imparting temporary electric conductivity to a gas.

§ (7) Detecting the Rays.—Although X-rays are not in the visible spectrum they can be detected photographically or by their power of exciting fluorescence in screens made of salts such as barium platino-cyanide, or calcium tungstate. Another method makes use of the ionising ability of the rays and measures the conductivity so produced in a gas. Certain chemical reactions are also induced by the rays and can be made to serve as the basis of various methods of detection and measurement.

[1] See "Positive Rays," Vol. II.

X-rays can penetrate all substances to a greater or less degree, and in general the shorter the wave-length the higher is the penetrating power. The penetrability of a material by a given beam of rays is governed by the number and mass of the atoms it encounters, that is, by the atomic weight and thickness. Chemical combination or temperature is without effect on the absorbing power of an atom. We have already mentioned that the rays travel in straight lines, and thus it will be seen that an X-ray photograph or radiograph is essentially nothing but a shadowgraph. Radiography was the first and still remains the most important application of the rays, and in the hands of the medical man has found enormous application. The late war brought this home in unexampled fashion, and the services which radiology then rendered can scarcely be overestimated.

The subject is referred to later, but mention may here be made of the necessity of protecting the X-ray operator from the rays. As many of the early workers discovered to their cost, indiscriminate exposure results in dermatitis, which may be followed by dangerous cancerous growths. With hard rays derangements of the internal organs and impoverishment of the blood corpuscles may result. Nowadays every precaution is taken and such casualties rarely occur. Heavy lead screening in some form limits the beam of rays and protects the worker.

II. X-ray Tubes

§ (8) Early Forms.—The vacuum tube with which Röntgen made his discovery had a flat cathode, the cathode rays impinging on the glass walls. Experience soon showed the way to improvements. Campbell-Swinton inserted a platinum target obliquely in the path of the rays, and later Sir Herbert (then Professor) Jackson replaced the flat cathode by a concave one, so that the cathode rays were brought to a focus on the target. The result was that exposures were enormously shortened and, owing to the small area of emission of the X-rays, the resulting photographs were improved out of all recognition in definition and detail.

The present-day method is essentially unaltered. The electrons (cathode rays) are given enormous speeds (of the order of 50 to 100 thousand miles a second) by means of high voltages, and are directed on a heavy metal anticathode or target. As a producer of X-rays the arrangement is still extremely

inefficient, although we take steps to increase the chances of an effective collision by choosing a target of high atomic weight or number.

As already mentioned, almost all the energy of the electrons is degraded into heat, and for this reason it is essential that the target shall be of a very refractory metal. Tungsten (with a melting-point of over 3000° C.) is nowadays almost always employed for a target, though platinum and other metals find application for certain purposes.

The X-rays radiate uniformly in all directions from the focus, travelling in straight lines just as light rays radiate from a lamp. The X-ray bulb is comparable to an X-ray lamp, in which the voltage applied to the bulb corresponds to the temperature of a luminous lamp. If we raise the temperature of the latter we increase the intensity and at the same time shorten the average wave-length; so with the X-ray bulb, if we raise the voltage we increase the intensity and shorten the average wave-length. In practice the voltages employed range up to 200,000 or even more. The quantity of radiation is dependent on the current through the tube, and a milliampere is a convenient measuring unit for the purpose.

There are two main types of X-ray bulbs in use (*a*) the hot cathode tube, (*b*) the gas tube. The Coolidge tube, invented by Dr. Coolidge in America, is the chief representative of the first class, in which the electrons are produced from a cathode consisting of a spiral of tungsten wire, raised to a white heat by an electric current. The vacuum in the tube is very high, and no discharge can pass if the cathode is not heated. The Coolidge tube has the valuable property of precise and reproducible control with a great range, advantages which cannot be claimed for the gas tube. In the gas tube very complete exhaustion is not attempted; a trace of residual gas is deliberately left in the tube, and this serves as a constant source of electrons through shock ionisation.

If we compare the characteristic curves of these two types of X-ray lamps by plotting current against voltage, we find differences which are fundamental (*Fig.* 2). Under the conditions in which a gas tube operates the current increases steadily with the voltage, while in the case of the Coolidge tube the current is independent of the voltage. In the latter case the current is limited only by the number of electrons emitted, which number increases or decreases with the temperature of the cathode filament. Thus we can alter either voltage or current independently of each other, and this fact gives the hot cathode tube a great advantage over the gas tube, in which independent control of voltage and current is impossible.

The hot cathode tube thus utilises its "saturation" current, and for that reason is much less affected by changes in the wave form of the exciting potential than is a gas

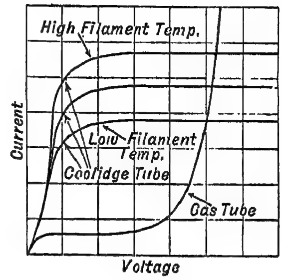

FIG. 2.

tube. On the other hand, the absence of saturation in a gas tube leads to a more effective use of very high voltages, and it is found that, at any rate, at low gas pressures a gas tube gives about twice the X-ray output of a Coolidge tube for the same milliamperage and voltage (*Fig.* 3, Dauvillier). But the gas tube is far from being the equal of the Coolidge tube as regards control and reliability, though experience counts for a good deal.

It may be added that both types of tube

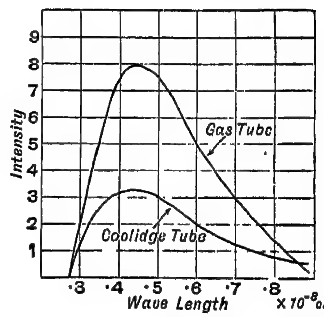

FIG. 3.

give heterogeneous X-rays, and there is little to choose between them in this respect.

§ (9) THE ELECTRODES OF AN X-RAY TUBE.—*The cathode* of the present-day X-ray gas tube is made of aluminium of robust design. It is mounted facing the anticathode or target, the distance between the two being a matter of nicety for the maker, who has to be guided largely by his experience and knowledge of the work for which the tube is intended. The lower the pressure or the "harder" the tube, the farther the focus of the cathode rays recedes from the cathode and the smaller the focal spot.

The material and size of the cathode are both important. Aluminium possesses advantages because it displays but little "sputtering"

or blackening, a feature which is common to almost all metals when functioning as a negative electrode in a vacuum. Aluminium shows the effect but slightly, but with very heavy discharges the central portion of the cathode may be melted, the molten globules so formed being projected right across the tube in some cases. No particular harm is usually done, except that the curvature of the cathode may be changed and the focal spot of the cathode rays moved in consequence.

The choice of metal for cathode is also important from the point of view of the occluded gas. There is little doubt that in the case of a gas tube the gases contained within the metal of the cathode play an important part. This is probably the explanation why some experimenters have found it useful to keep the cathode cool by some device.

The cathode of a Coolidge tube is described later.

§ (10) The Anticathode.—The primary essentials in an anticathode, whether for gas or hot-cathode tube, are:

1. A high atomic number to secure a large output of X-rays.
2. A high melting-point and a high thermal capacity to prevent the target fusing under a heavy discharge.
3. A high thermal conductivity to assist in dissipating the waste heat.
4. A low vapour pressure to avoid distillation and condensation of the metal on the walls of the tube.

In the light of the above requirements, tungsten stands almost alone as a material for anticathodes. Platinum was at one time almost exclusively employed, but tungsten has a much higher melting-point (3200° C. as against 1755° C.), has twice the thermal conductivity, and but a slightly inferior radiation value.

The very large heating effects experienced by the anticathode of a modern X-ray bulb have provided scope for much ingenuity in getting rid of the surplus heat. The anticathode is in many tubes kept cool by means of a water reservoir or a stream of air. In other cases the massiveness of the anticathode is increased by surrounding the tungsten target with copper, the support of which extends to the outside of the tube and is there provided with radiating fins, incidentally necessitating some very fine glass manipulation.

§ (11) The Anode.—The modern X-ray gas bulb is almost always provided with an additional anode of aluminium, which is connected externally with the anticathode. The precise benefits of the separate anode are distinctly doubtful, and in tubes of the Coolidge type it finds no place.

§ (12) The Gas Tube.—The gas tube depends for its action on the presence of a few ions in the residual gas in the tube. These ions or electrified atoms have their velocities increased by the electric field, positive ions being drawn to the cathode and negative to the anode. The positive ions bombarding the cathode release electrons in abundance which, being attracted to the anode, ionise freely by shock or collision those atoms encountered *en route*, generating more positive ions and more electrons. The electrons which hit the target generate X-rays and the cycle of operations continues so long as the voltage is applied.

The positive ions or positive atoms thus play a fundamental and essential part in the ionics of a gas tube. They are also responsible for one or two other effects, the elucidation of which has been very puzzling. One of the great difficulties in exact work with the gas tube is the continual tendency of the gas pressure to change. One would first look to the electrodes which, depending on the conditions, may either emit or absorb gas and do so control very materially the well-known "crankiness" of a gas tube. But it is found that, provided the current is not too heavy to overheat the electrodes, there is a continual and apparently unlimited disappearance of gas, more especially at high voltages, and ultimately the vacuum becomes so high as to render the tube unusable. To cut a long story short we now know that some of the positively charged atoms of gas by reason of their high velocity (about 500 miles a second) actually crash into the glass walls of the tube and are mechanically trapped there, an effect which is enhanced by the presence of volatilised metal.

Many devices have been introduced from time to time to overcome this hardening effect. In some cases, when the tube becomes too hard, the discharge is caused to pass through a small annexe containing absorbent material, such as asbestos, which liberates enough gas to soften the tube. Another method commonly employed is to rely on the diffusion of gas through a small platinum tube, which can be heated by a small flame.

If a gas tube is overloaded the result is sometimes to harden the tube, sometimes to soften it, depending largely on the behaviour of the cathode. Further, if the discharge is sufficient to make the target red-hot, it may then give off so much gas as to necessitate re-exhaustion of the bulb.

A very commonly met source of failure of gas tubes is due to cracking of the glass, almost always in the region round the cathode. In many cases this is preceded by a roughening of the glass at this point. These effects are produced by positive rays striking the glass walls. The positive rays are probably also responsible for the melting of the aluminium

cathode under very heavy discharges. There is little doubt that the positive ions produce the luminous blue glow which often accompanies high-voltage discharges, and also the positive electrification which is present on the glass walls of the bulb of a gas X-ray tube. Positive ion effects are always found to persist so long as the electrodes are giving off gas.

A common defect with gas tubes is the wandering of the focal spot. Such movement is, of course, prejudicial to good definition in radiography. Further, it is not unusual, after the tube has been subjected to a heavy discharge, to find that the focus has permanently changed its position.

Another characteristic of a gas tube is that the breakdown voltage is a good deal higher than the running voltage. This is due to the fact that in the gas tube the number of ions initially present is very small. When the circuit is closed the number of ions produced by collision increases enormously, and the voltage across the terminals of the tube falls in consequence.

The gas tube received a good deal of attention in Germany during the war. In the so-called "boiling tube" of Muller, the gas tube is employed to generate very penetrating X-rays primarily for use in deep therapy. The gas pressure is not only low, but tending to get lower. To prevent emission of gas from the (platinum) anticathode, it is kept at a constant temperature by boiling water, and water-cooling is also adopted for the cathode. The focus is very broad. The tube is operated at close on 200,000 volts and with small currents, 2 to 3 milliamperes, a condition which assists the hardening tendency. Puffs of gas are introduced by an osmosis tube heated by a small flame ignited and operated through a relay by an automatic regulator which is controlled by a milliammeter in series with the tube. In action the water quietly boils, and the tube may be run for hours at a time at a constant milliamperage. It is claimed that there is a greater proportion of homogeneous end radiation when the X-rays are filtered than there is from a Coolidge tube working under the same conditions.

Whether that is so or not, it must not be forgotten that an increase of potential always tends to render a beam of X-rays more homogeneous. Further, the spark-gap readings on a gas tube tend to indicate voltages higher than those which are actually operating the tube.

§ (13) THE COOLIDGE TUBE.—Consideration of the properties of a gas X-ray tube indicates that most of the limitations are incidental to the presence of positive rays. Dr. W. D. Coolidge[1] of the Research Laboratory of the General Electric Company, Schenectady, New York, saw that most of these disabilities would disappear if the vacuum in the tube were high enough, so that the positive ions did not play an essential rôle. This necessitated generating cathode rays by some other means, and Coolidge turned to the work of Richardson,[2] who had made quantitative measurement of the electrons produced by heating a negatively charged metal. There was considerable divergence of opinion at the time as to the mechanism of the effect, and certain workers had suggested that in the absence of gas such thermionic discharges would cease altogether. Langmuir[3] in some experiments on the thermionic currents in the case of tungsten, showed that the effect was a real one, and that instead of dying away the currents actually increased, up to a certain limiting value, as the tube became freer and freer from gas. In brief, Langmuir showed that a hot tungsten cathode, in a vacuum as high as it is humanly possible to make it, emits electrons continuously at a rate determined only by the temperature.

Dr. Coolidge was thus led to evolve the Coolidge X-ray tube, the main features of which are as follows:

The cathode consists of a small flat tungsten spiral which can be electrically heated by an independent circuit. Surrounding the spiral is a tube or bowl of molybdenum, which serves to focus the cathode ray stream upon the target. The temperature of the filament varies from about 1600° to 2300° C. The bowl is connected electrically to the cathode, and the anticathode or target functions also as anode. In the earlier or "universal" type of tube the target consists of a block of tungsten with a molybdenum stem. This design has been modified in later types.

Unusual precautions are taken to render the exhaustion of the bulb as complete as possible. Langmuir pumps with liquid air traps are used, and the whole tube, while connected to the pump, is heated in an electric oven to just short of the softening point of glass (about 470° C.). Periodically the tube is operated with heavy discharge currents, so that the tungsten target is raised to a white heat. The test of adequate exhaustion is the complete absence of a luminous discharge and phosphorescence of the glass walls. It is found that the time of exhaustion can be considerably shortened by previously heating the electrodes to a high temperature in a vacuum furnace. Metal thus treated may be left about in the air for some days and only absorb but a small fraction of the gas originally contained in it.

The great merit of the Coolidge tube is its capacity to reproduce completely any specified

[1] *Phys. Rev.*, 1913, ii. 409.

[2] *Roy. Soc. Proc.*, 1903, lxxi. 415.

[3] *Phys. Rev.*, 1913, ii. 450.

set of conditions. The output (or quantity) of X-rays depends only on the temperature of the filament. The penetrating power (which depends upon the wave-length) is controlled only by the voltage across the terminals of the tube. Furthermore, the tube allows current to pass in only one direction, so long as the conditions are such that the target is not raised in temperature to more than a dull red heat. The tube is, in fact, capable of rectifying its own current, when supplied from an alternating source. The latest form of radiator tubes permits the passage of a steady current of as much as 30 milliamperes. Care should be taken that the tube is not overloaded, as otherwise, if the target attains a white heat, a considerable amount of inverse current will be allowed to pass, with detrimental and ultimately disastrous effects on the bulb.

Another feature of the Coolidge tube is that the starting and running voltages are the same. As the positive ions play no appreciable part, there is little or no consequential heating of the cathode, and no evidence of appreciable cathodic sputtering. The Coolidge tube in operation shows none of the fluorescence of the glass displayed by gas bulbs, a result due to the fact that the walls of the tube become negatively charged, and so, unlike an ordinary gas bulb, repel the "reflected" cathode rays from the target.

In the prolonged use of a Coolidge tube a small amount of gas is usually liberated, as is indicated by a small drop of the milliamperes through the tube, which can be corrected by raising the filament temperature; such gas is promptly re-absorbed when the discharge is stopped.

Coolidge, by the use of the pin-hole camera, has shown that, in addition to the main body of X-rays from the focus, there is a very considerable emission of extraneous X-rays from the entire surface of the anticathode, which must therefore be bombarded by cathode rays from some source or other. We must look to the "reflected" rays for an explanation. These rays, which leave the focus with a velocity almost as high as that with which they approached it, are repelled by the cathode and the glass bulb, both negatively charged, and are compelled to return and collide once more with the anticathode. Doubtless in many instances this procedure occurs again and again, X-rays being produced at every collision. The pin-hole camera shows that, except in the region of the focus, the intensity of the X-rays is much the same, both back and front of the anticathode. Measurements show that the rays, whether from back or front, differ but little in penetration. Coolidge has devised a variety of apparatus for reducing the magnitude of the stray radiation, but in the end came to the view that the extent of the defect did not justify the loss of simplicity involved in providing a remedy. The use of a lead diaphragm as small as possible and as near the tube as possible is the best cure.

Coolidge has also developed various modifications of the original design of tube. In the radiator type of tube, referred to above, the anticathode is made up of a solid bar of copper, which is brought out through the glass to a copper radiator (*Fig.* 4). The head of the anticathode consists of a mass of specially purified copper, which is first cast in a vacuum around a tungsten button, and is then electrically welded to the stem. In this type of tube the great bulk of the heat generated is conducted away by the radiator, and, as a result, it has become possible to make the glass bulb very small, a little under 4 in. in diameter. It may be added that the type of anticathode just described greatly increases the difficulty of exhaustion. In a still more recent model the glass walls have been made very thick, about a quarter of an inch. One effect of this is, for some curious reason, greatly to increase the steadiness of the discharge. Lead glass is used with a thin transparent window, and the tube thus affords protection for the operator. It has been found possible to manufacture a workable lead glass which affords as much protection as one-quarter the same thickness of sheet lead.

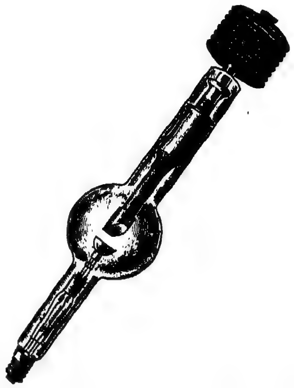

FIG. 4.—Radiator Type of Coolidge Tube.

In some experimental models Coolidge has worked with anticathodes cooled by currents of water. Such tubes permit enormous X-ray outputs. One tube ran continuously for 68 hours at 100 milliamperes and 70,000 volts. Other tubes have been run continuously for many hours at 200 milliamperes, the power input being of the order of 14 kilowatts. Doubtless this figure will be increased as time goes on.

The G.E.C. of America has adopted the methods of mass production to the various

forms of Coolidge tube, and is now turning out over 100 tubes a day. The bulbs and glass parts are blown in moulds at the glass factory, and the operation of assembly is carried out by girls with the aid of glass-blowing machines.

There is one feature of the Coolidge tube to which reference may be made. As already remarked, in consequence of the low pressure, "shock" ionisation of the residual gas is negligible or practically so, and the work of carrying the current is left solely to the electrons. Thus the space between the electrodes is filled with carriers of one sign, with the result that at high current densities there is an appreciable obstructing effect due to electrostatic repulsion between the electrons crossing over and those following. This "space-charge" sets an upper limit to the current through a Coolidge tube at high filament temperatures. Thus the current through a Coolidge tube may be set an upper limit either by the filament temperature or by the space-charge. The restricting effect of the space-charge can be lessened by raising the voltage or by introducing positive ions in some fashion, *e.g.* by a trace of gas. In the case of very heavy momentary discharges tungsten vapour is produced at the focal spot, and this also serves greatly to diminish the tube resistance.

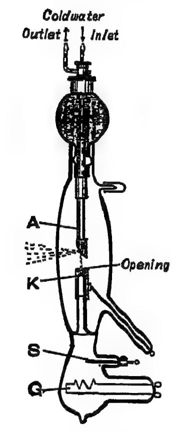

FIG. 5.

§ (14) LILIENFELD TUBE.—The Lilienfeld tube, introduced in 1913, and since extensively modified, may be said to act as a combination of hot cathode tube and gas tube, and, incidentally, is claimed to possess the advantages of both. In an annexe to the main discharge tube a hot cathode is separately excited by a moderate potential. The electrons pass through a hole in the main cathode and are there subjected to a much higher potential difference before they strike the anticathode (*Fig.* 5). Lilienfeld lays stress on the importance of using a coil discharge (as distinct from a transformer discharge) in that it yields higher momentary current densities. At high voltages (above 120 kv. and up to 170 kv.) the rays after filtering through 3 mm. of aluminium are stated to be homogeneous.

§ (15) METAL X-RAY TUBES.—From time to time various experimenters have worked with metal bulbs in an attempt to get rid of some of the energy limitations imposed by glass. Sir Oliver Lodge designed such a bulb in 1897, and since then Coolidge (*Fig.* 6), Siegbahn, and others have made use of them, and it is not unlikely that future commercial developments will be on such lines. Silica bulbs have also been used by Coolidge and other workers.

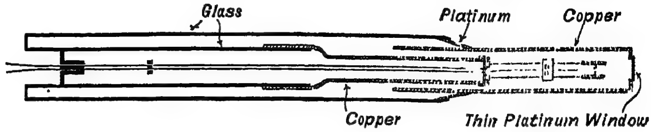

FIG. 6.

III. THE HIGH-POTENTIAL GENERATOR

The voltages which obtain in practice for exciting X-ray bulbs are, roughly speaking, of the order of up to 100,000 volts for radiography and superficial therapy, and up to 200,000 volts or more for deep therapy and metal-radiography.

§ (16) TRANSFORMERS AND INDUCTION COILS.—The high-potential generator is almost always a step-up transformer.[1] Less commonly, especially in this country, influence or static machines are employed, though they would have many advantages if they could be sufficiently improved to withstand atmospheric humidity.

It is customary in radiology to speak of "induction coils" and "transformers," though both are varieties of step-up, static, high-tension transformers. By an induction coil is meant an open-cored transformer which depends for its action on the interruptions of the primary current by an independent break or interrupter. By a transformer is implied a closed-core transformer fed with alternating current (almost always single phase) either straight from the main or (in the case of a D.C. supply) from the alternating side of a rotary converter. Such a transformer may be either oil-immersed or have "dry" insulation.

The coil ordinarily yields a "peaky" potential wave as compared with the approximately sinusoidal wave form of the transformer. With either type some sort of valve or mechanical rectifier is employed either to cut out or invert the half of the high-potential wave which would tend to pass in the wrong direction through the X-ray bulb. In the case of a coil and rotary interrupter the mechanical rectifier is a commutator mounted on an extension of the spindle of the interrupter. In the case of a transformer a similar

[1] See "Transformers, Static," Vol. II.

commutator is mounted, either on the shaft of a synchronous motor (if A.C. supply is used) or on an extension of the shaft of the rotary converter, as the case may be. If a valve is used instead, there are several types available, but choice is practically restricted to the hot cathode type such as the Kenetron. As already remarked, Coolidge tubes of the radiator type are self-rectifying.

The initial cost of a transformer outfit is approximately twice that of an induction coil outfit of corresponding power. A transformer outfit is rather more bulky, and any repairs are also usually more expensive. On the other hand, the efficiency of a transformer is roughly twice that of a coil (including a break and rectifier). Further, owing to the occasional vagaries of all interrupters, control is more precise and measurements are more definite with the transformer, and if A.C. is available and we dispense with the mechanical rectifier, there are no moving parts. Transformers produce greater heating effect on the target of the X-ray bulb, but this objection is met by arranging the rotating commutator so that it picks off only the regions round the crests of the loops, and thereby eliminates the less efficient lower voltages.

The induction coil is an empirically designed instrument, the present-day type of which is not fundamentally very different from the early models of Spottiswoode, although in detail it differs very considerably. The exact measurement of the performance of coils is difficult, and, as a consequence, coil makers have been led to adopt certain arbitrary standards of design which are based chiefly on practical experience. Some of the factors which arise in the design are conflicting, and it is in the methods of reconciling necessarily antagonistic factors that the skill of the coil designer finds chief scope.

The subject of induction coil design for X-ray purposes is a large one, and only certain broad conclusions can be touched upon here. A transformation ratio of from 50 to 200 and an efficiency of 0·3 to 0·6 are usual figures. Some form of sectional winding is adopted for the secondary coil, allowing about 4000 volts for every 1000 turns, and arranging that the outside diameter does not exceed 2½ times the bore. The resistance and, more especially, the self-induction of the secondary must be kept down. The primary should be capable of being connected directly to the 200-volt mains. The capacity of the condenser should be no greater than will prevent undue arcing in the interrupter. The interrupter should run at as high a speed as is expedient, and be of adequate design and robust construction.

About 15 lbs. of iron core should be allowed for every kilovolt-ampere input. The core may well have a length in the neighbourhood of up to 10 times the diameter. The primary windings should extend over almost the whole length of the core; the secondary windings over not more than the middle three-quarters, though care must be taken that this (the length of the secondary) is at least $\frac{4}{5}$ times the maximum spark length.

The induction coil is essentially a shock apparatus, and the shock excitation method of interruption may result in the presence of many superposed harmonics in the oscillation waves. These harmonics, which have high frequencies (several thousands a second), are reflected in the secondary circuit, where, from a practical point of view, they evince themselves in the reluctance with which they pass through an X-ray bulb. The resulting tendency to spark across the surface of the tube can only be met by lowering the gas pressure, by immersing the tube in oil, by lengthening the arms, or, of course, by suppressing the high-frequency waves before they reach the tube.

This is done in the so-called "symmetrical coil" which has been developed in Germany. In this apparatus two separate coils, mounted vertically side by side, have their secondaries connected in series, and also their primaries. In the two connecting leads between the secondaries are inserted a gas X-ray bulb in the one and an enclosed rectifying spark gap in the other. On each side of the spark gap and in series with it is a high resistance (water). The self-induction of the secondary circuit is low, but the resistance is very high and serves to damp out the high-frequency oscillations. The spark gap helps to enhance the breakdown potential of the gas bulb. High voltage (200,000) and low current (2 to 3 m.a.) are aimed at. An annular air space between primary and secondary assists natural cooling. A mercury break ($\sim = 47$) is used.

Interrupters.—Much of the progress that has been made with the performance of coils has resulted from the proper selection of interrupter. The hammer break, the accompaniment of most of the earlier coils, is now rarely fitted. The majority of present-day interrupters are of the motor-driven type, which employ mercury in a dielectric either of coal gas or a liquid such as paraffin oil. A large proportion of mercury interrupters are of the turbine variety, in which a jet of mercury is pumped against a series of rapidly revolving vanes.

The electrolytic or Wehnelt interrupter still finds favour with some workers. In the usual form it consists of two electrodes immersed in dilute sulphuric acid. The cathode is a large lead plate, the anode consisting of one or more platinum points, the exposed amount of which may be controlled by an adjustable porcelain sleeve.

There is still scope for much work on the design of interrupters, which may fairly be said to be the most untrustworthy feature of a present-day coil outfit. A large amount of energy is wasted in the interrupter, especially with heavy currents.

IV. The Measurement of X-rays

The output from an X-ray bulb must be specified with respect to (1) mean wave-length, quality, or hardness, and (2) intensity, *i.e.* quantity of rays per unit area.

The problem is complicated somewhat by the existence of two distinct types of radiation—(1) a general spectrum of X-rays with a large range of wave-lengths; (2) the "characteristic" or "monochromatic" rays which are wholly characteristic of the metal of the anticathode.

The proportions of these two classes depend on the conditions of discharge and on the material of the target. The characteristic radiations only appear when the exciting cathode rays are sufficiently fast. There is, in fact, a critical voltage for each metal, which is required in order to excite the characteristic rays, and the proportion of these rays increases rapidly as the voltage is raised above this critical limit.

§ (17) Methods of measuring Quality or Hardness.—The range of qualities of X-rays is very wide, embracing several octaves.

(i.) *Wave-length.*—We now know that the hardness, or penetrating power, of an X-ray is precisely defined by its wave-length—the shorter the wave-length, the harder the ray. The most precise means of measuring the quality of X-rays is by the crystal spectrometer. Measurements show that the majority of the wave-lengths of the X-rays, so far examined, lie between 10^{-7} and 10^{-9} cm.

The subject is dealt with elsewhere, but it has been shown by the Braggs, Moseley, and others that measurements of the diffraction of X-rays by crystals can be made to yield the wave-length of X-rays as well as the dimensions of the lattice-constant of the crystal concerned.

It may briefly be mentioned that in any crystal the atoms are regularly disposed in a network of intercrossing groups of planes, each of the planes in a group being parallel to and equidistant from its like neighbouring planes. The lattice-constant of a crystal is the distance separating the main atomic planes parallel to some specified crystal face.

In view of their importance in X-ray measurement we give below a table of X-ray wave-lengths for the three main series (K, L, M) of characteristic lines. Preceding this is a table of lattice-constants for several crystals on which extended measurements have been made.

(ii.) *X-ray Spectra.*—Up to now, about 16

Lattice-constants of Crystals

Crystal.	Lattice-constant.	Observer.
	$\times 10^{-8}$ cm.	
Rock salt, NaCl . . .	2·8140	W. L. Bragg, *Roy. Soc. Proc.*, 1913.
Calcite (cleavage face), $CaCO_3$	3·0290	Siegbahn, *Phil. Mag.*, 1919.
Potassium ferrocyanide, $K_4Fe(CN)_6 \cdot 3H_2O$ . .	8·408	" "
Gypsum, $CaSo_4 \cdot 2H_2O$.	7·621	" "

lines have been found to be associated with the characteristic X-ray spectrum of each element. Three series of lines are known at present—the K, L, and M, of which the K has the highest frequency. It has also been claimed that a J series exists, but the evidence needs confirmation. The K series contains at least 4 lines, α, β, γ, δ (some of them doublets), of which the δ line has the highest frequency. The L series contains probably 3 groups of lines, each group similar to the K series.

The values of the wave-lengths of the principal lines are given in the tables in Ångström units. It should be noted that all the values rest on W. L. Bragg's estimate of the lattice-constant of rock salt (see above).

(iii.) *Absorption Coefficients.*—A very usual method of determining the quality of X-rays is to measure their absorption in a standard material such as aluminium. Aluminium is commonly chosen because it is readily procurable in convenient form, and, so far as is known, does not, in the majority of cases, complicate matters by superposing a characteristic radiation.

Now it is found that if all the rays, both entering and leaving a plate of material, are homogeneous (that is, wholly of the same quality), then the rays are absorbed exponentially by the plate, *i.e.* if 1, 2, 3 . . . similar sheets are successively introduced, each additional sheet absorbs the same fraction of what it receives. In other words, if there is no "scattering" or transformation of the X-rays, and if μx is the fraction of the intensity which is absorbed when the rays pass normally through a very thin screen of thickness x (cm.), then for a plate of thickness d (cm.)

$$I = I_0 \, . \, e^{-\mu d},$$

in which I_0 is the intensity of the beam when it enters, and I that of the beam when it leaves the screen. e (=2·72) is the base of the hyperbolic system of logarithms. μ is termed the linear absorption coefficient.

D.P.G.V., Verh. der Deutsch. Phys. Gesell.; *P.M., Phil. Mag.*.

It follows that $\mu=(2{\cdot}3/d)(\log I_0-\log I)$; the logarithms being to base 10. If in a set of observations with homogeneous rays, log I is plotted as ordinate against d, the graph is a straight line and μ is 2·3 times the slope of the line.

With ordinary heterogeneous rays, μ is greater for thin screens than for thick, and so we can only deal with an average μ, which, however, varies more and more slowly as the screen becomes thicker (*Fig.* 7).

The logarithmic curve of absorption for

heterogeneous rays, such as are given out by an ordinary X-ray bulb, is not a straight line, but a curve which is steeper for thin screens than for thick (*Fig.* 8). For a method of finding analytically the absorption coefficients of the constituents of a complex beam of rays, see J. J. Thomson, *Phil. Mag.*, December 1915.

In the case of the characteristic radiations, an element exhibits a maximum transparency

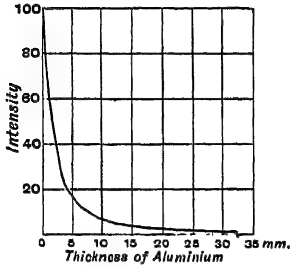

FIG. 7.

for each of its own characteristic radiations. For slightly harder rays than these, the absorption rapidly increases; the rays characteristic of the screen are produced and superposed on the transmitted rays to an extent which diminishes as the incident rays are increasingly

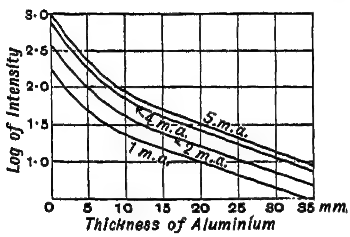

FIG. 8.

hardened. For incident rays softer than the critical type, no characteristic rays are produced. Thus, as the incident rays are gradually hardened, the transmitted rays reach a maximum intensity when the incident rays are of the same quality as each of the characteristic rays in turn.

A large value of μ corresponds to easily absorbed rays, and a small one to very penetrating rays. μ also varies with the nature of the absorbing screen, so that it is necessary to specify the material used. For medical purposes, it has recently been suggested that water should be chosen as the standard absorbing medium, since the absorptive power of water agrees closely with that of animal tissue.

Some workers prefer to think in terms of the thickness D, which reduces the intensity to half value. D is connected with μ by the expression $D=0{\cdot}69/\mu$. A notion of the order of values of μ may be got from the fact that for an X-ray beam of average hardness μ_{Al} lies between 4 and 8 cm.$^{-1}$; for hard rays between 2 and 4 cm.$^{-1}$. μ for fatty tissue varies from about 0·4 for hard rays to 0·7 for medium rays.

A more fundamentally important constant is obtained by dividing the absorption coefficient (μ) by the density (ρ) of the absorbing screen. This quantity, μ/ρ—usually called the mass-absorption coefficient—gives a measure of the absorption per unit mass of the screen for a normally incident pencil of rays of unit cross-section. Since it is mass alone that affects absorption, at any rate as determined by the usual methods of measurement, it is ordinarily more convenient to use mass coefficients than linear coefficients.

If, as was at one time supposed, the absorbing powers of different materials were truly proportional to their densities, then for the same rays μ/ρ would be a constant, no matter what the substance used as screen. In point of fact, dense substances are a good deal more absorptive, mass for mass, than light, and μ/ρ increases rapidly with the atomic weight of the screen. The increase is more noticeable with hard rays than with soft.

The accompanying table gives a series of values connecting wave-lengths and absorption coefficients in aluminium, derived from the results of Rutherford, Bragg, Moseley, and Barkla. A scrutiny of these results shows that if μ is the absorption coefficient and λ is the wave-length, then, when the effect of scattering has been allowed for,

$$\mu=k\lambda^n,$$

where k is a constant, and n lies between 5/2 and 3.

Wave-length λ.	μ/ρ_{Al}.	Wave-length λ.	μ/ρ_{Al}.

§ (18) THE SPEED OF THE CATHODE RAYS.—If the exciting voltage is uniform and a magnetic field be applied to the cathode rays, the band of rays is deflected as a whole to an extent dependent on the magnetic field and

the speed of the cathode rays. If the exciting voltage is pulsating, and a similar experiment be tried, a magnetic spectrum of cathode rays is formed, the least deflected band of rays corresponding to the highest speed rays which owe their velocity (v) to the maximum voltage (V) applied.

Since the energy of the electron is equal to the work done in expelling it, we have

$$\tfrac{1}{2}mv^2 = \mathrm{V}e,$$

where e and m are respectively the electronic charge and mass. Substituting the accepted value of e/m

$$\mathrm{V} = 2{\cdot}8v^2 . 10^{-16},$$

where V is in volts and v is in cm. per sec.

It is thus possible by measuring v by means of the magnetic deflection in a known field to arrive at the value of V.

§ (19) THE "QUANTUM LIMIT" TO THE X-RAYS.—The X-ray spectrometer has brought out the truth of a remarkably simple relation between the voltage applied to an X-ray bulb and the shortest wave-length emitted. It is now well known that, no matter whether the exciting voltage is constant or pulsating, a spectrum of X-rays is generated containing a wide range of wave-lengths. This spectrum is terminated very definitely at the short-wave

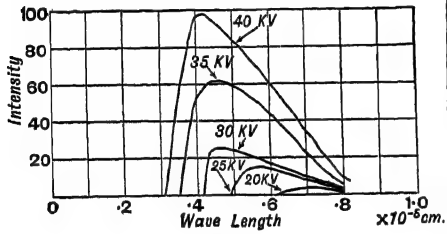

FIG. 9.

end (*Fig.* 9) at a point determined by Planck's quantum[1] relation

$$\mathrm{V}e = h\nu,$$

where

V is the maximum voltage applied,
e is the electronic charge,
h is Planck's universal constant,
ν is the frequency of the limiting wave.

Substituting the accepted values of the constants in the above equation, we have

Voltage = 12,400/wave-length in A.U.

It is obvious that the X-ray spectrometer can thus be utilised in some convenient form as a means of measuring the maximum effective voltage applied to a tube.

§ (20) THE MAXIMUM SPARK GAP.—The maximum voltage applied to a tube is most commonly measured by means of the alternative spark gap between points or spheres. Some experience is necessary, especially in the case of a gas X-ray tube, where the method tends to give too high values, especially with pulsating potentials. In the case of Coolidge radiator tubes excited by unrectified alternating potential, the spark gap will register the "inverse" voltage rather than the lower "effective" voltage.

The work of Peek and others has shown that a spark gap between spherical electrodes of equal size is preferable to that between points. The spark between points is now generally discredited for high voltages on account of its inconsistent dependence on atmospheric humidity and frequency of discharge. By reason of its time-lag, its readings may be largely in error, in the case of high-frequency steep impulses.

On the other hand, frequency and wave shape have no appreciable effect in the case of the sphere gap, and the effects of variation in the atmospheric conditions are well known, and can be readily corrected for.

The size of the spheres is important. A good rule is not to use a gap bigger than the diameter of either of the balls, though some latitude may be permitted in this direction. The main point is to avoid the break-down discharge being preceded by brush-discharge or corona, otherwise a pulsating discharge will, in general, give gap readings much too high. With the above precaution, a sphere gap is capable of measuring (peak) voltages from, say, 10,000 volts to 500,000 to an accuracy of about 2 per cent.

The table below is based on Dr. A. Russell's formula and incorporates the latest results of the American Institute of Electrical Engineers (1918). It includes also, for convenience, a column of figures for a needle point gap (No. 00, new sewing needles) which furnish a rough notion of the voltages for an instrument which is still much used. The A.I.E.E. recommend that for voltages above 70,000 (and preferably above 40,000) a sphere gap should always be employed.

The gap should not be exposed to any extraneous ionising influence, such as an arc or an adjacent spark, nor should the gap be enclosed. The first spark is the one for which the reading should be taken. The use of a water resistance in series with the gap will prevent arcing and pitting of the sphere surfaces.

§ (21) SPARK-GAP VOLTAGES AT 760 MM. PRESSURE AND 25° C.—Where any gap is being used outside its recommended limits, the figures are shown in brackets. The blank spaces indicate that the gap is no longer suitable. The gaps are given to three significant figures for interpolation purposes.

[1] See "Quantum Theory," § (1).

§ (22) CORRECTION FOR DENSITY OF AIR.—*Applicable only to sphere gaps.* The following table gives the relative air density under different conditions. The figures are relative to dry air at 25° C. and 760 mm. pressure :

TABLE B

Temperature ° C.	Pressure 720 mm.	Pressure 740 mm.	Pressure 760 mm.	Pressure 780 mm.
0	1·04	1·06	1·09	1·12
10	1·00	1·02	1·05	1·08
20	0·96	0·99	1·02	1·04
30	0·93	0·96	0·98	1·01

Within the limits of the above table the correction factor for a sphere gap agrees substantially with the relative air density. Thus for a given length of spark gap, the tabulated kilo-voltage in Table A must be multiplied by the appropriate correction factor in Table B. Alternatively, to calculate the gap which will just be sparked over by some specified voltage, the voltage must first be divided by the appropriate correction factor before Table A is used.

It will be seen that under normal conditions the correction is small or negligible.

§ (23) PENETROMETERS. (i.) *Benoist Penetrometer.*—Among medical men Benoist's radiochromometer or penetrometer enjoys extensive use as a measurer of hardness. It consists of a thin silver disc 0·11 mm. thick, surrounded by twelve numbered aluminium sectors from 1 to 12 mm. thick. The X-rays are sent through the instrument, and the observations consist merely in matching on a fluorescent screen or photographic plate the image cast

by the silver disc against the images of the aluminium plates: the thickness of the matching sector increases with the hardness of the rays. A notion of the discharge potential across a tube may be got from the very rough relation that the voltage is from 8000 to 10,000 times the Benoist reading of the X-rays.

(ii.) *Walter Penetrometer.*—This consists of a number of holes in a lead disc, which are covered by a sequence of platinum discs of gradually increasing thickness.

(iii.) *Christen's Half-value Penetrometer.*—Christen adopts as a definition of quality the thickness of a layer of water (or, in actual practice, bakelite), which will reduce the intensity of a beam of rays to half its original value.

The rays are sent through a stepped wedge of bakelite, alongside which is a perforated metal plate. This provides a standard of reference on a fluorescent screen, the two images being side by side. The holes in the plate are so designed that the area of the metal removed equals that which remains, so that the plate by this means reduces the intensity of a beam of rays to half-value. The holes are small enough to produce uniform illumination on a screen placed a short distance behind the plate.

§ (24) Qualimeters.—(i.) *Bauer Qualimeter.*—This is a type of semi-electrostatic voltmeter, which serves to measure the potential difference between the electrodes of a tube.

(ii.) *Klingelfuss Qualimeter* consists of an auxiliary search coil and electrostatic voltmeter. The instrument works similarly to the Bauer.

The hardness-numbers of the various penetrometers are all much the same as Benoist's, except those of Wehnelt, which are 50 per cent bigger for the same quality of rays.

§ (25) Methods of Measuring Intensity.—The intensity of the X-rays at a particular point is defined as the energy falling on one square centimetre of a receiving surface passing through the point and placed at right angles to the surface. The question is thus on all fours with that of illumination with visible light, and the need of a unit of "candle-power" in X-ray work is becoming pressing.

The work of a number of experimenters with the X-ray spectrometer has shown that the energy E emitted per second by an X-ray bulb may be written

$$E = kNiV^2,$$

where

V is the voltage on the tube,
i is the current through the tube,
N is the atomic number of the target,
k is a constant.

The value of k will depend on whether a gas or a hot-cathode tube is employed, and also on the type of exciting potential. The above expression refers only to the general or "white" X-radiation. If the voltage is such as to excite the characteristic radiations, the voltage comes in as a higher-powered term than V^2, and the efficiency increases correspondingly.

Measurements of the value of k have been made, and result in showing, unfortunately, that the efficiency of an X-ray bulb is deplorably small, of the order of 1 part in 1000. The chances that a cathode ray will ultimately come into suitable conflict with some atom and so generate an X-ray are slight. We raise those chances by increasing either the exciting voltage or the mass of the atom of the target.

The X-ray emission is virtually distributed over a sphere, or, more practically, over a hemisphere, since the target blocks out most of one half of the sphere of radiation.

Thus the intensity (comprising all wavelengths) falling on a square centimetre at distance d from the anticathode may be written

$$\frac{kNiV^2}{d^2}.$$

If the length of exposure is t secs. the total amount of energy received becomes

$$\frac{kNiV^2t}{d^2}.$$

It is apparent that we can base on this relation a system of X-ray intensities and "doses," provided we can measure i and V and be certain to what extent each is effective in generating rays which are of practical utility.

In practice we almost always filter out the long waves, and we shall need then to know the new value of k, so as to correct for the proportion of i which is not usefully employed.

The measurement of all the terms in the above expression, except perhaps i and V, offers no difficulty. i can be measured by a milliammeter of suitable design, which even with rapidly pulsating currents appears to indicate the mean current, as has been verified by the use of the voltameter and oscillograph.

The measurement of V has already been referred to above. If the exciting potential is constant, it can be measured by a resistance type of voltmeter in series with a high resistance. If the potential is fluctuating, recourse will usually be had to the sphere spark gap. The voltages are mostly too high for an electrostatic voltmeter.

In addition to the above method, the radiologist has employed a variety of means of measuring the intensity of X-rays at some selected point in the beam. To this end one or other of the properties of the rays have been utilised—heating, ionising, photographic, fluorescing, or chemical.

The heating effects are minute and the method is only fitted for the research laboratory.

(i.) *Ionisation Methods.*—When X-rays pass through a gas they impart to it a temporary electrical conductivity, the extent of which depends on the number of ions formed and thus on the amount of energy absorbed in the gas. An ionisation method of evaluating X-rays thus resolves itself into the measurement of a minute electric current. For this purpose an electroscope or electrometer is commonly employed, and the delicacy and convenience are such that the method has found almost universal acceptance among research workers.

But in medical radiology the method is only beginning to find favour, more especially in deep therapy. The iontoquantimeter of Szilard was one of the first instruments to be designed on this basis. In its most recent development a part of the quantimeter is sometimes actually introduced into the affected organ, and the rays measured which are actually received at the point concerned.

The ionisation method is unapproached in sensitiveness by any other method; it does not depend dominantly upon any selective process, and it is reasonable to anticipate that some unit of dosage thus developed and connected maybe with the accepted radium standard will ultimately receive recognition as a standard.

(ii.) *Photographic and Fluorescence Methods.*—Photographic plates record only about 1 per cent of the energy of the X-rays, but nevertheless a method of measuring intensity by this means has been developed and finds favour with some workers.

As is the case with most types of intensity meters the short-waved rays are recorded disadvantageously compared with the soft rays. Furthermore, a photographic film betrays marked selective absorption, and the photographic effect may be quite misleading in consequence.

To the worker with limited resources the photographic method of measuring intensity offers advantages because of its simplicity. Some form of opacity-meter for obtaining a measure of the density of the image is the chief requirement. The opacity meter measures the extent to which a standard beam of light is cut down by the photographic film whose density is required. If I_0 is the intensity of the (homogeneous) testing light which is incident on the developed film, and I_t that of the transmitted light, then, if μx is the fraction of the energy which is absorbed by a very small thickness, x, of the film,

$$I_t = I_0 e^{-\mu d},$$

where d is the thickness of the film. The film is assumed to be equally dense throughout its thickness.

For films of uniform thickness, d is constant, so that μ is proportional to $\log (I_0/I_t)$. μ is called the absorption coefficient; (I_0/I_t) is known as the opacity, and measures the number of times the incident light is cut down. $\operatorname{Log}(I_0/I_t)$ is termed the opacity logarithm. The transparency is the reciprocal of the opacity. Now, by definition, μ is proportional to the density of the image—*i.e.* to the amount of silver per unit area of film. Thus the ratio of two opacity logarithms gives the ratio of the film densities, and therefore the ratio of the photographic energies in the two cases. The opacity meter is graduated to read directly in opacity logarithms.

In fluorescence methods the luminosity is matched against some standard fluorescence excited by a steady source of radiation such as radium. The drawback to such methods is that the fluorescing salt becomes "tired" under the action of the rays. The sensitivity of a screen may also vary considerably from point to point, so that it is difficult to make a fair comparison. Barium platinocyanide is the material commonly used to sensitise a fluorescent screen. This salt, which has the formula $BaPt(CN)_4$, $4H_2O$, exists in three different forms, of which the green crystalline variety is by far the most efficient for fluorescing purposes.

(iii.) *Chemical and Other Methods.*—In the therapeutic use of X-rays, various chemical reactions brought about by the rays have been suggested and employed from time to time as aids to "dosage"; for example, the discolouring of various alkaline salts (Holzknecht, 1902); the liberation of iodine from a 2 per cent solution of iodoform in chloroform (Freund, 1906; Bordier and Galimard, 1906); the darkening of a photographic paper (Kienböck); the precipitation of calomel from a mixture of mercuric chloride and ammonium oxalate solutions (Schwarz, 1907); and the change of colour of pastilles of compressed barium platinocyanide (Sabouraud-Noiré and Bordier). X-rays resemble light in their property of lowering the electrical resistance of selenium; this property, if the pronounced fatiguing of the selenium could be overcome, would doubtless furnish the basis of a very convenient method of measurement, though Fürstenau in his intensimeter claims to have got over this difficulty. It must be admitted that most of these methods provide little more than the roughest notion of the intensity of a beam of ordinary heterogeneous X-rays.

Of all the various intensity-measurers, the pastille finds most favour with medical men. The barium-platinocyanide discs are some 5 mm. in diameter, and their colour, initially a bright green, changes, when exposed to the rays, to a pale yellow, and finally to a deep orange. The pastille is placed at a specified

distance from the anticathode of the bulb, and the colour is matched against one of a number of standard tints. The method is easy in practice, and is fairly reliable as a guide for short exposures, but it is not trustworthy for heavily filtered or very penetrating rays. The pastille method is defective in that it attempts to measure rays of all qualities by a surface coloration. Other platinocyanides show similar colour changes when exposed to X-rays. Levy has shown that the change of colour is due to a change from the crystalline to the amorphous condition. If the pastille is put aside, the reverse change slowly takes place, especially in the presence of light, so that the pastille should not be exposed to full daylight during the X-ray treatment. Ultra-violet light and radium rays cause similar browning in such pastilles.

The following table gives an idea of the relation between the different dosemeter scales:

5H units (Holzknecht; alkaline salt)
=Tint B (Sabouraud-Noiré; pastille)
=Tint 1 (Bordier; varnished pastille)
=3 to 4I (Bordier and Galimard; iodine solution)
=10X units (Kienböck; photographic plate)
=3·5 kaloms (Schwarz; mercury solution)
=Villard dose.

§ (26) Effect of Wave Form of Exciting Potential.—So long as radiologists confined their measurements on the X-ray bulb to the milliammeter and the point gap, little progress was made on the subject of the best form of exciting potential wave. It was realised that the milliammeter was often misleading if used alone, but insight into the problem only came with the use of the X-ray spectrometer and the oscillograph.

The oscillograph (preferably of the cathode ray type) should be arranged to give simultaneous graphs of both potential and current wave forms. The spectrometer analyses the resulting X-ray output and gives the distribution of intensity among the various wave-lengths.

Work such as this has shown the truth of what might have been anticipated on *a priori* grounds, *i.e.* the importance in pulsating discharges of keeping the conditions so that the potential and current curves are in phase. In other words, for efficient output of X-rays as much of the current as possible should be sent through the tube with the maximum potential actuating it.

As the output of X-rays depends on the square of the voltage, the ideal state of things would appear to be to rush the potential as quickly as possible to the maximum and keep it there for as long as any current is passing. Voltages lower than the maximum are less efficient.

In practice much depends on the type of X-ray bulb used—whether gas or hot cathode, and it will be instructive to compare the behaviour of three main types of exciting potentials (*a*) constant potential, (*b*) sinusoidal transformer discharge, (*c*) sharp-peaked pulsating coil discharge, all running under the same maximum voltage and the same milliamperage.

First take the case of the Coolidge tube. Owing to the existence of the saturation current, the shape and limits of the current curve are greatly dependent on the characteristics of the potential wave (*Fig.* 10).

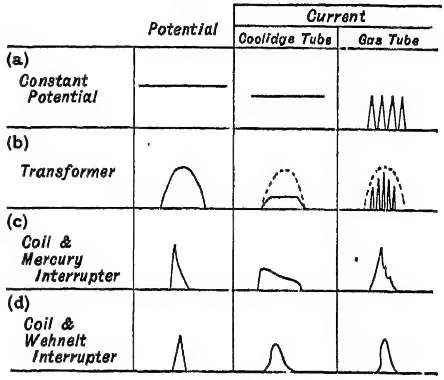

Fig. 10.

With constant potential, the current remains constant at its saturation value. In the case of the transformer loop the current rises gradually to its saturation value and dies away again as the potential loop terminates. In the case of the coil and interrupter, the current again rises to its saturation value, but as a whole the current curve is prone to lag behind the potential curve. The defect, which is due to arcing within the interrupter, increases as the current through the tube is increased. This is the explanation of the well-known fact that as the current is raised the output of X-rays increases only slowly and by no means proportionately. A partial cure is to raise the speed of the interrupter, as in the Wehnelt break.

We are led to anticipate the results of the spectrometer curves. Remembering that the area of each curve is a measure of the total output of radiation, we see from *Fig.* 11, which gives intensity in terms of wave-length (derived from Dauvillier), that the constant potential is the most efficient, then the transformer, and lastly the coil. Furthermore, the crest of the curve is of slightly shorter wave-length in the case of the constant potential. It may be added that the superiority of the constant potential becomes less marked as the potential rises.

If we now consider the case of the gas tube, the current curves prove, in most circum-

stances, to be quite different from those for the Coolidge tube (*Fig.* 10). The current curve now exhibits no saturation value, but consists instead of a succession of peaks, no

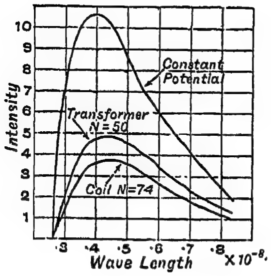

FIG. 11.

matter whether the exciting potential is constant or varying. The constant potential produces, so to speak, all the effects of an intermittent one. In the case of the transformer the middle portion of the potential loop produces a number of current peaks whose heights wax and wane with the potential. The coil produces one or more current peaks corresponding to each potential peak. We are led to infer that the spectral curves for the different excitants will not differ appreciably, and this proves to be the case. *Fig.* 12 gives the curves derived from three

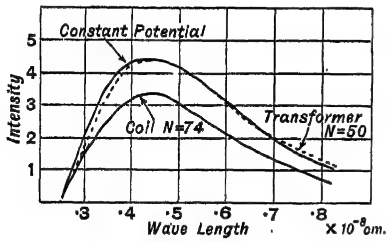

FIG. 12.

different excitants. Further, the maxima of the several spectral curves all agree in wavelength. We realise then that the shape and limits of the spectral curve are determined mainly by the tube rather than by the excitant.

In the case of both gas and hot cathode tubes there is a variety of factors which may modify the various curves and graphs appreciably in detail, without affecting the main outlines.

To sum up, we may conclude that for maximum efficiency in the case of a Coolidge tube we should raise the potential on the tube as high as is expedient or possible and keep it there. Thus the ideal excitant would appear to be constant potential or, failing that, a transformer of high frequency.

The "shock tactics" of a coil, which are largely wasted on a Coolidge tube, are doubtless well adapted to a gas tube owing to its characteristic way of breaking down under potential stress. From a practical point of view, the transformer potential wave is probably not quite so well suited to a gas tube, but constant potential should prove very effective apart from difficulties of generation, etc. The practical difficulties of obtaining an equally high constant potential or maximum transformer voltage (selectively rectified) are probably greater, but otherwise they would seem to offer advantages equal to those of the coil.

The interval between the discharges of a coil-driven bulb is not without its advantage in helping to keep down the temperature rise of the target. But with a mercury break under ordinary conditions this interval amounts to about 90 per cent of the time between successive impulses, and is needlessly long. In the case of a single-phase transformer the corresponding figure is of the order of 60 per cent.

We can raise the efficiency of the coil or transformer by increasing the frequency substantially, and so crowd in more impulses per second, though the increased heating of the target may have to be met. If, further, in the case of a coil, we raise the voltage on the primary and increase the capacity of the condenser, we can produce a series of flat-topped peaks with little or none of the "tail" in evidence. We are thus approximating more and more to the transformer (selectively rectified) and, in the limit, the ideal steady potential. During these changes the readings of the milliammeter will approach more and more the effective values from an X-ray point of view.

§ (27) CONSTANT POTENTIAL.—The value of constant potential has been referred to. It is not only an efficient means of generating X-rays, but it permits precise measurement. As already remarked, the superiority of constant over varying potential is less marked as the voltage is increased, except when the characteristic radiations begin to be generated, when the constant potential increases its relative effectiveness. Moreover, constant potential is admirable in its precision for therapeutic purposes. In radiography it generates sufficient diversity of wave-lengths to give good contrast and detail.

Those workers who have used the influence machines in America and elsewhere speak highly of the results. There is a great future for a static machine of engineering design and large output which will defy the varying and generous humidity of this country.

The only other means of obtaining steady potential are by use of the transformer

together with the Kenetron or hot-cathode valve. These latter can now be obtained to rectify 100,000 volts. By the use of 3-phase current and 6 kenetrons a voltage fluctuating only 15 per cent can be obtained. There are a variety of ways of combining kenetrons with

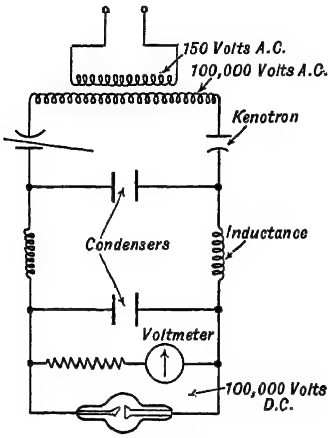

FIG. 13.

condensers and inductances, so that the variation in the resulting potential is trifling. For example (*Fig.* 13), Hull of the G.E.C. Laboratory at Schenectady has so transformed and rectified 150 volts A.C. ($\omega = 2000$) to 92,000

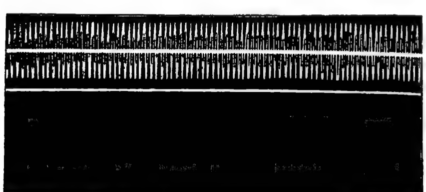

FIG. 14.—Upper Curve unrectified, Lower Curve rectified.

with a fluctuation of about 1 per cent (*Fig.* 14); or 50,000 volts with a fluctuation of only $\frac{1}{10}$ per cent.

§ (28) HOMOGENEOUS X-RAYS.—An ideal of the radiologist has always been a means of producing homogeneous X-rays, so that, among other things, a precision dose can be the better formulated in therapy. While all X-ray beams are heterogeneous, they tend to become less so as the voltage is raised and the rays are filtered by the right choice of substance of a suitable thickness. This may be seen either from absorption curves or, more accurately, from spectral distribution curves.

But the nearest approach to homogeneity can be reached by operating the X-ray bulb at a voltage somewhat above one of the critical values necessary to generate one of the three known characteristic radiations (K, L, M) of the anticathode, and then filtering by a screen either of the same element as the anticathode or, preferably, by an element of slightly smaller atomic number. We have already remarked that above the critical voltage the characteristic radiations are generated more copiously than the general radiation. The voltage should not be too high, however, or short-wave general radiation will begin to make its appearance and will not be removed by filtration. There is, in fact, an optimum voltage. For example, while the critical voltage for the K radiation of tungsten (At. No. = 74) is about 70,000 volts, the optimum voltage is about 100,000 volts A filter of tungsten or tantalum (At. No. = 73), 0·15 mm. thick (*Fig.* 15; Hull),

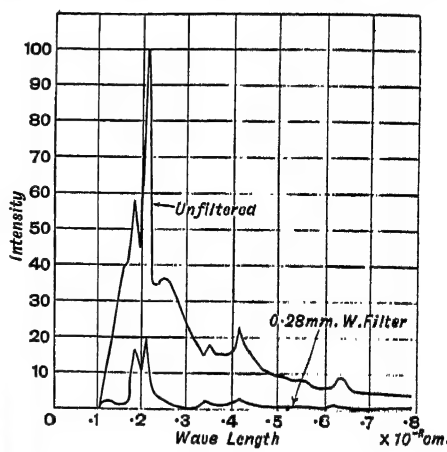

FIG. 15.

removes most of the general radiation, but leaves both the β and α components of the K radiation. An equally thick filter of ytterbium (At. No. = 70) would leave only the α component, with an intensity at least 30 times that of the remaining general radiation. Similarly for molybdenum (At. No. = 42) the optimum voltage is about 30,000 and the best filter zirconium (At. No. = 40) (see *Fig.* 16; Hull). Tungsten would be a good filter for platinum radiation (At. No. = 78).

At the National Physical Laboratory there is a battery of X-ray tubes each with a different anticathode, so that a variety of homogeneous rays can be obtained. Unfortunately such beams are of feeble intensity.

V. X-RAYS AND MEDICINE

§ (29) RADIOGRAPHY.—X-rays have become one of the handmaidens of medicine, a fact which is bound up with the great improve-

ments of recent years in X-ray equipment and technique, which have given the diagnostic methods of physicians and surgeons a facility and exactness never dreamt of at one time. Exposures have been enormously shortened (*Figs.* 17 and 18), and snapshots of any part of the body can now be taken.

In surgery of the bone, not only fractures, but the intimate lamellar structure of the bone can be examined; we have, moreover, learned that tumours and cysts in bones are not specially rare, and that nearly all sprains are accompanied by slight fractures of the bone. When a bone is badly splintered the dead bone splinters can be sorted out from the living.

Tumours in any part of the head can be detected and their position determined. The diagnosis and location of diseases of all parts of the alimentary canal are routine—stricture of the oesophagus, stomachic disorders, diseases of the appendix and colon, etc., can all be demonstrated by the X-rays with the assistance of special food containing matter opaque to the rays.

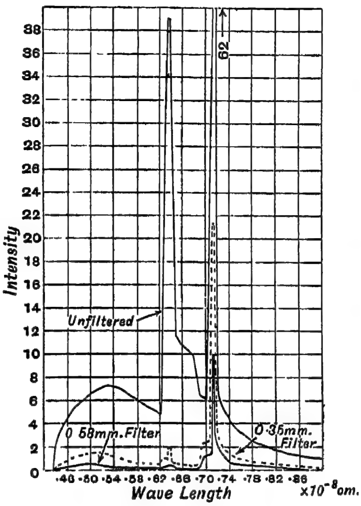

FIG. 16.

FIG. 17.—Radiograph of Hand (January 1896); Exposure 20 min. (Campbell-Swinton).

Stones in the kidney and (more recently) the gall-bladder, diseases of the liver and pelvic organs, incipient tuberculosis in the lungs and joints can be diagnosed with certainty and without pain or danger.

Dental radiography has become an important subject. By suitably disposing a photographic film radiographs of individual teeth can be obtained, revealing in perfect fashion the condition of both the tooth and surrounding bone.

During the war many thousands of radiologists helped to build up the triumphs which X-rays achieved. The X-ray became as indispensable as the dressing or the splint, and it was an essential adjunct in prescribing and directing as well as avoiding operations. The detection of bullets and shell fragments in any part of the body was commonplace, and the X-rays were also used to guide the surgeon during his actual efforts to remove foreign bodies. Cleverly designed X-ray motor-lorries permitted early examination in the field. In the case of eye wounds X-ray

FIG. 18.—Radiograph of Hand (January 1920); Exposure $\frac{1}{100}$ sec. (Knox). Showing immense advance in technique, although exposure only $\frac{1}{120000}$ of exposure in *Fig.* 17.

stereoscopy attains its fullest delicacy, and the location of small foreign bodies can be carried out to the hundredth part of an inch. Another war development of radiology was its employment by the orthopaedic surgeon in his efforts to restore damaged limbs. Many hundreds of thousands of radiographs were taken at the various hospitals during the war.

§ (30) Radiotherapy.—The X-rays possess valuable properties in the treatment of malignant disease. The living cells have the power of resisting or responding to X-rays, while malignant cells disappear with suitable "dosage." The treatment has, for example, been largely and successfully employed for rodent ulcers, and much attention is being paid to the cure of cancer.

In many skin diseases the X-rays have proved to be of notable service. For example, they are now the accepted and certain means of curing ringworm. The "dose" is all-important, for the sweat glands and hair follicles are also affected and, with excessive exposure, may even be destroyed, the result being baldness.

The corpuscles of the blood are prejudicially affected by X-rays, resulting in a form of aplastic anaemia. Curiously enough, the rays seem to have little or no action on bacteria or their spores, and in this respect stand out in marked contrast to ultra-violet light.

Deep-seated organs are now frequently treated by X-rays. In deep radiotherapy modern technique is tending in the direction of administering massive doses of X-rays in the shortest possible time, always having regard to the safety of the overlying skin. In other words, "shock tactics" are used, and the wave form of the exciting potential may prove to be important in this connection. The soft rays are removed by using metal filters (Al or Zn) with a coating on the side nearest the skin of wood or leather, so that no characteristic radiation may play on the skin. Over-dosage of the skin is also avoided by employing multiple parts of entry, each of the various beams being properly directed at the deep affected tissue.

The chief hindrance to precise radiotherapy at the present time is probably the lack of a means of measuring the dose of radiation absorbed by the particular region concerned, especially if it be at a depth in the body. On physical grounds, at any rate, it would seem that it is only those rays which are absorbed which can produce physiological changes, and only such rays should be included when speaking of a dose. It may be, of course, that selective action is present, and that only a restricted range of wave-lengths is appropriate for the conversion of energy in the correct spot. With this reservation it would seem that the degree of reaction should be a function of the absorbed and converted energy. The problem is complicated by the lack of homogeneity of the primary beam.

Among the tragedies of the war, few were more pathetic than the ghastly disfigurements caused by shell wounds of the face and head. Fortunately it was often possible, by the wonderful grafting operations of the surgeon, to restore at least a semblance of the patient's former appearance. Lips were renewed, new noses built up, eyelids replaced, cavities in the palate filled in by flaps taken from the skin or scalp. The scar-tissues and flaps were kept pliant and adaptable by "spraying" with X-rays, which also served to depilate hair and to stimulate the healing process in both flaps and bone.

§ (31) X-ray Protection.—As already remarked, the X-rays possess in a marked degree the property of affecting animal tissue. As many of the earlier workers found to their cost, the effects of over-exposure to the rays may ultimately prove fatal. In view of the great public interest which the subject has excited, and the fact that complete safeguards are possible, the recent (1921) report is appended of a representative committee which reviewed the whole question in the light of present-day knowledge. The recommendations are many-sided and cover most of the points which experience has suggested both in X-ray and radium practice.

It may here be remarked that with exciting voltages in the region of 200,000, 3 mm. of lead reduces the intensity of X-rays over 10,000 times; 10 mm. of lead over 1 million times. Good lead-impregnated rubber sheet is ordinarily equivalent to about ⅓ or ¼ of the same thickness of lead sheet. For lead glass the corresponding figure is ⅓ to ⅙, although it is possible to obtain glass with a figure of ¼.

The dangers of scattered X-rays should be realised, particularly with very high exciting voltages. One of the best remedies is to enclose the bulb itself as completely as possible with adequate protective material. The report in question is as follows:

Introduction

The danger of over-exposure to X-rays and radium can be avoided by the provision of efficient protection and suitable working conditions.

The known effects on the operator to be guarded against are:

(1) Visible injuries to the superficial tissues which may result in permanent damage.

(2) Derangements of internal organs and changes in the blood. These are especially important, as their early manifestation is often unrecognised.

General Recommendations

It is the duty of those in charge of X-ray and Radium Departments to ensure efficient protection and suitable working conditions for the personnel.

The following precautions are recommended:

(1) Not more than seven working hours a day.

(2) Sundays and two half-days off duty each week, to be spent as much as possible out of doors.

(3) An annual holiday of one month or two separate fortnights.

Sisters and nurses, employed as whole-time workers in X-ray and Radium Departments, should not be called upon for any other hospital service.

Protective Measures

It cannot be insisted upon too strongly that a primary precaution in all X-ray work is to surround the X-ray bulb itself as completely as possible with adequate protective material, except for an aperture as small as possible for the work in hand.

The protective measures recommended are dealt with under the following sections:

I. X-rays for diagnostic purposes.
II. X-rays for superficial therapy.
III. X-rays for deep therapy.
IV. X-rays for industrial and research purposes.
V. Electrical precautions in X-ray Departments.
VI. Ventilation of X-ray Departments.
VII. Radium therapy.

It must be clearly understood that the protective measures recommended for these various purposes are not necessarily interchangeable; for instance, to use for deep therapy the measures intended for superficial therapy would probably subject the worker to serious injury.

I. *X-rays for Diagnostic Purposes*

(1) *Screen Examinations.*—(*a*) The X-ray bulb to be enclosed as completely as possible with protective material equivalent to not less than 2 mm. of lead. The material of the diaphragm to be equivalent to not less than 2 mm. of lead.

(*b*) The fluorescent screen to be fitted with lead glass equivalent to not less than 1 mm. of lead and to be large enough to cover the area irradiated when the diaphragm is opened to its widest. (Practical difficulties militate at present against the recommendation of a greater degree of protection.)

(*c*) A travelling protective screen, of material equivalent to not less than 2 mm. of lead, should be employed between the operator and the X-ray box.

(*d*) Protective gloves to be of lead rubber (or the like) equivalent to not less than ½ mm. of lead and to be lined with leather or other suitable material. (As practical difficulties militate at present against the recommendation of a greater degree of protection, all manipulations during screen examination should be reduced to a minimum.)

(*e*) The X-ray bulb to be used at as great a distance and emitting as little radiation as is consistent with the efficiency of the work in hand. Screen work to be as expeditious as possible.

(2) *Radiographic Examinations* ("*Overhead*" *Equipment*).—(*a*) The X-ray bulb to be enclosed as completely as possible with protective material equivalent to not less than 2 mm. of lead.

(*b*) The operator to stand behind a protective screen of material equivalent to not less than 2 mm. of lead.

II. *X-rays for Superficial Therapy*

It is difficult to define the line of demarcation between superficial and deep therapy.

For this reason it is recommended that, in the reorganisation of existing or the equipment of new X-ray departments, small cubicles should not be adopted, but that the precautionary measures suggested for deep therapy should be followed.

The definition of superficial therapy is considered to cover sets of apparatus giving a maximum of 100,000 volts (15 cm. spark-gap between points; 5 cm. spark-gap between spheres of diameter 5 cm.).

Cubicle System.—Where the cubicle system is already in existence it is recommended that

(1) The cubicle should be well lighted and ventilated, preferably provided with an exhaust electric fan in an outside wall or ventilated shaft. The controls of the X-ray apparatus to be outside the cubicle.

(2) The walls of the cubicle to be of material equivalent to not less than 2 mm. of lead. Windows to be of lead glass of equivalent thickness.

(3) The X-ray bulb to be enclosed as completely as possible with protective material equivalent to not less than 2 mm. of lead.

III. *X-rays for Deep Therapy*

This section refers to sets of apparatus giving voltages above 100,000.

(1) Small cubicles are not recommended.

(2) A large, lofty, well ventilated and lighted room to be provided.

(3) The X-ray bulb to be enclosed as completely as possible with protective material equivalent to not less than 3 mm. of lead.

(4) A separate enclosure to be provided for the operator, situated as far as possible from the X-ray bulb. All controls to be within this enclosure, the walls and windows of which to be of material equivalent to not less than 3 mm. of lead.

IV. *X-rays for Industrial and Research Purposes*

The preceding recommendations for voltages above and below 100,000 will probably apply to the majority of conditions under which X-rays are used for industrial and research purposes.

V. *Electrical Precautions in X-ray Departments*

The following recommendations are made:

(1) Wooden, cork, or rubber floors should be provided; existing concrete floors should be covered with one of the above materials.

(2) Stout metal tubes or rods should, wherever possible, be used instead of wires for conductors. Thickly insulated wire is preferable to bare wire. Slack or looped wires are to be avoided.

(3) All metal parts of the apparatus and room to be efficiently earthed.

(4) All main and supply switches should be very distinctly indicated. Wherever possible, double-pole switches should be used in preference to single-pole. Fuses no heavier than necessary for the purpose in hand should be used. Unemployed leads to the high-tension generator should not be permitted.

VI. *Ventilation of X-ray Departments*

(1) It is strongly recommended that the X-ray Department should not be below the ground level.

(2) The importance of adequate ventilation in both operating and dark rooms is supreme. Artificial ventilation is recommended in most cases. With very high potentials coronal discharges are difficult to avoid, and these produce ozone and nitrous fumes, both of which are prejudicial to the operator. Dark rooms should be capable of being readily opened up to sunshine and fresh air when not in use. The walls and ceilings of dark rooms are best painted some more cheerful hue than black.

VII. *Radium Therapy*

The following protective measures are recommended for the handling of quantities of radium up to one gram:

(1) In order to avoid injury to the fingers the radium, whether in the form of applicators of radium salt or in the form of emanation tubes, should be always manipulated with forceps or similar instruments, and it should be carried from place to place in long-handled boxes lined on all sides with 1 cm. of lead.

(2) In order to avoid the penetrating rays of radium all manipulations should be carried out as rapidly as possible, and the operator should not remain in the vicinity of radium for longer than is necessary.

The radium when not in use should be stored in an enclosure, the wall thickness of which should be equivalent to not less than 8 cm. of lead.

(3) In the handling of emanation all manipulations should, as far as possible, be carried out during its relatively inactive state. In manipulations where emanation is likely to come into direct contact with the fingers thin rubber gloves should be worn. The escape of emanation should be very carefully guarded against, and the room in which it is prepared should be provided with an exhaust electric fan.

Existing Facilities for ensuring Safety of Operators

The governing bodies of many institutions where radiological work is carried on may wish to have further guarantees of the general safety of the conditions under which their personnel work.

(1) Although the Committee believe that an adequate degree of safety would result if the recommendations now put forward were acted upon, they would point out that this is entirely dependent upon the loyal co-operation of the personnel in following the precautionary measures outlined for their benefit.

(2) The Committee would also point out that the National Physical Laboratory, Teddington, is prepared to carry out exact measurements upon X-ray protective materials and to arrange for periodic inspection of existing installations on the lines of the present recommendations.

(3) Further, in view of the varying susceptibilities of workers to radiation, the Committee recommend that wherever possible periodic tests, *e.g.* every three months, be made upon the blood of the personnel, so that any changes which occur may be recognised at an early stage. In the present state of our knowledge it is difficult to decide when small variations from the normal blood-count become significant.

VI. X-RAYS AND MATERIALS

In wellnigh every branch of industry the testing of materials has come to be of importance. With increasing knowledge and the stress of competition, a variety of testing methods have been evolved to ascertain quality and uniformity as determined by the several physical, chemical, and visual characteristics. Such tests are commonly conducted on samples which are selected to be as representative as possible. From the nature of things the value of the results is limited, and the engineer in particular is ever on the look-out for opportunities for further insight into the materials he employs.

The employment of X-rays in the examination of materials lies at present in two main directions:

(1) X-ray crystallography or the study of crystal structure.

(2) Radiography or X-ray shadow photography.

§ (32) X-RAY CRYSTALLOGRAPHY.—We can only refer to the great potentialities of the results of X-ray analysis as applied to crystal structure.[1] It is a matter of great satisfaction to Englishmen to know how much the subject owes to Sir Wm. Bragg and his son, whose published work on the subject is of the highest fascination and importance. Several methods have been employed. In 1912 Laue at Munich sent a heterogeneous beam of X-rays through a thin crystal and photographically showed that a diffraction pattern was produced. The Braggs followed with the X-ray spectrometer in which monochromatic X-rays are reflected from the several faces of a crystal, and by that means proceeded to disclose the atomic architecture of a large number of crystals.

The practical possibilities were greatly enlarged when Debye and Scherrer (at Zürich) and Hull (at the G.E.C. Research Laboratory, Schenectady) showed that large crystals were not essential, but that the method could be applied to an aggregate of finely powdered crystalline material, provided the orientation of the crystals were sufficiently random. This was a big step forward, for it enables the crystalline structure of a body to be examined even when the individual crystals are microscopic or ultra-microscopic in size. We now know that almost every solid substance betrays crystalline structure, and it would seem that the various physical properties—elasticity, hardness, melting points, etc.—are all manifestations of the various atomic forces which reveal themselves in the crystalline form. The very formation of solids may be merely an outward and visible sign of crystallisation, and a definition of a "solid" may be so derived which is, at any rate, as adequate as

[1] See also "Crystallography," § (11).

others which have been framed. Not only the growth but the decay, the change-points, etc., can all be followed and watched without harming the body in any way.

We have thus a new tool of research which, although at present rather delicate and tentative in application, would seem to offer boundless possibilities. The metallurgist, to whom crystalline formation means so much, need no longer have to content himself with inferring from their external forms what the internal structure of the crystals in his metals and alloys may be. He may also find that the method will throw light on the fundamental nature of the effect of heat treatment, tempering, rolling and ageing on steels and other crystalline metals and alloys. It has been shown that amorphous carbon really consists of minute graphite crystals; colloidal gold and silver are made up of minute, yet perfect, crystals, so small that they contain only a few score atoms. Even the particles "sputtered" from a cathode in a discharge tube are possible of examination and are found to be crystalline.

These are but a few of many examples. There is a great opportunity for the metallurgist and physicist to get together. At present the main difficulties are those of technique. Monochromatic X-rays have to be used, and as these can be obtained only of feeble intensity, protracted exposures have hitherto been necessary, though these can now be greatly shortened by the use of more sensitive plates.

§ (33) Industrial Radiography.—As was anticipated by Röntgen and others, when the art of radiography had sufficiently advanced in medicine it extended its scope to industry. As already remarked, the method of X-ray inspection has the advantage of not injuring a body in any way. Furthermore, it provides in many cases the only means of detecting concealed defects in a material, or of scrutinising in a structure the accuracy of assembly of component parts which are hidden from view.

The development of industrial radiology has been bound up with that of the Coolidge tube, and, both during and since the war, the X-rays have been applied to a variety of branches of industry. As already explained, the method depends on receiving the shadow of the object on a fluorescent screen or photographic plate, and it should be made clear at the outset that a radiograph shows only the gross structure of a material and gives no information as to the crystalline or microscopic structure from point to point.

While the general technique is much the same as in medicine, mention should be made of one of the chief experimental precautions in the X-ray photography of metals. Even in medical radiography the experienced worker is well aware of the effect of the scattered radiation which is generated whenever a beam of X-rays strikes any particle of matter. Such scattered radiation, if allowed to reach the photographic plate, tends to fog the main image. The various surfaces of the bodies encountered are the chief offenders, and even the air contributes its quotum.

The effect is especially marked with metallic objects which require relatively long exposures; worthless results will be obtained in the absence of suitable precautions. These consist in enveloping the photographic plate, back and front, with sheet lead (preferably with an inner lining of aluminium), a hole being left no bigger than necessary for the reception of the direct image of the object. If the object is continuous and flat there is no difficulty, for it can be brought into close contact with the plate. If, however, the body is irregular in contour, it may conveniently be cemented with paraffin wax to the bottom of a cardboard or aluminium tray, and mercury, fine lead shot, or the like poured round it. Wax filling is also necessary, both to fill up any pockets or cavities and to prevent the mercury or shot from straying into the path of the projected image.

Considerable gain may result from the use of the Bucky grid between the object and the plate. This consists of a rectangular metal grid, the faces being spherical in contour and the dividing cell-walls of the grid everywhere radial. The grid, while allowing direct X-rays from the focus to pass, kills the majority of the scattered radiation. The grid is kept in slight motion to prevent its being registered on the photograph. Still greater freedom from the effects of secondary radiation may be obtained by using specially sensitive plates and so shortening the exposure.

Naturally the orientation of the object with reference to the beam of X-rays may make or mar a radiograph. Distortion may be reduced by avoiding undue obliquity of the rays, and to this end it is wise to keep the distance between the object and bulb as great as is expedient. For good definition the rays should be stopped down as much as possible.

The present practicable depths which can be penetrated in various materials are:

4 to 5 mm. of lead.
12 mm. of tin.
7·5 cm. of steel (carbon) or iron.
10 to 15 cm. of aluminium and its alloys.
30 to 40 cm. of wood.

The limiting factor in practice is the exposure, which hitherto has been very protracted with the greater thicknesses. However, with the latest type of X-ray plate the exposures are greatly reduced, and 1 inch of steel, for example, now requires an exposure of rather less than a minute, using a voltage of about 130,000 and a few milliamperes through the tube.

Within the above limits we can, with considerable delicacy, hunt out anything which is so disposed as to cast a measurable variation in the shadow, provided the body is not too complicated in design to render the shadow too confusing to interpret. The method is surprisingly sensitive; for example, tool-marks and fine mould-marks often show up in a radiograph. The opacity is merely a measure of the number and weight of the atoms encountered, and so different qualities of a metal possessing different densities display different intensities in a radiograph; for example, a wrought rivet in a casting of the same metal shows a darker image. For the same reason, equal thicknesses of carbon, nickel, and tungsten steels differ markedly in transparency, a property which has been turned to account.

FIG. 19.—Defective Weld in Steel Plates.

Electric and oxy-acetylene welding have come into great prominence during and since the war; an indifferent welder can turn out what appears on the surface to be an excellent weld, but is quite an unreliable job notwithstanding. There appears to be no adequate mechanical test for a weld, and in any event any such test, whether mechanical or microscopical, destroys the weld, good or bad. The X-rays promise to be of great use in this connection. If the component parts are not actually fused together a narrow dividing line comes out on the plate. Blisters and blowholes show up as light spots. X-ray photography of welds up to 1 inch thick is now quick, easy, and certain: with modern equipment, lengths up to 2 feet can be taken at once, the exposure being a fraction of a minute. The amount of detail revealed is extraordinary, and the process compares favourably with that of photomicrography, which is only very local in its test and, as already remarked, involves the destruction of the weld. The X-ray method has proved to be a somewhat severe critic of present-day welds as commonly carried out (*Fig.* 19).

Hidden cracks in a metal, which are a bugbear to metallurgists, can often be detected, though if they are very fine or tortuous (hair cracks) the method is rarely suitable. Such cracks are sometimes the sequel to "pipes" or blowholes in the ingot, and it is easier to detect them in the ingot than after working.

In the case of alloys, the uneven distribution of any component results in a "patchy" or streaky radiograph. X-ray examination will often diagnose defective soldering or brazing, the substitution of one metal by another, hidden stopping or pinning, and so on. The method has also found application in detecting hidden corrosion (as in gas cylinders, in ferro-concrete, and the armouring of cables), in scrutinising steel turbine discs for segregations, etc., and so on.

Naturally enough, the X-rays found a great opening, during the war, in the manufacture of explosives and related devices. In some instances, *e.g.* the correct filling of liquid-gas grenades, the examination of opaque cordite, the interior detail of detonators, Stokes igniters, vent-sealing tubes and other pyrotechnic stores, no other method of inspection was possible. The X-rays also proved of value in examining enemy ammunition of unknown design, where, for reasons of safety, it was desirable to ascertain the internal construction before opening up. They have also proved useful in checking the contents of packing boxes. Most of this work was carried out by the Research Department at the Royal Arsenal, Woolwich, and the Editor is indebted to the Department for *Figs.* 20-23, illustrating some of the results arrived at.

In the case of timber, the different varieties absorb X-rays to different degrees. Peculiarities in the structure and path of the fibres (such as the contortions which produce "figure") are easily discerned. The denser heart wood is differentiated from the sap wood, the summer and spring growths of the annual rings are readily identified (*Fig.* 24),

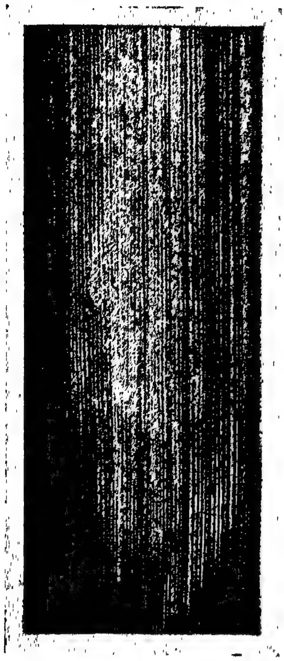

FIG. 24.—Perfect Specimen of Aeroplane Spruce.

and defects such as knots or grub-holes show up with astonishing clearness (*Fig.* 25).

A method of utilising the X-rays to examine

FIG. 25.—Concealed Knots and Grub-hole in Laminated Spar.

the wooden parts of aircraft was developed on behalf of the Air Ministry during the war. At a time when the submarine was seriously endangering the country's supplies of high-grade timber from Canada and the States, designs for building up aeroplane parts from smaller timber were developed, using laminated or "box" structures. The workmanship

FIG. 26.—Defective Shaping of End Block of "Box" Spar; also Block Split by Screws.

required has to be of the finest, and much of it is hidden of necessity, but the inspector now has a powerful ally in the X-rays, which unerringly reveal hidden faults such as knots, large resin-pockets, defective gluing, and poor workmanship (*Figs.* 26, 27, 28). Wood is

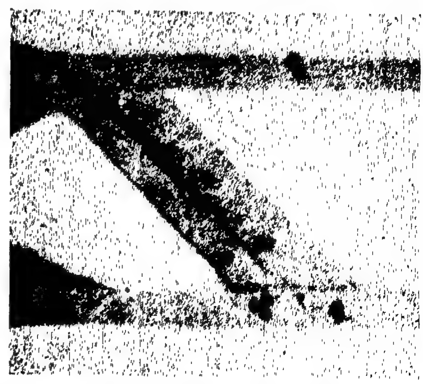

FIG. 27.—Aeroplane (Box) Spar showing forbidden Joint in Plywood Side.

very transparent to X-rays, and thicknesses up to 18 inches or more can be dealt with, screen examination being possible in most cases. The method is also useful for watching the behaviour of the various hidden

members and joints of a composite wooden structure while it is being subjected to test.

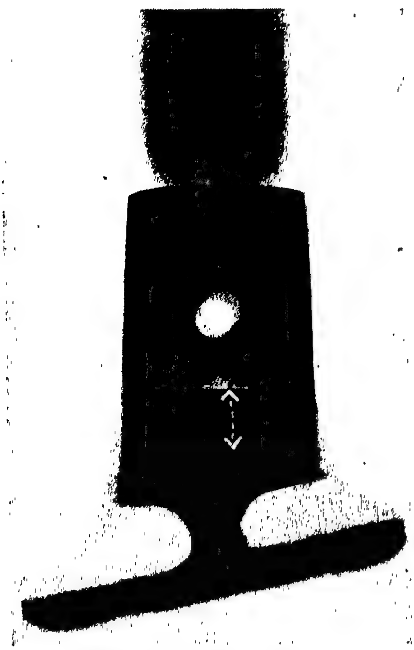

FIG. 28.—Defective "Bottoming" of Aeroplane Strut in Aluminium Socket.

X-rays are also being turned to account by the tyre manufacturer in his efforts to improve the union between the rubber and the Egyptian cotton fabric. In the manufacture of golf balls, fine rubber tape is wound on a round core either of soft rubber or liquid. If care is not taken the core is distorted, becoming either roughly ellipsoidal or even dumb-bell shaped. The resulting ball is defective from the point of view of accurate flight, but such balls can be readily sorted out by the help of the X-rays. The method is now in extensive use, no other being readily available (*Fig.* 29). The Post Office has long used the rays for testing the amount of mineral matter in gutta-percha.

The help of the X-rays has also been effectively sought by the manufacturer of carbon and graphite brushes and electrodes, to reveal mineral matter and internal cracks and flaws. The makers of electrical insulators —ebonite, built-up mica, fibre, paper, etc.— find the method invaluable for detecting the presence of metallic particles, often from the steel rollers used in the preparation of the material.

The manufacture of optical glass became a key industry during the war, as hitherto we had relied wholly on Germany for our supplies. One of the greatest troubles which was encountered was the destructive action of the molten glass on the fire-clay pot, in which the components were fused. It was found that the effect was caused by the presence of iron and other impurities in the clay. Recourse was had to the X-rays, and it was found that on examining the pots before they were fired, those containing prejudicial foreign matter could readily be sorted out. In this way much expense can be saved. The "melt" of optical glass can also be examined for inclusions before working.

X-ray photographs are useful for displaying the arrangement of concealed wiring, for example, when embedded in the interior of insulating panels or in radio apparatus. In much the same way, during the war, the X-rays were useful in scrutinising the wiring within the leather of aeroplane pilots' electrically heated clothing.

A similar field of work which the X-rays have found is the examination of the interior of moulded articles, for example, the distributors of magnetos. During construction the insulation is moulded round the metal work, and subsequently machined. If, during the machining, blowholes are met with, the entire distributor has to be rejected.

Among the miscellaneous uses of the X-rays we can only make mention of the examination of oysters for pearls; the differentiation of lead

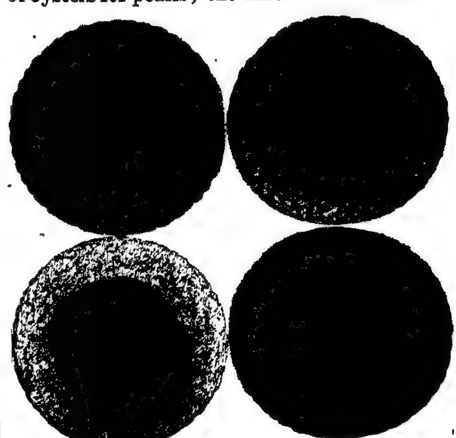

FIG. 29.—Golf Balls showing Unsymmetrical Cores.

glass jewels from the more transparent genuine gems; the scrutiny of artificial teeth; the detection of contraband by the customs officials; the sorting of fresh from stale eggs; the detection of heavy elements in minerals, of metal particles in chocolate, of weevils in grain, of mineral adulterants in certain powdered drugs (*e.g.* asafoetida), and of moths in tobacco for cigars.

In quite a different direction, an enterprising American shoe store has installed a screen outfit, so that the potential customer can see his "footigraph" and satisfy himself visually whether or not the shoe he is trying on is a good fit.

The application of the cinematograph principle to X-ray photography offers wide possibilities.

We can only refer to the more academic applications of the X-rays by the conchologist to examine the interior of shells and fossils, without in any way spoiling a rare specimen. These have valuable educational possibilities.

The use of the X-rays for revealing the interior of plant life is comparatively recent. Considerable differences exist in the mineral content and density, and hence the transparency of the different parts of a plant—root, stem, leaf, flower, fruit, seed, etc.—and thus it happens that even the most delicate structures of plants can be laid bare without tearing the plant to pieces in order to study it. Microscopic detail is of course not revealed. Long-waved X-rays are required for such work.

§ (34) X-rays and Old Masters.—The first artistic oil-painting of which there is any record was executed in the year 1399 by Hubert van Eyck, a Dutchman, and from then up to the early Italian and Flemish school, painters had possibly only eight or nine pigments, mostly mineral in origin. To-day there are over 200 in use, many of them vegetable or coal-tar in origin.

As is well known, the imitating of valuable pictures has always enjoyed a great vogue, and there are thousands of spurious paintings in existence—copies of both late and modern masters—which have been passed as genuine and sold for outstanding amounts. For example, so far as is known, Rembrandt painted some 700 pictures, yet Maximilian Toch estimates there are fully 4000-5000 in existence, all of which are regarded as genuine and have commanded great prices. Again it would have been absolutely impossible for any human being to have painted all the Rubenses that there are in existence. The remark is probably true of every great painter.

There are various scientific methods of determining the originality and age of paintings. Photomicrography is of great help: for example, in the case of a panel of a picture 300 years old the protoplasm in the cells of the wood has entirely dried out, a feature distinct from a modern panel. Chemical analysis of tiny detached fragments often throws light on the subject; for instance zinc white (zinc oxide) was not known 300 years ago, and the Flemish painters used flake white (white lead). Again bitumen, at first transparent, gradually becomes opaque and insoluble with the passage of time.

But not only pictures, but all works of art, are imitated in the same way. Furniture, pottery, bronzes, old weapons and brass work are so completely simulated that experts are frequently baffled. Sheraton furniture is a familiar example. We know that Sheraton had a little shop and did most of his work himself with only occasional help from a few expert artisans. The amount of Sheraton furniture in existence would indicate that Sheraton had a factory of several acres employing a thousand men who were lifelong supporters of mass production.

It would appear that the X-rays may usefully be called in, in certain cases, as a supplementary method of scrutiny for the expert. A start has been made with pictures, as we shall now proceed to show.

In any picture we have to consider three media, (1) the surface which is painted on—usually canvas or wood, though paper, porcelain, or other materials may be used; (2) the priming or sizing—nowadays almost always white lead, though formerly carbonate of lime and glue were employed; (3) the actual pigments.

Both wood and canvas are very transparent to the X-rays, though different kinds of canvas vary a good deal. The white lead primer is much more opaque than carbonate of lime, and the former, moreover, penetrates much farther into the interstices of the canvas. This in itself is sufficient to show a marked difference under the X-rays between modern and older pictures.

As to pigments, they vary greatly in X-ray opacity from the opaque salts of lead, zinc, and mercury to the transparent aniline derivatives and bitumen. Both modern and ancient whites are usually opaque, most of the blacks (new or old) are transparent, and modern reds are more transparent than the old reds. But, as already remarked, most of the earliest pigments are mineral in origin and opaque.

In a modern picture the sizing is very commonly more opaque than the pigments, and X-ray examination is, for that reason, usually inconclusive. But fortunately in the pictures of the old masters the reverse conditions hold, and thus it is that with a little experience the X-rays can be employed most usefully as a means of identifying a modern fake, or detecting alterations to an old picture. It is a practical certainty that, however skilfully the process has been carried out, the several materials used—whether canvas, priming, or pigment—will differ from those in the original painting and will, in consequence, be differentiated in the radiograph.

Notable work on this subject has been carried out by Dr. Heilbron of Amsterdam and, more recently, by Dr. Chéron of Paris.

Among the sixteenth century paintings examined by the former was the "Crucifixion" by Cornelis Engelbrechtsen, which contained in the right foreground the portrait of a woman which it was suspected was that of a former "donatrice," who (after a fashion not unknown in those days) had thus sought to perpetuate her association with the picture. A radiograph of the painting showed many "restorations," especially on the right half, and beneath the portrait of the donatrice was revealed the picture of a monk in surplice and stole, the head being smaller than that of the over-painted lady. The evidence was so clear that the picture was sent to be restored at the Rijks-museum in Amsterdam, the result being to bring to light once more the monk who had been hidden for 400 years.

Among the other paintings examined by Heilbron was a panel of the "Madonna" by Geertgen van St. Jans (*c.* 1500) which had always excited comment because of the apparently stiff and unnatural position of the arms. The radiograph showed that the presence of the Child in the arms of the Madonna fully explained their attitude. St. Jans is known to have painted his children disproportionately small, and the presumption is that this defect was the cause of some former owner having the Child painted out.

Other examples of Heilbron's work include a panel by De Meester van Allmaar, where the portrait of a lady (again supposed to be the donatrice) is found to be painted over the original figures. There is some chance that the panel will be restored to its original state. A radiograph of a panel by van Dyk, representing a waterfall, a knight with a horse, dogs, etc., shows that the artist originally painted a much bigger waterfall, the current of water appearing to pass through the animals. We are led to infer that the painting is an original and not a copy, for only in the case of the original can we trace such alterations in the ideas of the artist.

Dr. Chéron X-rayed a Flemish panel attributed to van Ostade and showing a party of country dancers and revellers. The radiograph revealed only a farmyard scene containing peacocks, ducks, and chickens. The supposed van Ostade is almost certainly modern, since practically all its colours are transparent to the rays. The farmyard picture is apparently old, since the sizing is not opaque.

Another picture of the French school of the fifteenth century which was examined by Chéron was that of the Royal Infant at Prayer hanging in the Louvre. The black background was found to mask a badly deteriorated original background—confirming documentary evidence to that effect.

The X-rays may find another field in the examination of palimpsests and ancient manuscripts which, hitherto regarded as carrying only their face value, may bear under the trivial inscriptions of mediaeval times older matter of priceless worth. Again it is well known that before millboard came into general use for book covers (about the middle of the sixteenth century), binders were accustomed to make them up from such loose pages as came to hand. Many discoveries of rare and valuable MSS. have been made when the bindings of old volumes have happened to fall to pieces. The X-rays may have useful application here.

As regards antique furniture and the like, it is not improbable that examination of constructional or other detail, which cannot otherwise be viewed except by destroying the article, would suffice to reveal in a fake craftsmanship out of tune with the reputed period.

§ (35) Future Developments of Industrial Radiology.—Our ideal should be to make the taking of an X-ray photograph as easy as that of light. The present limitations of radiometallography are largely those prescribed by equipment and technique. Considerable improvements will have to come if the subject is to extend its scope and become an attractive commercial proposition in heavy engineering. If great thicknesses are to be tackled, means will have to be found so that exposures are not intolerably long. There appear to be two means to this end—(*a*) by using much heavier X-ray outputs, at much higher voltages, or (*b*) by using much more sensitive screens, plates, or other detectors.

We have already considered the probable developments of the high-potential generator, and, as we should anticipate, all experience agrees in demanding higher and higher voltages for work with metals. The ordinary Coolidge tube will, however, take no more than 180,000 volts, preferably less. This can be increased to 300,000 by lengthening the arms of the tube and completely immersing it in oil. If there is a demand for it, the electrical engineer will doubtless overcome the difficulties in the way of supplying half a million or more volts. Such transformers have already been made for other purposes, but their bulk, weight, and cost are formidable. For example, a single-phase transformer giving a peak voltage of one million occupies a floor space of 13 ft. × 8 ft., is 15 ft. high, has terminals 28 ft. high, weighs 20 tons, and costs about £10,000. With such voltages both transformer and tube will doubtless be contained in a common oil tank, thus reducing the danger and the considerable losses by brush discharge.

Heavier discharges will demand more elaborate cooling arrangements, and probably glass X-ray tubes will not stand up to the work. We may have to turn to metal tubes radically different in design, capable of

absorbing 50 h.p. or more. Furthermore, we shall have to improve the deplorable efficiency of the whole outfit.

It may be mentioned that some of the γ-rays of radium are far more penetrating than the hardest X-rays we can produce at present (being equivalent to X-rays excited by about two million volts), but unfortunately the intensity is so weak (not more than a few per cent of that from a good bulb) that exposures are intolerably protracted.

As regards fluorescent screens and photographic plates, great improvements are called for. No screen at present available is sensitive enough for thicknesses exceeding about $\frac{1}{4}$ inch steel, and only then with difficulty. Photography must be resorted to in such cases, and the time taken over the process may then become prohibitive, at any rate for routine "mass inspection."

A photographic plate registers only about 1 per cent of the X-rays passing through it. Progress has mainly consisted in thickening the emulsion or richly loading it either with more silver or with heavier metals. Exposures may be shortened either by backing up the emulsion with a sheet of a heavy metal, such as lead, or more appreciably by the use of an intensifying screen, containing a fluorescing salt, such as calcium tungstate. All X-ray plates are much more sensitive to visible rays than to X-rays, but such screens, which are more efficacious with "hard" rays than "soft," are apt to impair the detail in certain classes of work owing to "grain." It is important to have the closest contact between the screen and the emulsion. This is secured in the new "Impex" plate, in which the fluorescing salt is contained in a superimposed gelatine film which is dissolved off before the plate is developed. Such plates reduce the exposure as much as thirty times with very hard rays, though the efficiency is much less with longer waves.

Another real advance in X-ray photography has proved to be the duplitized film, *i.e.* a film coated with emulsion on both sides of the celluloid. A "pile" of several of these sandwiched with thin fluorescent screens, gives a very sensitive detector.

The ionisation method of detecting the X-rays offers great promise, for it can be made more sensitive than any photographic method at present available. An explorer built on these lines and of convenient design would have corresponding advantages.

To conclude, the subject of industrial radiology is young and, although progress has been rapid, we must in all fairness be careful not to claim too much for it. From such experience as we have had, it does appear, however, that the method is settling down to be a valuable laboratory tool, supplementing those which are already available for testing materials. Incidentally the existence of the method is not without its moral effect on the personnel, as regards standard of workmanship.

G. W. C. K.

Radiometer: an instrument for investigation of the infra-red spectrum; a modification of the instrument, devised by Crookes, in which mica vanes, accurately mounted on a central spindle *in vacuo*, rotate when placed in the path of radiant energy. See "Wave-lengths, The Measurement of," § (7).

Radiometry: the measurement of radiant energy or radiant power. See "Spectrophotometry," § (2).

Radio-micrometer: an instrument for investigation of the infra-red spectrum; a type of galvanometer in which the current is generated by radiation falling on the junction of a thermocouple. See "Wave-lengths, The Measurement of," § (7).

Radiotherapy: X-ray treatment of malignant disease. See "Radiology," § (30).

RADIUM

§ (1) Discovery.—Radium was discovered by M. and Mme Curie shortly after the property of radioactivity of uranium compounds had been discovered by Henri Becquerel in 1896. From observations of the activity of different compounds of uranium, Mme Curie had concluded that the radioactivity of uranium was an atomic property; that is, the total radiation emitted by a compound was proportional to the amount of uranium present, irrespective of the other inactive elements with which it was held in chemical combination. When, however, a number of uranium minerals were examined it was found that some specimens of pitchblende, notably those from Austrian mines, showed much greater activity than the metal uranium itself. It was suspected that this abnormal activity was due to the presence of small quantities of an unknown element or elements of activity greatly exceeding that of uranium. With the object of testing this conclusion, M. and Mme Curie undertook careful analyses of some of the uranium minerals, and their work resulted in the discovery of two new radioactive elements, namely polonium and radium, the activity of the latter being several million times that of an equal weight of uranium.[1]

§ (2) Occurrence.—The two principal commercial ores of radium are pitchblende and carnotite. Pitchblende has no definite composition and is a very complex mineral.

[1] M. and Mme Curie and G. Bemont, *Comptes Rendus*, 1898, cxxvii. 1215.

It contains in varying quantities nearly all the known metals, but it is rich in the oxides of uranium. Carnotite has a more definite composition, being a potassium uranyl vanadate (K_2O, $2UO_3$, V_2O_5, $3H_2O$) containing small quantities of barium and calcium. Of less importance are autunite, a hydrated calcium uranium phosphate [$Ca(UO_2)_2(PO_4)_28H_2O$] and torbernite, a hydrated copper uranium phosphate [$Cu(UO_2)_2P_2O_8$, $8H_2O$].

Pitchblende deposits are found at St. Joachimsthal, Bohemia; at Johanngeorgenstadt, Saxony; in Cornwall, England; in North Carolina and Connecticut, U.S.A. The mines of St. Joachimsthal have been worked for the last twenty-five years for uranium; previously they were worked for bismuth and cobalt, and before that for silver. The veins show that deposition occurred in three periods; the cobalt and nickel deposited first, then the uranium, and afterwards the silver. Dolomite spar is always present and generally has a white or yellowish-white colour, but changes to brownish red where pitchblende begins to appear, and is a dirty grey where it is actually in contact with the ore. The veins in the Saxony mines resemble those at Joachimsthal, the pitchblende occurring in the spar in pieces 2 to 3 in. in diameter. In Cornwall also the mineral pitchblende is associated with nickel and cobalt veins, although here only part of the veins are highly argentiferous. In the United States there are five mines that have produced pitchblende in quantity, and of these the Kirk mine is probably the most important. During the last twelve years about 20 tons of ore with an average content of 35 per cent U_3O_8, and over 100 tons with a content of 3 to 4 per cent U_3O_8, have been mined. The other mines produce lower grade ores in some quantity. Pitchblende has been found in small quantities, but of very high quality, in East Africa, and recently considerable amounts of an exceedingly rich uraninite have been found in India.

Carnotite deposits are found mainly in Dolores, San Miguel and Montrose counties, Colorado, and Utah, and extend over a belt about 60 miles long by 20 miles wide. The most usual ore is a sandstone so impregnated with yellow carnotite that the colour is decidedly noticeable and contains pockets of brown sandclay. The deposits are invariably in pockets, many of which, however, are of considerable size. A survey of the carnotite fields, carried out by the Bureau of Mines in 1912, revealed the fact that the carnotite deposits of Colorado and Utah constituted by far the largest source of radium-bearing ores in the world.[1] It is estimated that these deposits should be capable of yielding at least 500 grammes of radium element. During the period from 1913 to 1919 the Standard Chemical Company, Pittsburg, Pa., alone produced 50·8 grammes of radium element from this ore.[2] Carnotite is also found at Olary, South Australia, but this variety, being mixed with ilmenite, is very different from the American carnotite. Autunite is found in commercial quantities in Portugal in the district between Guarda and Sabugal. It is occasionally found in very pure condition, but for the most part as a very low grade ore, bearing from 0·5 to 1 per cent of U_3O_8. It is also found together with torbernite near Farnia in South Australia.

All common rocks and minerals of the earth's crust contain minute amounts of radium (of the order of 10^{-12} gramme of radium per gramme of rock). The atmosphere also contains radium in the form of emanation.

§ (3) Extraction and Separation of Radium from Radioactive Ores.—The chief ore employed in the preparation of radium in the early stages of radioactivity was pitchblende. The following account of the extraction of radium from pitchblende is given by Mme Curie.[3] The crushed ore is roasted with sodium carbonate, and the resulting material washed first with warm water and then with dilute sulphuric acid. The solution contains the uranium, whilst the insoluble residue contains all the radium. This residue chiefly contains the sulphates of lead and calcium, silica, alumina, and ferric oxide. In addition, nearly all the metals are found in greater or smaller amount (copper, bismuth, zinc, cobalt, manganese, nickel, vanadium, antimony, thallium, rare earths, niobium, tantalum, arsenic, barium, etc.). Radium is found in this mixture as sulphate and is the least soluble sulphate in it. In order to dissolve it, it is necessary to remove the sulphuric acid as far as possible. To do this, the residue is boiled with concentrated soda solution. The sulphuric acid combined with the lead, aluminium, and calcium passes into solution as sulphate of sodium, which is removed by repeated washing with water. The alkaline solution removes at the same time lead, silicon, and aluminium. The insoluble portion is well washed and treated with ordinary hydrochloric acid, which completely disintegrates the material and dissolves most of it. The radium remains in the insoluble portion. This is well washed with water and again treated with boiling concentrated solution of sodium carbonate. This operation completes the transformation of the sulphates of barium and radium into

[1] R. B. Moore and Karl L. Kithil, U.S.A. Bureau of Mines, *Bull.*, 1913, No. 70.

[2] *Science*, 1919, xlix. 227.

[3] Translation of Thesis for Doctorate, *Chem. News*, 1903, p. 134.

carbonates. The solid is filtered off, washed with sodium carbonate solution and then with water, and dissolved in HCl quite free from H_2SO_4. The filtered chloride solution is treated with sulphuric acid to precipitate radium and barium sulphates which are contaminated with traces of lead, iron, and calcium sulphates. The crude sulphates thus obtained have an activity from thirty to sixty times as great as that of metallic uranium. To purify the sulphates they are boiled with sodium carbonate and transformed into the chlorides. The solution is treated with sulphuretted hydrogen, which gives a quantity of active sulphides containing polonium. This precipitate is removed by filtering, and the remaining solution oxidised by means of chlorine, and precipitated with pure ammonia; the precipitate which contains actinium is removed, and the filtered solution treated with sodium carbonate. The precipitated carbonates formed are washed and converted into chlorides. These chlorides are evaporated to dryness and washed with pure concentrated hydrochloric acid to remove traces of calcium chloride. The calcium chloride dissolves almost entirely, whilst the chlorides of barium and radium remain insoluble.

From 1 ton of Joachimsthal residues about 8 kilograms of a mixture of barium and radium chlorides are obtained, the activity of which is about sixty times that of metallic uranium. To extract pure radium chloride from barium chloride containing radium the mixture of the chlorides is subjected to fractional crystallisation in pure water, and then in the later stages in water to which hydrochloric acid has been added. The crystals of radium chloride which separate out are elongated needles, having exactly the same appearance as those of barium chloride. Both crystals show double refraction. Crystals of barium chloride containing traces of radium are colourless, but when the proportion of radium increases they have a yellow coloration after some hours verging on orange and sometimes a beautiful pink. The maximum coloration is obtained for a certain degree of radium present. This fact serves as a useful check on the progress of fractionation. Giesel pointed out that the separation of barium and radium by fractional crystallisation in water from a mixture of the bromides is more rapid and efficient than from that of the chlorides.[1] Another method of separating barium and radium is given by Marckwald.[2]

A method of extracting radium from pitchblende by fusing the ore with sodium sulphate was employed on a large scale by Haitigner, Luding, and Ulrich.[3] This method has also been used in Australia by Radcliffe in treating carnotite obtained at Olary, South Australia.

Fusion with sodium carbonate was employed in America on carnotite ores, but this method has the great disadvantage that it carries a large part, if not all, of the silica into solution. This adds greatly to the cost of the operation and tends to give radium-barium sulphates of a rather high degree of impurity which require special treatment. The method adopted at present by the Bureau of Mines, U.S.A.,[4] is based upon the fact that strong nitric acid dissolves radium-barium sulphates in considerable quantities, as well as the other soluble constituents of the ore. The use of strong nitric acid is advocated because the radium-barium sulphate can be precipitated at once in a remarkably pure form, and the nitric acid can be largely recovered in the form of sodium nitrate and used again. The radium usually exists in the ore in the proportion of 1 part in 200,000,000; a recovery of 90 per cent of the radium present is claimed for the nitric acid method. H. Schlundt[5] gives a method of extracting radium from carnotite ores with concentrated sulphuric acid, and has applied it with success to carnotite ores from Colorado and Utah. By boiling carnotite ores with concentrated sulphuric acid the barium and radium compounds present are converted into bisulphates, which remain in solution in an excess of the acid and may then be separated from the insoluble components by filtration, followed by washing the residue with concentrated sulphuric acid. From the acid liquors thus obtained the radium is recovered by diluting with water, whereby radium-barium sulphate is precipitated. Two types of carnotite ores were dealt with, a low-grade ore containing 1·66 per cent U_3O_8, 4·03 per cent V_2O_5, and 4·88 parts of Ra per billion, and a high-grade ore containing 14·39 per cent U_3O_8, 9·67 per cent V_2O_5, and 42·78 parts of Ra per billion. By using sulphuric acid of more than 78 per cent concentration, at least 90 per cent of the radium present in these ores may be recovered by the above method.

Plum[6] gives the following summary of the method employed by him in separating radioactive products from carnotite concentrates. One kilogramme of carnotite concentrates was boiled for several hours with 2 litres of a solution containing 400 grammes of anhydrous sodium carbonate. The filtrate yielded 88·1 grammes

of uranyl sodium carbonate, $UO_2CO_32Na_2CO_3$, which represented 88 per cent of the total uranyl in the samples. The filtrate still held 2 per cent of the uranium in solution. A second treatment of the ore with 300 grammes of sodium carbonate under the same conditions as above dissolved out only 2·8 per cent of the uranium. The residue was treated with 400 c.c. hydrochloric acid diluted with about a litre of water, and boiled for about 8 hours. The radium-barium sulphate separated from the filtrate weighed 7·36 grammes. The residue was next heated for a day with 200 c.c. of nitric acid diluted with about a litre of water. The radium-barium sulphate precipitated in this filtrate weighed 0·453 gramme. The percentage of radium in these combined sulphates was 89·8 per cent of the total amount in the ore. Reprecipitations of barium sulphate in the two acid filtrates carried down 2·7 per cent more of the radium. The lead sulphate separated from bismuth and containing radio-lead, weighed 0·49 gramme. The polonium precipitated with bismuth and then deposited on copper was 50·1 per cent of the total amount in the ore. The residue was finally treated with twice its weight of sulphuric acid after being diluted with about an equal weight of water and then heated until most of the sulphuric acid had escaped in fumes. The activity of the ionium found in this solution was 61 per cent of the total amount in the original carnotite. The residue left, after all extraction processes had been carried out, weighed 507 grammes and its activity showed that only 4·2 per cent of the radium still remained in it.

§ (4) Metallic Radium has been isolated by Mme Curie and Debierne [1] by the electrolysis of pure radium chloride. The radium amalgam so obtained was heated to about 700° C. in a current of hydrogen to volatilise the mercury. A white metal remained. Metallic radium melts at about 700° C. and the vapour given off rapidly attacks quartz. The metal turns black in air, possibly owing to the formation of a nitride; it chars paper and dissolves rapidly and completely in water and in dilute hydrochloric acid. It decomposes water with the evolution of hydrogen forming radium hydroxide solution.

§ (5) Atomic Weight.—Mme Curie made several determinations of the atomic weight of radium, by treating purified radium chloride with silver nitrate and estimating the amount of silver chloride obtained. The last determination made by her gave a value 226·4 for the atomic weight.[2] Employing the same method and about 1·35 grammes of purified radium chloride O. Honigschmid [3] obtained the value 225·95. A similar set of experiments with the bromide gave 225·96. A spectroscopic examination of the final bromide preparation used showed that it contained less than 0·002 per cent of barium. The value 226 is at present accepted as the atomic weight of radium.

§ (6) Spectrum.—Demarçay [4] showed that radium gave a well-marked and characteristic spectrum. Twelve lines were observed between $\lambda=5000\ \mu\mu$, and $\lambda=3500\ \mu\mu$, together with well-marked bands. The general aspect of the spectrum is that of the alkaline earths—these metals have well-marked line spectra with a number of bands. Later the spark spectrum of radium was examined by Runge,[5] Exner and Haschek,[6] Crookes,[7] Runge and Precht.[8] The chief lines observed, in order of decreasing intensity, were: 3814·6, 4682·4, 4340·8, 5729·2, 4826·1, 4436·5, 5813·8, 6200·6, 5958·4, 5660·8, 4533·3, 2813·8 $\mu\mu$. Radium salts give a fine carmine coloration to the Bunsen flame. The flame spectrum of radium was examined by Runge and Precht.[9] The following lines and bands showed up clearly: 4826, 6130–6330, 6329, 6349, 6530–6700, and 6653. A good test of the completion of the separation of barium and radium is the relative intensities of the lines 4533·3 (radium) and 4554·2 (barium). These two lines are of same intensity when only 0·6 per cent barium is present in the radium salt. An activity fifty times as great as that of metallic uranium is required to distinguish clearly the principal radium line (3814·6 $\mu\mu$) in the spark spectrum. With a sensitive electrometer the radioactivity of a substance, only one-hundredth of that of metallic uranium, can be detected, so that the ionisation method of detecting radium is much more sensitive than the spectroscopic method.

§ (7) Salts of Radium.—The salts of radium resemble the corresponding salts of barium. Radium sulphate is less soluble than the barium salt, the carbonate also is sparingly soluble. For a 50 per cent or weaker solution of sulphuric acid the solubility of radium sulphate is practically the same as that in water, namely $2{\cdot}0\times10^{-8}$ gm. $RaSO_4$ per c.c. at 25° C. This value is that predicted from comparison with the decreasing solubilities of Ca, Sr, and Ba sulphates. On increasing the concentration of H_2SO_4 above 65 per cent, a marked rise in solubility of $RaSO_4$ takes place; it is more than twelve times as soluble in 70 per cent as in 65 per cent acid.[10]

The bromide and chloride crystallise with two molecules of water: $RaCl_2 2H_2O$, $RaBr_2 2H_2O$, and these crystals are isomorphous with the corresponding barium salts. The radium halides are much less soluble than the barium halides. Several other salts, for instance nitrate, azoimide, cyanoplatinate, have been prepared. The radium salts when freshly made are white, but they afterwards become yellow and brown, particularly if the salts are impure. Solutions of radium salts have a blue luminescence and the salts are all luminous in the dark. The following table gives the percentages of radium element in some of the radium salts:

TABLE I

Salt.	Formula.	Percentage of Radium Element in Pure Radium Salt.
		per cent
Radium bromide crystalline	$RaBr_2 2H_2O$	53·6
Radium bromide anhydrous	$RaBr_2$	58·6
Radium chloride crystalline	$RaCl_2 2H_2O$	67·9
Radium chloride anhydrous	$RaCl_2$	76·1
Radium sulphate	$RaSO_4$	70·2
Radium carbonate	$RaCo_3$	79 0

§ (8) RATIO OF RADIUM TO URANIUM IN MINERALS.—In the early stages of radioactivity Rutherford and Soddy had suggested that radium was a disintegration product of one of the radioactive substances in pitchblende and, since radium was always found associated with uranium, it appeared probable that uranium was the primary source from which radium was derived. If this were the case the weight of pure radium per gramme of uranium in a mineral in radioactive equilibrium should be a definite constant. A large number of radioactive minerals were examined by different investigators with a view to testing this conclusion. The ratio of the amount of radium to uranium in the older minerals showed remarkable constancy; minerals of more recent formation, however, in which radioactive equilibrium had not been established, showed variation, and according to expectation the values of the ratios were always lower than in the older minerals. The weight of pure radium per gramme of uranium in a mineral in radioactive equilibrium was found by Rutherford and Boltwood[1] to be $3{\cdot}23 \times 10^{-7}$ gramme, so that 323 milligrammes of radium element are present per ton of uranium element approximately. This value of the "equilibrium ratio" has been confirmed by Lund and Whittemore[2] who examined samples of carnotite representing large quantities of the ore (a few hundred pounds to several tons). Samples from small quantities of ore—hand specimens up to a few pounds—tended to exhibit abnormal ratios; in one instance the ratio was as low as $2{\cdot}48 \times 10^{-7}$, in another it was as high as $4{\cdot}6 \times 10^{-7}$. These abnormal differences are put down to local variations which are equalised in large samples.

§ (9) ESTIMATION OF RADIUM.—The quantity of radium in a preparation is estimated in terms of the International Radium standard. This standard is a specially purified specimen of radium chloride containing 21·99 milligrammes of radium chloride prepared by Mme. Curie. It is kept at the Bureau International des Poids et Mesures, Sèvres, Paris. Copies of this standard have been supplied to the National Physical Laboratory, Teddington, and to the official testing institutions of other countries, who undertake the determination of the quantity of radium contained in preparations submitted to them.

Two general methods have been employed for determining quantitatively the amount of radium in a preparation, namely, the γ-ray method which is suitable for measuring quantities of radium varying from 0·1 milligramme to 1 gramme, and the emanation method which is suitable for measuring small quantities of the order of 10^{-6} milligramme.

(i.) *The γ-ray Method.*—This method of measurement depends upon the fact that the radium in a radium salt, hermetically sealed in an enclosure, is in equilibrium with its products of disintegration in about a month's time after the preparation of the salt, and emits a very penetrating γ-radiation, the intensity of which is proportional to the amount of radium present. The radium itself emits no γ-radiation, neither do the next three products which follow it, except radium B which gives off soft γ-radiation; the penetrating γ-rays of radium are entirely due to the fourth product radium C, and it is for this reason that it is necessary to enclose the salt in a hermetically sealed tube, so that equilibrium has been established before measurements are taken. It is only when equilibrium has been attained that the γ-radiation gives a measure of the radium present in the tube.

(a) *Rutherford's Direct Method.*—To measure the quantity of radium in a sample in terms of the standard the γ-ray activity of each preparation is measured under identical conditions by means of an electroscope and ionisation chamber. The apparatus employed is shown in *Fig.* 1. The rates of fall of the electroscope leaf after correcting for natural leak are directly proportional to the amounts of radium in the tubes and thus give a direct comparison

of their amounts. It is essential for accurate measurements that the electric field inside the ionisation chamber is strong enough to produce saturation. The most accurate comparisons are those made when the sample and standard contain about the same quantity of material; comparisons correct to about 1 per

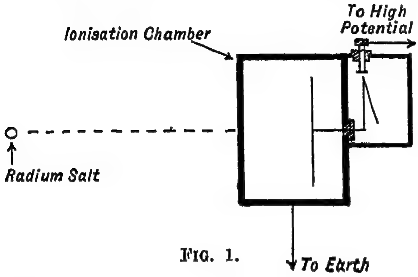

FIG. 1.

cent can be made, however, when one sample is ten times as strong as the other if a sufficient number of readings be taken. It is advisable to make comparisons at different distances from the ionisation chamber and also to place different thicknesses of absorbing screens in front of the chamber. The ratio of the activity of the two samples should remain constant during these modifications. Measurements should not be made with the samples too near the electroscope because a small displacement relative to the electroscope introduces a large error. It is essential to prevent radiation other than γ-radiation from entering the chamber. The latter is therefore made of lead at least 3 millimetres thick and the windows of the electroscope should be made of thick lead glass and be well guarded by lead shields. These precautions prevent the entry of β-radiation, but scattered γ-radiation from objects in the neighbourhood of the apparatus will always enter the apparatus, and for this reason such objects should not be moved during the course of a comparison. It is of advantage to enclose the radium in small tubes so that they act as point sources, also the walls of the tubes should not exceed 0·2 millimetre in thickness. If they do not exceed this thickness the correction due to absorption of the rays in the glass is negligible. For thicker walls, a correction will have to be applied, the absorption coefficient of the rays in glass being 0·10 per cm. It is convenient to have at hand a series of graduated standards, say 0·1, 1, 5, 10, 30 milligrammes radium element for the comparisons. The error introduced on account of lack of saturation may be serious when quantities of radium of very different activities are compared by the above method. The graduated standards would be useful in this connection, because they could be combined together to give an amount of radium approximately equal to that in the tube to be tested.

(*b*) *Rutherford and Chadwick's Method.*—Another delicate method of comparison has been devised by Rutherford and Chadwick.[1] The method consists in balancing the current produced in an ionisation vessel by the γ-rays from the two specimens of radium to be compared in turn against that produced in a second vessel by uranium placed inside it. The ionisation in this vessel remains constant whilst that in the other one is varied by altering the distance of the radium from it. When the ionisation currents have been balanced the position of the radium on a scale gives a measure of the quantity present.

The disposition of the apparatus is shown diagrammatically in *Fig.* 2. In the apparatus described by Rutherford and Chadwick, the vessel A consists of a lead cylinder 2 cm. thick, 10 cm. long, and of internal diameter 15 cm. The end of the vessel, through which the γ-rays enter, is covered with a lead plate 1 cm. thick. This vessel is placed at one end of a graduated scale about four metres long along which a slide carrying the radium R can be moved to any desired distance from it. The insulated electrode of the chamber is connected to that of the chamber B by a wire which is enclosed in an earthed tube T, about

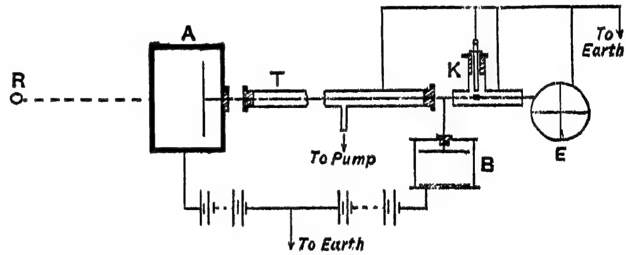

FIG. 2.

3 to 4 metres long, which can be evacuated. This prevents the production of ionisation in the tube by stray γ-rays which would vitiate the results. The vessel B is a brass cylinder 4 cm. high and 4 cm. in diameter. The ionisation in this vessel is produced by the α-rays emitted by a film of uranium oxide deposited on a plate placed at the bottom of the chamber. The ionisation can be varied over a large range by opening or shutting an iris diaphragm placed above the uranium. The insulated system is connected through

[1] *Phys. Soc. Proc.*, 1912, xxiv. 141.

an earthing key K to one pair of quadrants of the electrometer E, the other pair of quadrants being earthed. In order to produce ionisation currents in opposite directions in the two chambers, the one chamber is connected to a potential (usually about 200 volts) equal and opposite to that on the other. The electrometer and ionisation chamber B are both enclosed in a box covered with lead 5 mm. thick, and as a further protection from the γ-rays, the vessel B is enclosed in a lead cylinder 6 cm. high and 3 cm. thick, and insulated from it. It is convenient to arrange the apparatus so that the movement of the spot of light on the scale can be watched at the same time that the earthing key is worked and the slide carrying the radium is moved along the scale.

In making a comparison of two preparations of radium, the only measurements required are the distances of the balancing points from the surface of the chamber. It is necessary, however, to know the depth of the ionisation chamber A, and a correction has to be made for the absorption of the γ-rays in the air between the sources and the vessel A. In the calculation use is made of the fact that over a wide range of distance the intensity of the radiation producing ionisation is inversely proportional to the square of the distance of the radium from the ionisation vessel.

If r is the distance of the radium from the front surface of the ionisation vessel and t the thickness of the lead plate covering it, then if μ_1 is the absorption coefficient of the γ-rays in lead and μ their absorption coefficient in air, the intensity of the radiation in the ionisation vessel is proportional to $e^{-\mu_1 t}\cdot e^{-\mu r}/r(r+d)$, where d is the depth of the ionisation vessel, which is small compared with r.

Hence if R_1 milligrammes of radium, placed at a distance r_1, produce the same ionisation in the vessel as R_2 milligrammes placed at a distance r_2, then

$$\frac{R_1 e^{-\mu r_1}}{r_1(r_1+d)}=\frac{R_2 e^{-\mu r_2}}{r_2(r_2+d)},$$

i.e.

$$\frac{R_2}{R_1}=\frac{r_2}{r_1}\cdot\frac{r_2+d}{r_1+d}\cdot e^{-\mu(r_1-r_2)}.$$

This method can be employed to measure quantities of radium greater than one milligramme to an accuracy of about 1 part in 400. Smaller quantities than this have to be brought so near to the ionisation vessel that the inverse square law no longer holds.

(*c*) *Mme Curie's Method.*—A γ-ray method due to Mme Curie is shown in *Fig.* 3. The radium is placed on top of a large circular plate condenser C consisting of two sheets of lead about 80 cm. diameter and 5 mm. thick. An insulated aluminium plate situated between the lead plates, with a clearance of about 2 millimetres on either side, serves as the electrode. To obtain saturation the lead plates are connected to a high potential. The ionisation current produced is balanced by the use of a quartz piezo-electrique Q. The relative saturation currents produced by the test and standard preparations afford a definite measure of the radium present.

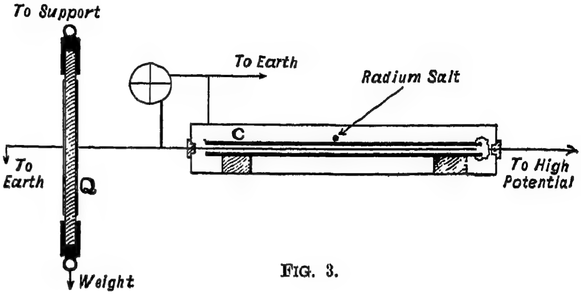

FIG. 3.

(*d*) *Soddy's Method.*—Soddy describes a γ-ray method by which the radium content of a low-grade preparation can be estimated.[1] A spherical flask is filled with a known weight of the salt and sealed up. After equilibrium has been attained a comparison is made between this and the standard by the first method described above. An accurate correction can be made in this instance for the absorption of the rays in the salt. Suppose I is the intensity of the radiation observed from the flask and I_0 what it would be if no absorption of the radiation occurred. Then it can be shown that

$$\frac{I}{I_0}=1-\tfrac{3}{4}\mu R+\tfrac{4}{10}(\mu R)^2-\tfrac{1}{6}(\mu R)^3+\tfrac{2}{35}(\mu R)^4-\tfrac{1}{60}(\mu R)^5+\ .\ .\ .\ ,$$

where μ is the absorption coefficient of the radiation in the material and R the radius of the flask. The value of μ/ρ where ρ is the density may be taken as 0·040, the density of the substance being taken as the mass divided by the known volume V of the flask. The series is rapidly converging, and three or four terms will suffice in most cases.

For a rapid approximate estimation of radium in minerals Soddy employs a large lead electroscope, about 20 cm. high by 20 cm. diameter and of wall thickness 0·4 cm.

[1] Soddy, *The Chemistry of the Radio-elements*, 1917, i. 93.

The windows are made of lead glass and are shielded by lead so as to prevent the entry of secondary radiation into the electroscope. The leaf system is of the simple type and is insulated by sulphur. In comparing pitchblendes and other minerals a lump of 20 to 100 grammes, according to the richness of the mineral, is taken and placed on top of the electroscope. The increase in the leak is compared with that produced by a similar lump of a standard pitchblende, the uranium content of which is known. These measurements supply enough data to calculate the amount of radium in the mineral. For example:

	Per cent. U	Weight.	Leak of Electroscope.
Standard . .	60	21 gms.	12 div. per min.
Specimen tested .	x	30 ,,	8 ,, ,, ,,

$$x = \frac{21}{30} \times \frac{8}{12} \times 60 = 28 \text{ per cent.}$$

The "equilibrium ratio" of radium to uranium in a mineral of old formation is $0{\cdot}323 \times 10^{-6}$, that is, there are 323 milligrammes of radium element present per ton of uranium element. Hence the amount of radium in the above sample is $0{\cdot}28 \times 0{\cdot}323$, *i.e.* 0·090 gramme per ton of mineral.

(ii.) *The Emanation Method.*—This method is very suitable for accurate measurements of minute quantities of radium. It depends on the fact that radium produces a gaseous product, the emanation, of a comparatively long period of transformation which can be separated completely from radium solutions. The emanation reaches its equilibrium value after the radium solution has been sealed up in an enclosure for about a month; when this stage is reached the amount of emanation present is proportional to the radium content of the solution. As a standard of comparison it is necessary to prepare solutions containing a known quantity of radium which has been measured by one of the γ-ray methods. A standard solution is prepared as follows: A known quantity of radium salt, say 1 milligramme, is dissolved in distilled water containing a little dilute hydrochloric acid so as to get it all into solution. This is made up to a litre by the addition of water. One cubic centimetre of this solution is measured carefully, either by means of a pipette or by weighing, and transferred to another flask, and water added up to a known volume, say 1 litre: 1 cubic centimetre of this solution would therefore contain 10^{-6} milligramme of radium. A number of solutions of different strengths are prepared in this manner and kept as standards of reference. It is essential to take great precautions that all the radium is initially put into solution, and it is advisable to add a little hydrochloric acid to the standard solutions when they are made, so as to ensure that the radium remains permanently dissolved. After the standard solution is made, it is placed in a distilling flask which can be sealed up. Before sealing up, however, the solution is thoroughly boiled to drive off all the emanation. Boiling for a few minutes suffices for this purpose. The flask is sealed up before it cools and is kept for a month to allow the emanation to accumulate.

When the radium content of a sample is required, it is put into solution in a manner similar to that described above in the case of the standard. In a month after the vessel containing the solution is sealed, the emanation is transferred into an electroscope. This transference is effected by means of the apparatus shown in *Fig.* 4. The distilling

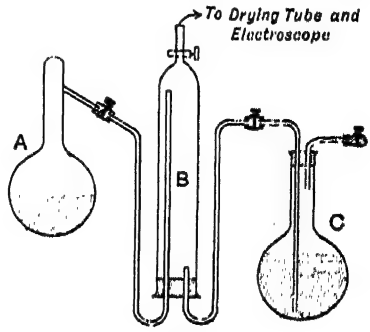

Fig. 4.

flask A, containing the radium solution, is opened and the air rushes into the partially exhausted vessel so that there is no loss of emanation. This is then connected to the gas burette B, which is filled with hot water forced into it from the flask C. The flask A is then heated for about five minutes so as to drive the emanation into the gas burette; the emanation collects in the top of the burette and does not dissolve in the hot water. Cold water dissolves the emanation to an appreciable extent. The flask A is again sealed, and the emanation in the burette sucked into an electroscope where its activity is measured. To do this the electroscope is evacuated by means of a water pump and the emanation passed into it through a drying tube. The burette is finally disconnected from the drying tube and a stream of dry air allowed to pass into the electroscope until atmospheric pressure is established. The electroscope is then closed. The rate of leak due to the emanation in the electroscope increases rapidly at first and then more slowly, reaching a maximum in about three hours

after the introduction of the emanation. The increase of leak is due to the production by the emanation of its products — radium A, radium B, and radium C. During this interval it is advisable to keep the leaf of the electroscope negatively charged so as to concentrate the active deposit on the central rod. Owing to the intense field near the central electrode, saturation is obtained more easily than if the active deposit were driven to the walls of the electroscope. For accurate work it is desirable to take measurements of the leak when at its maximum. The emanation should be swept out of the electroscope as soon as the measurements are made, so as to avoid contamination from radium F, which will increase the natural leak.

The same procedure is gone through with the standard solution. The ratio of the leaks in the two cases gives a measure of the amount of radium in the sample in terms of the standard.

The emanation method is very accurate and reliable. The emanation from 10^{-6} milligramme of radium gives a comparatively rapid discharge, and it is possible to measure one-hundredth of this quantity with certainty.

§ (10) Mesothorium. — The γ-ray method does not differentiate between radium and mesothorium, both of which emit penetrating γ-radiation. The penetrating power of the rays from radium is slightly greater than that of the rays from mesothorium, and a careful comparison of the absorption of the rays in lead will reveal the contamination of radium by mesothorium without the necessity of opening the tube containing the preparation. A more satisfactory, although a more laborious method of detecting the presence of mesothorium is to dissolve the salt and drive off the emanation. If the solution contains no mesothorium the γ-ray intensity will almost vanish after three hours; this will not be the case if there is any mesothorium present. The objection to this method is that the tube containing the preparation must be opened, which involves the risk of the loss of some of the material.

The carnotites are known to contain only a negligible amount of mesothorium. Tests made at the Bureau of Standards, Washington, on radium produced from this ore indicated that the mesothorium present did not exceed 0·2 per cent of the radium content of the material. Consequently it is quite safe to assume that the radium produced from these deposits is practically free from mesothorium.

§ (11) Radium Constants.—Radium itself emits $3{\cdot}57 \times 10^{10}$ α-particles per second per gramme of radium; when in equilibrium with its products $14{\cdot}3 \times 10^{10}$ are expelled per second per gramme of radium. The total charge carried by the α-particles emitted per second from 1 gramme of radium and from each of its products in equilibrium with it is 33·2 e.s.u. or $1{\cdot}11 \times 10^{-9}$ e.m.u.[1]

The quantity of emanation in equilibrium with 1 gramme of radium is known as a *curie* of emanation, and one-thousandth part of it is a *millicurie*. Similarly the quantity of radium A, radium B, and radium C in equilibrium with one gramme of radium are known as one curie of radium A, radium B, or radium C respectively. The total ionisation current due to α-rays from one curie of emanation is $2{\cdot}89 \times 10^6$ e.s.u. when the emanation is by itself and $9{\cdot}94 \times 10^6$ e.s.u. when it is with its α-ray products.[2] The total charge carried by the β-particles emitted per second by Ra B or Ra C in equilibrium with 1 gramme of radium is 18·3 e.s.u.[3] The volume of the emanation from 1 gramme of radium in equilibrium is 0·63 cubic millimetre, which agrees closely with the value calculated from the knowledge of the number of α-particles emitted per second, per gramme of radium itself, namely, 0·62 cubic millimetre.[4] The total heating effect of 1 gramme of radium and its products in equilibrium with it is 134·7 gramme calories per hour. The contribution to this total amount by each of the products is as follows:

Radium alone .	. 25·1	gramme calories per hour.
Radium emanation .	28·6	,, ,, ,,
Radium A . .	. 30·5	,, ,, ,,
Radium B } Radium C } .	. 50·5	,, ,, ,,

The production of helium by radium was investigated by Ramsay and Soddy.[5] Purified emanation from about 50 milligrammes of radium bromide was introduced into a small spectrum tube. No helium could be detected spectroscopically immediately after the introduction of the emanation, but after standing for four days the helium spectrum appeared with all its characteristic lines. This showed that helium is produced directly by the transformation of the radium emanation. It was the first definite evidence of the production of a known element during the transformation of radioactive matter. Boltwood and Rutherford[6] found experimentally that 164 cubic millimetres of helium are produced per gramme of radium per year; this figure is in good agreement with that found by calculation, namely, 163 cubic millimetres.

From the number of α-particles emitted per second by 1 gramme of radium Rutherford and Geiger calculated that the half-value

[1] Rutherford and Geiger, *Roy. Soc. Proc.*, 1908, A, lxxxi. 141.
[2] Geiger, *ibid.*, 1909, A, lxxxii. 486.

[6] *Phil. Mag.*, 1911, xxii. 586.

period of transformation of radium was 1690 years. Boltwood[1] determined this quantity experimentally by separating the whole of the ionium present in a uranium mineral and determining the growth of the radium from it in terms of the equilibrium amount of radium in the mineral. He found that the half-value period was about 2000 years. A more recent determination by this method, and employing four different minerals, has been made by Mlle. Gleditsch.[2] The mean of the four determinations gave the value 1660 years for the half-value period, which agrees more closely with the above-calculated value. If I_0 is the initial activity of radium and I its activity after an interval of time t, then $I/I_0=e^{-\lambda t}$, where λ is a constant known as the "radioactive constant." It may be defined as the fraction of the total amount disintegrating per unit of time, assuming the time unit to be so small that the quantity at the end of the time unit is not sensibly different from that at the beginning. For radium $I/I_0=0\cdot5$ when $t=1690$ years, so that $\lambda=4\cdot10\times10^{-4}$ per year. An atom disintegrating according to the above law can be shown to have an average life of $1/\lambda$, which in the case of radium would be 2440 years.

RANGE-FINDER, SHORT-BASE

§ (1) **Early History of the Range-finder.**—The evolution of the short home-base range-finder provides one of the most interesting stories in the whole range of applied optics. From the earliest times, the distances of inaccessible objects have been determined by simple triangulation methods. This has resulted in a constant demand for instruments of the theodolite type, designed to measure angles in azimuth with the greatest possible accuracy. When, however, the problem of determining ranges during a battle, under the eyes and fire of the enemy it might be, became an urgent one, it was soon discovered that what were in essence surveying methods suffered under great disadvantages. They necessitated the use of a comparatively long base, and the employment of a number of men, for the carrying out of an operation which took a considerable time, and had to be conducted under conditions which made accurate work difficult. Thus arose the demand for the short-base, single-observation range-finder.

In the earlier forms of short-base range-finders two theodolites in effect were mounted at the ends of a known and rigid base. The theodolite telescopes were directed either successively by a single observer, or simultaneously by different observers, on to the distant object, and the convergence angle determined from the readings of the theodolites.

In later forms of this type the two telescopes were fixed rigidly to the ends of the base with their axes parallel to one another and at right angles to the base. In making an observation the image of the object was brought on to the fixed cross-wires of one telescope, by rotating the range-finder in azimuth, and then the displacement of the image from the axis in the second telescope was determined by an ocular micrometer, graduated, it might be, to give ranges. This marked a decided advance. In effect the object was brought into position along the axis of one telescope, and the range determined from the parallactic displacement of its image in the field of view of the other telescope.

The two-independent-telescope type, however, was open to manifest objections. When two observers were employed it was difficult to ensure that the same object was being ranged upon in each telescope, and ranging upon a moving object presented even greater difficulties. It was thus realised that the two telescopes employed should project their images into a single common eyepiece, so that the two images given by the two telescopes could be observed simultaneously by a single observer.

One of the earliest forms of coincidence, or

rather superposition range-finders, was that invented in 1775 by an optician named Magellan. In this apparatus, as shown by *Fig.* 1, sliding telescopic tubes *a* and *b* carry mirrors M′ and M at their outer ends, the latter mirror being fixed in front of a telescope L. Thus a distant object can be seen directly in the telescope L, and indirectly, after suc-

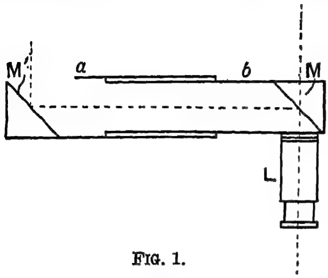

FIG. 1.

cessive reflection of the light by mirrors M′ and M. These mirrors are inclined at a small angle to one another so that within certain limits superposition of the image can be effected by adjustment of the base length. From this base length and the constant angle of convergence of the mirrors the range can be determined. A notable instrument of this type was also invented for military purposes by Brander, a description of which was published in 1781.

An interesting range-finder was that patented in 1858 by General Clark (see *Fig.* 2). In this instrument a single telescope only was employed. Light from the object fell simultane-

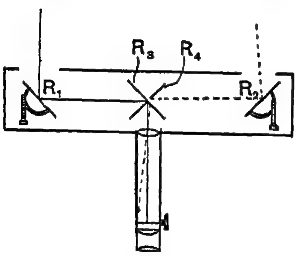

FIG. 2.

ously upon two end reflectors R_1 and R_2, from which the light passed to inclined reflectors R_3 and R_4 mounted in front of a telescope object-glass. Two pictures, displaced horizontally with respect to one another, were thus seen in the focal plane of the eyepiece. This horizontal displacement, which was a measure of the range, was measured directly by means of a micrometer screw.

It should be noted that Clark's instrument was not, strictly speaking, a coincidence range-finder, since the actual displacement of one picture with respect to the other was determined directly. It was, however, one of the earliest instruments of fixed base length which permitted of simultaneous observation by a single observer in a single eyepiece.

In 1860 Adie took out what would now be called a master patent for a short, constant base, coincidence range-finder. Up to this time coincidence, or superposition, had been secured by varying the base length ; or, the base length being fixed, the parallactic displacement in the ocular field had been measured directly. *Fig.* 3 is taken from Adie's specification. An outer tube *d* carries a telescope system consisting of an object-glass *b′*, prisms p^2 and p^3, and an eyepiece a^2. An inner tube *d′* pivoted at *c* carries a second telescope object-glass *a′* and prisms *p*, *p′*. Each of the telescopes therefore projects an image into the focal plane of the eyepiece a^2. When the inner tube is rotated about its pivot *c* by the operation of a micrometer d^2, the image produced by the telescopic system on the left is moved horizontally across the

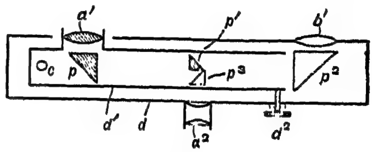

FIG. 3.

line of sight in the field of view, and can thus be superposed, or brought into coincidence with the image produced by the telescope on the right, and the range determined. With such a simple system of reflecting separating prisms, partial fields with a sharp dividing line cannot be obtained, a condition which has been shown to be essential to accurate work.

An interesting specimen of Adie's telemeter is to be seen in the Science Museum, South Kensington. It has a base length of 3 ft. The parallactic angles are read off directly, whilst reference to a table carried by the instrument gives the corresponding ranges from 100 to 2000 yards. The instrument was used on H.M.S. *Triton*, from 1885 to 1904, during the survey of the East Coast of England.

Very soon after the date of Adie's invention, the German optician Steinheil, and the French optician Tavernier, brought out coincidence range-finders in which the coincidence was brought about by a rotation of one of the end reflectors. Marindin as late as 1901 patented a range-finder in which coincidence was secured by a similar tilting of an end reflector.

In 1868 Paschwitz described a range-finder in which coincidence was obtained by swinging a plane-parallel plate in the beam passing along

one of the telescopes, that is in a convergent beam.

The pentagonal prism appears to have been first applied to range-finders by Colonel Goulier of the French Army about 1864.

In 1885 Mallock introduced a range-finder in which an optical square made up of two plane reflectors, inclined at 45° to one another, was used as an end reflector. Coincidence was brought about by tilting a reflector by means of a micrometer.

Finally, in 1888, Messrs. Barr & Stroud invented their well-known range-finder, which embodied in one instrument so many of the features which experience has shown to be essential for efficiency in a service instrument.

Thus far we have dealt with the history of the coincidence or monocular type of range-finder only. Quite early, however, as we shall see, it was recognised that a second type, depending upon the plastic character of binocular vision, was possible.

§ (2) STEREOSCOPIC RANGE-FINDERS.—In binocular free vision, objects can be relatively positioned in the line of sight with very considerable accuracy, but a limit is imposed by the fact that before an object can be stereoscopically resolved, or seen in relief, it must have a certain minimum dimension in the line of sight, a dimension which, according to Helmholtz, must subtend angles at the eyes of the observer, the sum of which is at least equal to one minute of arc. This limiting angle, it may at once be said, has been reduced to 20 seconds of arc, and even less, by later workers. The sum of these angles, it can easily be shown, measures the change in the convergence angle of the axes of the eye when directed first at the nearer, then at the more remote end of the object; thus, put in other words, the statement means that in order that two objects at different distances from an observer shall be seen as at different distances, the convergence angle of the axes of the eyes must change by at least 20″ in passing from one object to the other.

Now assuming an average inter-pupillary distance of $2\frac{1}{2}$ inches, the distance at which this inter-pupillary distance subtends an angle of 20″ is equal to $2\frac{1}{2}/\tan 20''$ inches, a distance of about 700 yards, whilst for an object at infinity the convergence angle is of course zero. Obviously, then, no two objects which occur in space outside a sphere with a radius of 700 yards can be stereoscopically resolved, *i.e.* the radius of the spherical stereoscopic field of free vision is about 700 yards. Nothing beyond that can be seen in relief as compared with an object even at an infinite distance. A point of light, for instance, beyond 700 yards away cannot be seen to be in relief against stars in the sky.

Accepting the principle of Helmholtz's limit, it is obvious that the greater the inter-pupillary distance of an observer, the greater must be the radius of his stereoscopic field of view. Herschel and Helmholtz, independently of one another, very ingeniously took advantage of this fact about the years 1855–58, and by optically magnifying the inter-pupillary distance of an observer, gave to him increased stereoscopic power. This was done by a reflecting system of four mirrors R_1, R_2, R_3, R_4 (*Fig.* 4). Light from a distant object point

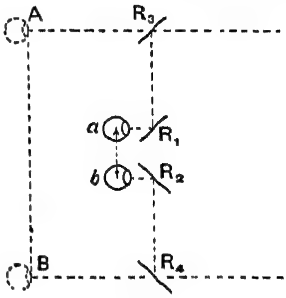

FIG. 4.

reaches the eyes respectively by successive reflections from the mirrors R_3 and R_1, and R_4 and R_2. The effect of this is that the inter-pupillary distance *ab* is optically magnified to the distance AB, with a corresponding increase in stereoscopic power. The limit of 20″ now becomes $(20 \times AB)/ab$ seconds. Herschel and Helmholtz both proposed, further, to combine the reflecting system shown with a binocular telescope, and thus obtain a further increase in the final convergence angle, and thus, it may be remarked, a further increase of the radius of the spherical stereoscopic field of view.

A remarkable reference to a stereoscopic range-finder occurs as early as 1738, in Smith's *A Compleat System of Optiks*.[1] The instrument and its use is described in the following words:

"Having opened the points of a pair of compasses, somewhat wider than the interval of the eyes, with your arm extended, hold the head, or joint, in the ball of your hand, with the points outwards, and equidistant from your eyes, and somewhat higher than the joint. Then fixing your eyes upon any remote object lying in the line that bisects the interval of the points, you will first perceive two pairs of compasses (each leg being doubled) with their inner legs crossing each other, not unlike the old shape of the letter W. [The old W referred to was like two V's slightly overlapping.] But by compressing the legs with your hands, the two inner points will come

[1] See *A Compleat System of Optiks*, vol. ii. p. 388.

nearer to each other, and when they unite (having stopped the compression) the two inner legs will also entirely coincide and bisect the angle under the outward ones, and will appear more vivid, thicker and longer than they do, so as to reach from your hand to the remotest object in view, even in the horizon itself, if the points be exactly coincident."

We have in the words quoted a very complete and interesting anticipation of what we shall subsequently refer to as the "wandering-mark" type of stereoscopic range-finder. It is, however, to Hector Alexander de Grousilliers, who took out a patent in 1893 for an "Improved Stereoscopic Telemeter," that the modern instrument is due. The specification in question is a remarkable document. It sets out the theory of the instrument in the following words:

"Assuming A_1A_2 to be points at which, in both fields of view, an infinitely distant object A is depicted, and N_1N_2 to be the points at which is depicted an object N, situated at a finite distance E from the observer; the difference between the linear distances A_2, N_2 and A_1, N_1, *i.e.* the parallactic difference between the image of the one object, situated at an infinite distance, and the other object, placed at the finite distance E, will be

$$A_2N_2 - A_1N_1 = \delta = \frac{\Delta}{E} \cdot f,$$

f being the equivalent focal length of the telescope-lenses, and Δ the distance between their respective axes.

"In the case of two objects N and N′, both of which are located at finite distances E, E′ from the observer, the parallactic difference in the two images will consequently be

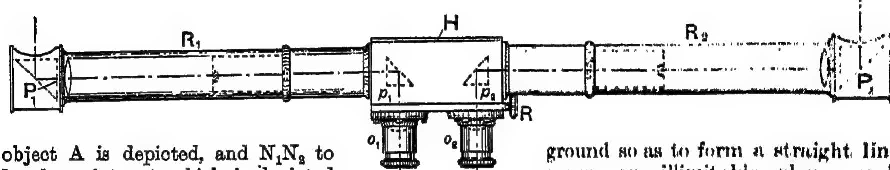
$$N_2N_2' - N_1N_1' = \left(\frac{1}{E} - \frac{1}{E'}\right)\Delta \cdot f."$$

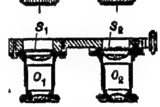
Finally Grousilliers describes and claims three types of the range-finder, namely: (1) the *fixed scale*, in which each eyepiece has a fixed scale, which bears for each range a range mark corresponding to a similar mark on a similar scale in the other eyepiece; (2) the *wandering-mark*, in which a single fixed mark occurs in one eyepiece, and a similar mark, but capable of micrometric displacement in the plane of the instrument and across the line of sight, in the other; and (3) what may be called the *wandering-picture* type, in which one of the images, or pictures, of the object may be displaced in a similar way to the wandering-mark in the second type, to bring the stereoscopic image of the object into the same plane as that of the stereoscopic image of two fixed marks, one in each eyepiece.

In effect, in the first type, when a range is taken, the pair of corresponding scale marks is selected which has the same inter-eyepiece separation as the two images of the object point under observation. In the second type, the wandering-mark is adjusted to obtain this equality of separation; whilst in the third type, one of the pictures is traversed across the line of sight until the separation of the two images of the object point is made equal to the fixed separation of the two range marks.

The fixed scales required in the first type of range-finder might be produced in the following way:

Let a number of pegs be driven into the ground so as to form a straight line across an illimitable plane, and, further, let each peg be marked with its distance from a certain place. Now suppose that from this place a pair of stereoscopic photographs of these pegs are taken with a binocular prismatic telescope, from which the oculars have been removed, to allow of photographic plates being fixed in the two focal planes of the objectives. Those photographs, after development, could be returned to the binocular telescope so as to occupy the positions that they did during the taking of the photograph. In the field of a binocular, equipped with scales produced in this way, and directed to a distant landscape, that landscape would be seen in stereoscopic relief in the usual way, and passing through it, or over it, would be seen, also in relief, a distance scale, to a position along which any object might be assigned and its distance thus determined. Stereoscopic scales are not, as a matter of fact, usually prepared in this way. It is more convenient to calculate and rule them.





FIGS. 5 and 6.

Figs. 5 and 6 are taken from Grousilliers' specification. Two broken telescopic systems are mounted in tubes R_1 and R_2, secured collinearly to the ends of a box-like casing H. End reflectors P_1 and P_2 deflect the light along the axes of these telescopes, whilst reflectors p_1, p_2 reflect the beams outwards parallel to one another, through eyepieces o_1 and o_2, in the focal planes of which stereoscopic

scales s_1 and s_2 are mounted, the one on the right being movable by means of a micrometer R, to effect the necessary adjustment and thus determine the range. Since the telescopes are provided with ordinary erecting systems the reflections by P_1, p_1 cancel one another, with the result that the images are seen erect.

Grousilliers' claim for the fixed-scale modification is as follows:

"An improved telemeter, consisting of a double telescope (which term includes telestereoscopes with an enlarged distance between the object-glasses) within the ocular fields of which scales are so arranged that, when viewed binocularly, they present the image of a series of distance marks extending downwards and situated at predetermined distances from the observer: the image of such series of marks being projected into the image or panorama of a landscape, as seen through the double telescope, so that the distance of any object viewed may be immediately read off the scale according to the point between any two marks of such scale to which the object can be made to correspond with regard to the visual depth."

§ (3) Theory of the Short Home-base Range-finder.—The theory of the range-finder is based upon a method—well known to schoolboys—for finding the distance of an inaccessible object.

Let A, *Figs.* 7 and 8, be the object, and let a rectangle BDEC, with sides of length b and f,

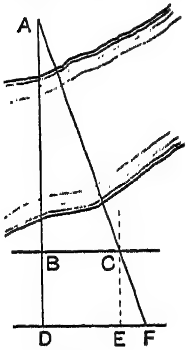


Fig. 7.

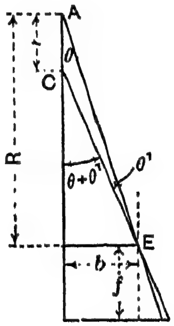

Fig. 8.

be so positioned that the object A is seen along the lines DB and FC, F being in line with C and A. With the object A at an infinite distance, it would be sighted along the two parallel lines DB and EC. The length EF, equal to d, say, is therefore the parallactic displacement along the line DE of the intersection of the line of sight CA, whilst BAC is the corresponding parallactic angle, *i.e.* the angle subtended at the object point A by the base b.

Now, since the triangles ABC and CEF are similar, it follows that R, the range, equal to BA, is to b as f is to d, that is, the distance of the object A is equal to the product bf, divided by the parallactic displacement. This is the fundamental equation for both coincidence and stereoscopic range-finders:

$$R = \frac{bf}{d}.$$

In the case of both these range-finders, b represents the optical base length of the instruments, f the focal length of each of the two telescope objectives, R the range, and d the parallactic displacement in the common focal plane of the two objectives when the range-finder scale is set to infinity. The accuracy of the range-finder then depends fundamentally upon the accuracy with which the parallactic displacement d can be measured, and this in the limit depends on the eye.

§ (4) The Accuracy of Range-finding as determined by the Eye. (i.) *Coincidence Type.*—In this type the accuracy of the results depends upon the aligning power of the eye, as exemplified, for example, in the setting and reading of a vernier. In the case of the range-finder, this aligning takes place usually across a sharp horizontal line, which divides the field of view into two parts. A flagstaff, for instance, that is being ranged upon, is seen with its top part, carrying the flag, displaced laterally with respect to the bottom. In adjusting for coincidence these parts are brought into alignment, so that the accuracy with which this operation can be done determines the accuracy of the range, other things being equal. The important question then is—given two collinear straight lines in the field of view, through what angle a can one be moved laterally with respect to the other before the fact that they are no longer collinear is detected by the eye? For practical range-finding purposes this angle has been taken as equal to about 12 seconds of arc in free vision, and the same, therefore, in the image-space, or final field of view presented by a range-finder. There is no doubt, however, that under favourable conditions many trained observers can work down to an angle of the order of 5 or 6 seconds of arc. Further, on artificial objects such as lines drawn on silvered glass plates placed in the focal planes of collimators, higher accuracy even than this can be obtained — 2 to 3 seconds of arc. Now let θ' (*Fig.* 8) represent in actual space—the object-space—the angle corresponding to a in the image-space, then an object accurately ranged upon in the position A may move up through a distance r, subtending the angle θ', at the range-finder,[1] until the angular parallactic

[1] For the purpose of simplifying the diagrams we have supposed the object to move up along the axis of one of the telescopes.

displacement in the field of view is equal to α, before an object at C can be differentiated, with respect to its distance, from an object at A. The possible error under these circumstances in ranging upon an object at A is equal to the distance r, and it may obviously occur in either direction.

(ii.) *Stereoscopic Type.*—In this case the following considerations apply: If two pins be stuck into a table close together, and at the same distance from an observer, then one pin can be moved backwards and forwards in the line of sight through a certain distance before the observer can see with certainty that they are no longer at the same distance away; that is, a certain change in the angle of convergence of the optic axes of the eyes is necessary in order that two objects can be seen to be at different distances. Helmholtz, as mentioned above, made a number of experiments in this way and came to the conclusion that in free vision a difference between the convergence angles of one minute of arc was the least difference necessary for differentiation of distance in the line of sight. Later workers have, however, reduced this limit to something of the same order as that claimed for the coincidence range-finder. We shall revert to the question later.

(iii.) *Coincidence and Stereoscopic Types.*—We will assume, therefore, that the possible error angle α represents (i.) in the case of the coincidence range finder, the greatest angular parallactic displacement in the field of view which can occur without loss of coincidence being detected; whereas (ii.) in the case of the stereoscopic range-finder, it represents the maximum difference of the convergence angles in the field of view which can occur without apparent change of the range of the object under observation.

§ (5) FUNDAMENTAL RANGE-FINDING EQUATIONS.—In *Fig.* 8 the range-finder with base length b subtends at the object A the angle θ. Whilst the range changes by a length r, the angle of parallax changes by an angle θ'. To find the relationship between these changes, the angles θ and θ' being expressed in circular measure. Now

$$\theta=\frac{b}{R}, \quad . \quad . \quad . \quad . \quad . \quad (1)$$

and since in any triangle the sides are proportional to the sines of the opposite angles, and in the triangle ACE the angles θ and θ' are small, we have

$$\frac{CA}{CE}=\frac{\theta'}{\theta},$$

and since CA $=r$ and CE (very nearly) $=$R,

$$\frac{r}{R}=\frac{\theta'}{\theta}. \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Substituting the value of θ from (1),

$$r=\frac{R^2\theta'}{b}. \quad . \quad . \quad . \quad . \quad . \quad (3)$$

Let P_e be the percentage error for a given range R, then

$$P_e=\frac{100r}{R},$$

and substituting the value of r from (3),

$$P_e=\frac{100R\theta'}{b}. \quad . \quad . \quad . \quad . \quad (4)$$

Let α be the error angle, as set out above, for both the coincidence and the stereoscopic types of range-finders, and M the magnifying power of the telescopic systems employed; then, in the case of the coincidence range-finder (see *Fig.* 8), it is evident that the length AC, in the object-space, subtending an angle θ', at the window of the range-finder, will appear to the observer, *i.e.* in the image-space, under an angle $M\theta'$; whilst in the case of the stereoscopic range-finder, the angles of convergence in the object-space, which are θ for the point A, and $\theta+\theta'$ for the point C, become $M\theta$ and $M(\theta+\theta')$ respectively, in the image-space, so that the change in the convergence angles is equal to $M\theta'$. Thus for both types,

$$\theta'=\frac{\alpha}{M}.$$

Substituting in (3) and (4), we obtain

$$r=\frac{R^2\alpha}{bM}, \quad . \quad . \quad . \quad . \quad . \quad (5)$$

and

$$P_e=\frac{100R\alpha}{bM}. \quad . \quad . \quad . \quad . \quad . \quad (6)$$

Thus, α, b, and M being constants, the percentage error varies directly as the range.

To express θ' in (3) in seconds of arc, instead of in circular measure,

$$\theta^1=\frac{br}{R^2}206000. \quad . \quad . \quad . \quad . \quad (7)$$

Assuming a value for α of 12 seconds of arc, as is usually done, equation (6) enables us to formulate a very useful rule, namely, that

"The percentage error of any range-finder at one thousand yards is equal to 6 divided by the bM value," since

$$P_e=\frac{100\times 1000\times\cdot 00006}{bM}$$

$$=\frac{6}{bM}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

b being expressed in yards.

The corresponding error in range r is obtained from

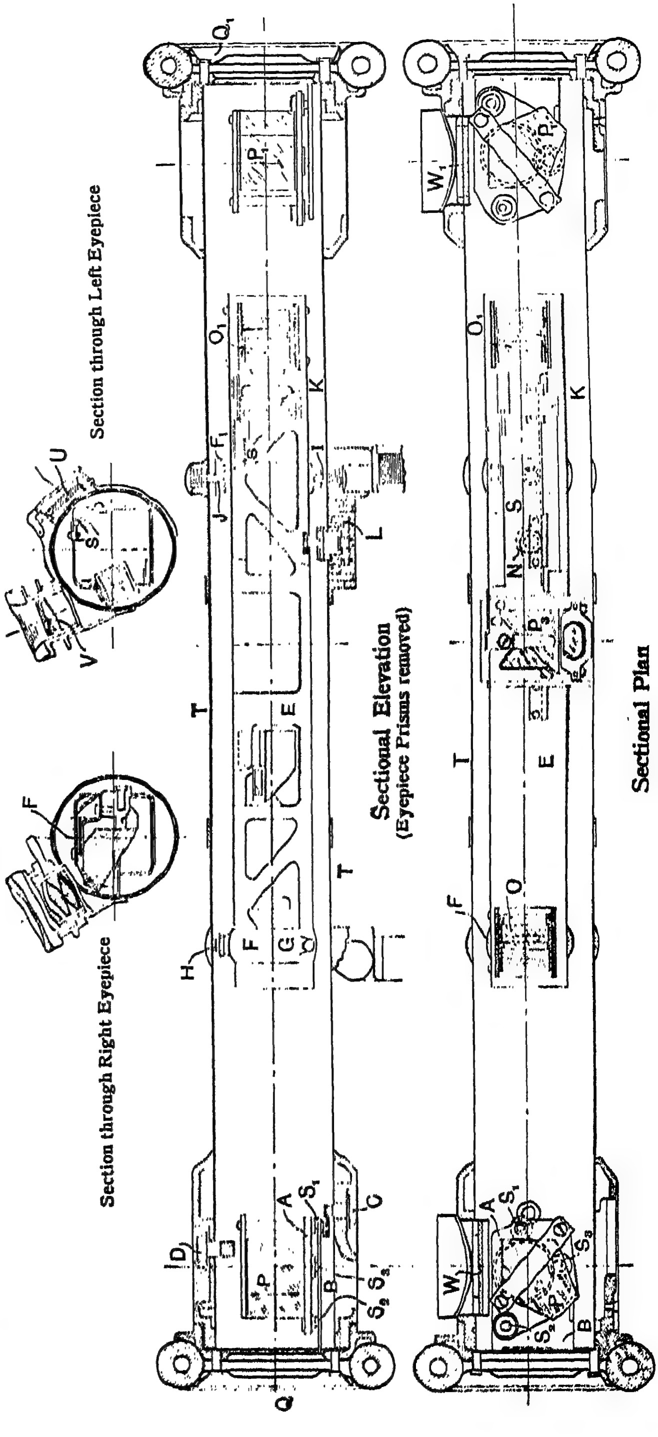
$$r=\frac{6\times 10}{bM}. \quad . \quad . \quad . \quad . \quad . \quad (9)$$

Knowing the range error r for 1000 yards, it follows from equation (5) that the range error for any other range R_t, expressed in thousands of yards, is equal to rR_t^2. Thus the error at 1000 yards being 5 yards, that at 10,000 yards would be 500 yards.

A word of caution is, perhaps, necessary here. The numeral in equation (8) assumes a value of 12 sec. for the angle α; but, in the opinion of many experts, this angle is in practice considerably greater for the stereoscopic than for the coincidence range-finder, and equation (6) shows that the percentage error for a given range-finder and a given range varies directly as the angle α.

I. Details of Construction

§ (6) General Construction of Coincidence Range-finders. (i.) *Barr & Stroud's Range-finder.*—*Figs.* 9 and 10 show in sectional elevation and plan respectively a small Barr & Stroud coincidence range-finder with a base length of 50 cm., a magnification of 7½ times, and scale for ranges from 350 to 1500 yards. The optical system, and the principal features of the mechanical design shown, are practically identical with those adopted in instruments of much greater power. The instrument consists of an outer cylindrical tube T, with end fittings carrying the windows W and W_1, and end caps Q, Q_1 carrying the supporting plates for the prisms P and P_1. The inner tube E, of rectangular cross-section, carries the objectives O, O_1 and the separating prism P_3, which deflects the light entering by



Section through Left Eyepiece

Section through Right Eyepiece

Sectional Elevation (Eyepiece Prisms removed)

Sectional Plan

Figs. 9 and 10.

the objectives O and O_1 to a common focal plane, in which the coincidence is secured by observation through the single eyepiece. The deflecting prism K slides backwards and forwards in the tube E between the O.G. O_1 and the separating prism P_3, to give a variable lateral displacement to the corresponding image, and thus effect coincidence under the action of a finger button L. The range-scale S is attached to the mount of the prism K, and slides in guides carried by the inner tube. The scale is observed through an eyepiece V and a system of reflecting prisms as shown. U is a condenser by means of which the scale is illuminated from the back.

It is important that any strain of the outer tube T should not be communicated to the inner tube E. To secure this end the tube E is fitted with rings F and F_1, the former of which carries, at approximately 60° apart, two fixed radial pins G and a spring pin H, engaging with the inner surface of the outer tube. By this arrangement the tube is left free to move longitudinally whilst secured co-axially with the outer tube. The second ring F_1 carries on its lower side a cup, which engages with a stud I, whilst the upper part of the rim carries a longitudinal slot, which engages with the stud J. The stud I prevents longitudinal displacement of the tube E, whilst the stud J prevents any lateral displacement of the axis of the tube E.

The adjustment of the range-scale for an object at infinity is obtained by rotating in its own plane the window W, which is in the form of a weak refracting prism with its refracting edge horizontal, by means of a finger pinion D. The prism P is clamped to a plate A, secured to the base-plate B, carried by the end-cap Q, by screws S_2 and S_3, which permit of a rocking motion of the plate A and prism P with respect to the plate B, about an axis passing through the points S_2 and S_3. The forward part of this plate A can be raised and lowered by means of a screw S_1 operated by means of a finger pinion C, to raise and lower the image in the corresponding partial field of view and thus effect the "halving" adjustment. This adjustment secures, when coincidence has been effected, that the image on one side of the separating line is a complete reflected image of that on the other, or, in the case of a circular object, like the moon, that the image is single and circular.

(ii.) *Cooke & Sons' Range-finder.* — Mr. Dennis Taylor, of Messrs. Cooke & Sons, has done a large amount of work in the development of a type of range-finder which differs from that already described in several important particulars.

Fig. 11 shows a section of one of the modifications of this range-finder as originally patented in 1904. Two optical squares of the pentagonal type are mounted in a tube T′, at a distance apart which determines the base length of the instrument. At one end of this tube a telescope of the ordinary terrestrial type

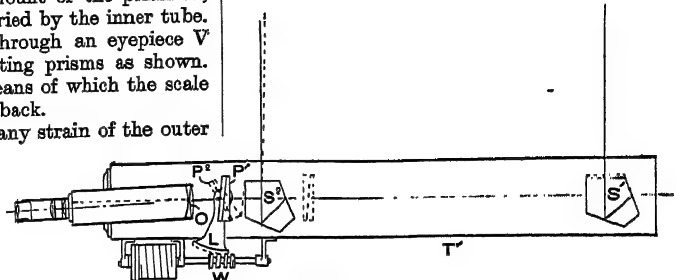


FIG. 11.

is shown. The optical squares are mounted on different levels, so that the light rays from a distant object, passing into the instrument by the reflector S′, enter the upper half of the telescope object-glass O only, whilst light entering by the reflector S² enters the telescope by the lower half of the O.G. In this way, in the example shown, two pictures are projected simultaneously into the focal plane of the eyepiece, which overlap to an extent depending upon the adjustment of the instrument and the distance of the object. The squares being angle-true and adjusted parallel to one another, the images of an object at infinity would overlap and coincide, whereas under the same conditions an object at a short distance would give two images, the separation being dependent upon the range. To bring about coincidence of the two images given in general, two weak achromatic prisms P′ and P² are employed, the first P′ being fixed in position to give minimum deviation to the rays passing through it from the square; whilst the second prism P² is adapted to rotate as shown about an axis parallel to its refracting edge by means of a sector L and worm W. The light reflected by the square S′ passes through the prism P′, and the light reflected by the square S² passes through the prism P². In use, therefore, the worm W, which carries co-axially the range drum D, is rotated to swing the prism P² through the angle necessary to secure coincidence of the two images in the field of view. Thus the range is determined and indicated on the drum D directly.

As an indication of the sensitiveness of this swinging prism micrometer, it may be stated that a prism producing a minimum deviation of 2° has to be swung through an angle of

about 30°, to increase the deviation by 15 minutes of arc. One important advantage claimed for the swinging prism over the sliding prism is that it gives a much more open scale for long ranges. It must, however, be mounted in a parallel beam: in a vergent beam it spoils the definition.

In a later modification of the Cooke 9 ft. naval range-finder, patented in 1920, several features of novelty are introduced. The end optical squares reflect in opposite directions, on to superposed cross mirrors mounted near the middle of the range-finder, from which mirrors the light beams pass, parallel to their original direction, to a single mirror, mounted to direct both beams into a single telescope, which is inclined at an angle of 45° to the axis of the range-finder, but broken by an erecting prism system, which finally directs the light to the eyepiece in such a direction that the observer looks in the direction of the object being ranged upon.

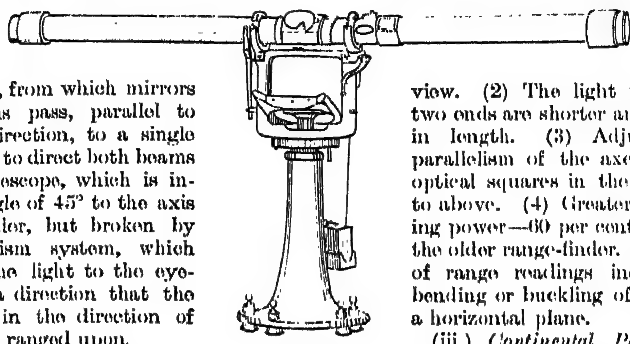

FIG. 12.

Two simultaneously operated swinging coincidence prisms are employed, one behind each of the optical squares. To prevent the intrusion of light from one partial field of view to the other, an ingenious "halving grid" is employed. This consists of a number of stretched threads or cords mounted side by side in a plane containing the axis of the telescope, each thread being at right angles to that axis. This grid practically extends from the object-glass to the eyepiece, thus dividing the telescope into upper and lower halves. To obviate the serious and unsuspected errors which may arise from the fact that the axes (virtual meeting edges) of the end squares are not parallel to one another, and normal to the plane of triangulation, an auto-collimating telescope is mounted within reach of the observer, by means of which a beam of light from a fiducial mark in the eyepiece can be directed to one of the optical squares, by which it is reflected back again to the telescope. Should the axis of the square not be normal, the image of the fiducial mark is seen displaced with respect to the fiducial mark itself. The necessary adjustment having been made, parallelism of the axes is effected simultaneously with any necessary adjustment for halving.

Several advantages are claimed for this modification, as compared with the 1904 range-finder:

(1) Coincidence of the images can be obtained for all ranges across the field of view. (2) The light paths for the two ends are shorter and more equal in length. (3) Adjustments for parallelism of the axes of the two optical squares in the way referred to above. (4) Greater light-gathering power—60 per cent greater than the older range-finder. (5) Accuracy of range readings independent of bending or buckling of the tubes in a horizontal plane.

(iii.) *Continental Patterns.*—The coincidence range-finders as made on the Continent, by Zeiss and others, do not vary substantially in general design from those made in England. A variable-power deflecting prism, mounted in a parallel beam of light, is, however, usually substituted for the travelling prism of the English range-finder, although the latter too is employed.

FIG. 13.

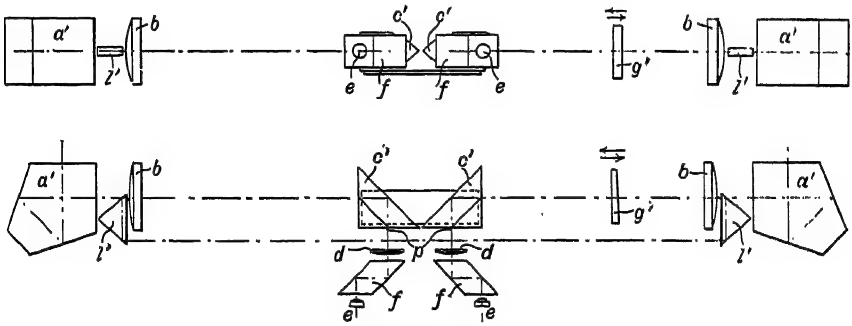
(iv.) *Modern Barr & Stroud Pattern.*—*Fig.* 12 shows the Barr & Stroud 9 ft. base naval range-finder with which the British Fleet was equipped at the battle of Jutland. The range-finder itself, fitted with bearing rings, is adapted to rotate about its own axis in bearings carried by the upper ends of the "Y," which is free to rotate about a vertical axis under the action of a hand-wheel. Adjustment in altitude is effected by means of a radial handle seen on the left of the support.

Finally, *Fig.* 13 represents a monster coincidence range-finder of 100 ft. base which has been constructed by Messrs. Barr & Stroud

for purposes of coast defence. Optically the instrument is practically identical with that of smaller base length. For the purpose of comparison the man in the centre of the figure is shown using the smallest range-finder with a base length of 30 in.

§ (7) Stereoscopic Range-finders, General Construction of.—*Figs.* 14 and 15 show diagrammatically, in plan and elevation respectively, the optical system of a typical stereoscopic range-finder, invented by Carl Zeiss in 1907. The end squares *a′* direct light through telescope object-glasses *b* to right-angled roof prisms *c′*, which deflect the light into the focal plane of the object-glasses, in which two fixed stereoscopic marks *p* occur. These marks are in the focal plane of eyepieces, each of which consists of a pair of lenses *d* and *e*, between which a rhomboidal prism *f* occurs. A ray passing outwards through the eyepiece, left ocular. The image thus produced should superpose on the real mark. It will be noticed that, in this adjusting arrangement, each objective acts as a collimator for its corresponding stereoscopic mark. In operation, therefore, the light from one of the marks is collimated by its corresponding object-glass, from which it passes as a parallel beam to the second object-glass to be brought to a focus in the focal plane of the other mark. These adjusting arrangements will be found dealt with more fully below.

(i.) *Forbes Range-finder.*—One of the pioneers of the stereoscopic range-finder in this country was Professor George Forbes. In 1901 he patented a range-finder constructed of two separate parts, namely, a portable base having a set of reflectors rigidly fixed to it at each end, and a binocular field-glass. In the approved form of the instrument the wander-



Figs. 14 and 15.

therefore, suffers reflections as shown by the surfaces of this rhomboidal prism, with the result that a lateral displacement of the ray occurs. By simultaneous rotation in opposite directions, therefore, of the eyepieces about the axes of the lenses *d*, the separation of the two eye lenses *e* can be adjusted to suit individual observers. It will be noted that this adjustment is secured without any alteration of the distance between the two stereoscopic marks *p*.

In this instrument, which is of the wandering-mark type, the necessary lateral displacement of the picture produced by the right telescope is effected by the axial displacement of a prism *g′*. To detect readily any defect in the infinity adjustment, a subsidiary optical system is employed to project an image of each of the marks *d* into the plane of the other one. Light, say from the mark *p* on the right, is reflected by the prism *c′* to the object-glass *b*, thence by reflection by a prism *l′*, on the right, to a similar prism *l′*, on the left, and finally through the object-glass *b*, on the left, to the prism *c′*, and thence to the mark *d* in the ing-mark was adopted, namely, a fixed line in one eyepiece combining stereoscopically with a similar line in the other eyepiece traversed laterally by means of a micrometer. The marks employed were "pictures of ordinary objects such as a balloon as shown, the ends of the trailing ropes marking the centres of the field." An important advantage was obtained by the use of this balloon mark. The observer naturally brought it over the object being ranged upon, and thus in many cases avoided the psychological difficulty, which so often occurs in stereoscopic range-finding, of being compelled to see the scale, as if behind an object, such as a brick wall, known to be opaque.

In a second specification, taken out in 1903, fixed marks are employed in the focal planes of the eyepieces, and one of the pictures is displaced laterally with respect to the other one, by means of a rotating prism, to bring up the stereoscopic picture into the same plane as that of the image of the two fixed marks. This type, however, as we have seen, was described by Grousilliers.

(ii.) *Zeiss Submarine Range-finder.* — The 3-metre base stereoscopic range-finder made by Carl Zeiss for use in submarines probably represents the highest development of this type of instrument. The range-finder *per se* is contained in a horizontal tube, which forms the horizontal branch of a "T," the vertical branch of which represents a periscope passing into the interior of the boat through the deck. The two pictures of external objects are projected upon stereoscopic graticules, mounted close together and parallel to one another, transverse to the axis of the range-finder, and near its middle. The images in the planes of these graticules, and the range marks, are projected by means of a binocular periscopic system into the focal planes of a pair of oculars at the lower end of the vertical tube. The optical system employed for the range-finder is comparatively simple in character. Light enters by the windows and is reflected along the tube in opposite directions by the usual optical squares, each beam being brought to a focus in the plane of its corresponding graticule by a long focus lens of the telescope object-glass type. These graticules are fixed after being adjusted, and the final stereoscopic picture itself is caused to "wander," *i.e.* move backwards and forwards in the line of sight, for ranging. In one half of the tube a weak refracting prism is mounted to slide backwards and forwards, along the axis of the tube, between the object-glass and the graticule, for the purpose of displacing laterally the image seen in the corresponding ocular, for the purpose of bringing about that adjustment, or wandering of the stereoscopic image in the line of sight, necessary to bring it up to the fiducial mark—the crossing point of the two linear stereoscopic scales. In the other half of the range-finder, a plane-parallel plate is mounted between the object-glass and the graticule, as so to tilt about a horizontal and transverse axis, for the purpose of raising and lowering the picture in the corresponding ocular, to bring it to the same vertical height as the picture with which it has to be stereoscopically fused.

Direct observation of the graticules being impossible, the range-finder is combined with a binocular periscopic system, with the aid of which the graticules can be observed from a position inside the submarine. For this purpose a pair of optical squares are mounted between the two graticules to face in opposite directions and deflect the beams of light passing through the graticules at right angles to the range-finder, and in a horizontal plane, each beam being again reflected vertically downwards, through a collimating lens, and into a telescope by which, finally, an image of the corresponding graticule is presented to the observer. This periscopic system is duplicated for the second half of the range-finder.

§ (8) Height-finders.—In the early days of the war the need for a height-finder as an auxiliary to anti-aircraft guns was recognised. Many tentative solutions of the problem were proposed from time to time, but the final solution, resulting in the provision of an efficient short-base service instrument, was due to Messrs. Barr & Stroud in 1917.

In ranging on an aeroplane, a horizontal range-finder is rotated about its axis to elevate the line of sight and bring the aeroplane into the field of view. Coincidence is then effected and the range determined. It will be observed that in this operation we have got the two necessary elements for solving the right-angle triangle defined by the observer, the target (aeroplane), and a point on the ground immediately below the target. The range gives the hypothenuse of this triangle, and the angle of elevation, or sight, one of the acute angles. With these two elements, it is a simple slide-rule problem to determine either the height of the aeroplane above the ground, or its horizontal range, that is, the distance from the observer to the bottom of the perpendicular dropped from the aeroplane. This was the principle upon which some of the first height-finders were constructed. One of the scales of the range-finder was operated more or less automatically by the motion in altitude of the range-finder, to set off the logarithm of the sine of the angle of sight, and then, by a hand-setting of the range, the equation, log H = log R + log sine angle, was solved and the height H determined. All these arrangements, however, gave the range primarily, so that so long as the range of the target was altering constant adjustment of the working head was necessary. What was wanted was an instrument the constant-coincidence surface of which was not a hemisphere, as in the range-finder, but a horizontal plane—a height-finder.

(i.) *Barr & Stroud.*—In Barr & Stroud's specifications the invention described gives both range and height automatically. It consists of a known range-finder of the coincidence type so modified as to function also as a height-finder. This in effect is carried out by fitting the range-finder with an automatically operated slide rule. The two sliding parts are constrained to move, one proportionately to the logarithm of the range, and the other proportionately to the logarithm of the sine of the angle of sight. The height can thus be read off directly. The motion of the adjusting head of the range-finder and the elevation of the range-finder are transmitted to the sliding scales through the medium of logarithmic toothed gearing.

The working head is transferred from the range-finder to the height-indicating attach-

ment, so that the instrument acts primarily as a height-finder. No manipulation of the working head, therefore, is necessary, so long as the target under observation retains its height.

Fig. 16 shows the range-finder, with a base length of two metres, mounted on a tripod

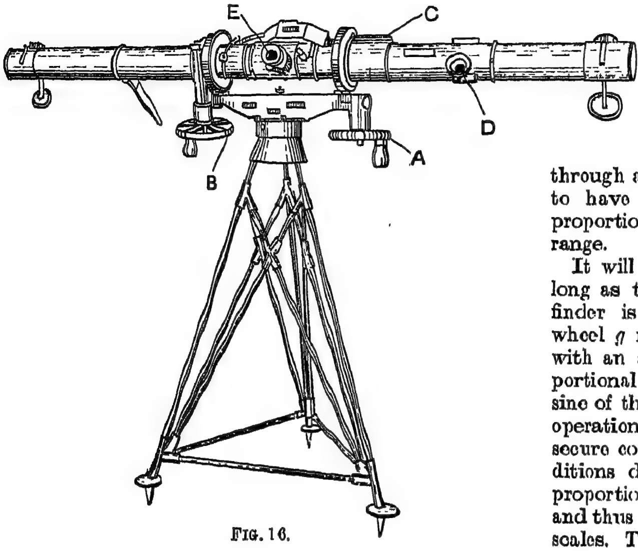


FIG. 16.

stand, upon which it is rotated about a vertical axis by the operation of a two-speed hand-wheel A. The operation of a second hand-wheel B rotates the range-finder about its own axis to elevate the line of sight. Coincidence is maintained by the working head C, whilst D is a finder.

Three observers are required: the first looks into the eyepiece E and operates, as required for the maintenance of coincidence, the working head C, and the hand-wheel B to direct the line of sight in altitude. The second observer uses the finder D and is responsible for the training of the range-finder by means of the hand-wheel A. The third observer reads off the height- and range-scales.

The instrument is essentially a range-finder with a gearing attachment, as shown by *Fig.* 17, which automatically, as the target is kept in the field of view and coincidence maintained, indicates the height and range. The end of the shaft of the working head *a* carries a pinion *e*, which gears with a bevel-wheel *f*, carrying the height-scale, and also—on a radial shaft—the jockey wheel *d*, which gears with the upper and lower members of a differential pair of spur wheels *g* and *h*. The upper member *g* of this pair is driven directly from the elevating head *b*, through logarithmic spiral gear which gives to *g* an angular displacement proportional to the logarithm of the sine of the angle of sight. The lower member *h* of the differential pair carries the range-scale, and is geared up to the deflecting range-prism through a clutch, not shown, so as to have an angular displacement proportional to the logarithm of the range.

It will be seen, then, that so long as the elevation of the range-finder is not changed the upper wheel *g* remains fixed in a position with an angular displacement proportional to the logarithm of the sine of the angle of elevation. The operation of the working head, to secure coincidence, under these conditions drives simultaneously and proportionately the wheels *f* and *h*, and thus also the height- and range-scales. These conditions are realised by ranging on a target flying away from the observer along a straight line. With the working head fixed, the elevation of the instrument operates the upper wheel *g*, and also, through the jockey wheel *d*, the lower wheel *h*, and thus the deflecting prism and

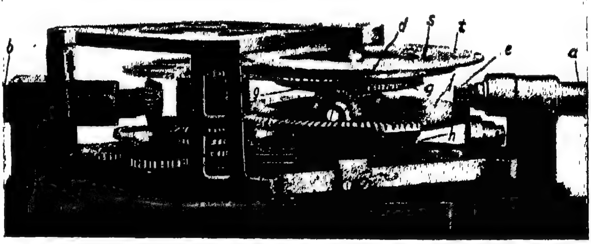

FIG. 17.

the range-scale. Since, however, the wheel *f* remains fixed, the height-scale is unaffected. This represents the conditions of use when the target ranged upon is moving about in a horizontal plane.

(ii.) *Rottenburg and Willan.*—An ingenious optical solution of the height-finder problem was patented by Rottenburg and Willan in 1916. By this invention a second prism is combined with the deflecting prism, and the

two prisms rotated equally and oppositely, about the axis of the instrument, by the adjustment of the instrument in altitude necessary to keep a target in the field of view. The result of this arrangement is that whereas, in the ordinary Barr & Stroud range-finder, a simple deflecting prism of constant power is employed, in Rottenburg and Willan's invention a variable-power coincidence prism is employed, the power of which is such a function of the elevation, or angle of sight, that the instrument is adapted to operate as a height-finder; no operation of the working head being necessary so long as the target remains at the same height.

II. Optical Elements of the Range-finder

§ (9) End Reflectors: Optical Squares.—In the early days of the range-finder, plane-reflectors, or right-angle total-reflecting prisms, were employed as end reflectors, but these forms were open to the serious objection that any bending of the frame of the range-finder in a horizontal plane, due to unequal heating, for instance, caused these end reflectors to turn in effect about a vertical axis and thus alter the angle through which the rays were deflected; and it was not until these reflectors were replaced by optical squares that the difficulty was overcome.

When a ray of light is reflected in succession by a pair of plane reflecting surfaces, as in the case of the sextant, the angle through which the ray is deviated is equal to twice the angle included between the reflectors, so long as the reflections take place in a plane at right angles to the meeting edge of the reflectors. If then these reflectors are inclined at an angle of 45° to one another, the deviation produced by successive reflections is equal to a right angle, and we have an optical square; that is, an optical device which gives us an angle of deviation which is independent of the angle at which the entering ray strikes the first reflecting surface. The end reflectors of small range-finders are now, almost invariably, optical squares made from a single pentagonal-shaped block of glass. In use, any given ray passes through the entrance face practically normally, and after internal reflections at the two bounding surfaces meeting at an angle of 45°, passes through the exit face, again practically normally, with a deviation of a right angle which is independent of any small rotational displacement of the prism in its own plane. The conditions of accuracy for such a square are (1) homogeneous glass; (2) reflecting surfaces inclined at an angle of 45°; and (3) plane entrance and exit faces, meeting under an angle of 90° in an edge parallel to the meeting edge of the two reflecting surfaces.

Such squares in large sizes become impracticable, mainly on account of the loss of light incurred by absorption, so that considerable attention has been devoted of late years to the designing of optical squares comprising two plane reflectors, the included angle of which shall be maintained with great accuracy, in spite of bending stresses and temperature changes. Mr. Dennis Taylor has paid particular attention to this subject, as will be seen by reference to his various patents.

§ (10) Deflecting Systems for Coincidence Range-finders.—The following optical micrometrical devices for effecting coincidence have been used, but the first three are now those commonly employed:

(*a*) A longitudinally travelling prism in a convergent beam, *i.e.* between the telescope O.G. and the separating prism (Barr & Stroud and others).

(*b*) A tilting prism in a parallel beam (Taylor).

(*c*) Oppositely rotating prisms in a parallel beam, acting as a variable-power prism (Zeiss).

(*d*) Rotary end reflectors.

(*e*) Laterally displaced object-glasses.

(*f*) A tilting plane-parallel plate of glass in a convergent beam.

(*g*) Differently magnified images brought into coincidence by the rotation of the range-finder about a vertical axis (Eppenstein).

The first of these systems has the great merit of simplicity, and less liability, therefore, to derangement. The prism itself, as has already been pointed out, carries an ivory scale some seven or eight inches in length, graduated in ranges which are read off opposite a special eyepiece provided for the purpose. In the second system the advantage of a more open scale at long ranges is secured. In the third system two weak prisms are mounted, face to face, between the end squares and the O.G.'s, so as to rotate equally and oppositely. In this way a variable deflecting prism is obtained which produces deflections in a horizontal plane only. This system is open to the defect that the maximum deflecting power of the combination is obtained by a rotation through 180 degrees only, of the prisms. This difficulty has been, to some extent, overcome in the Zeiss range-finder by the introduction of a multiplying system of gear wheels, which gives to a circular range-scale an angular displacement practically twice that of the deflecting prisms.

In the ordinary coincidence range-finder it is important that the two images brought into coincidence should be magnified equally, otherwise different range-readings will be obtained according as the coincidence happens to be made near the middle or towards the ends of the separating line in the field of view.

In a new type of range-finder, introduced

within the last few years by the firm of Zeiss, and invented by Eppenstein, the two images are differently magnified; so that as the range-finder is rotated about a vertical axis, the more magnified image moves more rapidly across the field of view than the less magnified image does—starting behind it, it may be, catching it up, and then passing it. From this it follows that for every range between infinity and the minimum range required, there is one place, and one place only, along the separating line in the field of view, at which coincidence of the two images can occur. A range-scale is therefore drawn along the separating line, extending from infinity on the left to the minimum range required on the right. In ranging on an object, therefore, no adjustment is required beyond that of rotating the range-finder about the vertical axis until the two images of the object being ranged upon are seen to be in coincidence.[1]

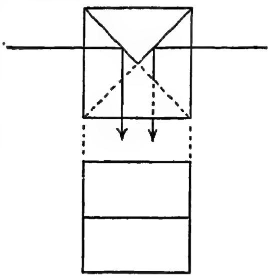

FIG. 18.

§ (11) ASTIGMATISERS.—When the object being ranged upon is ill-defined and illuminated in patches, or a point such as a searchlight,

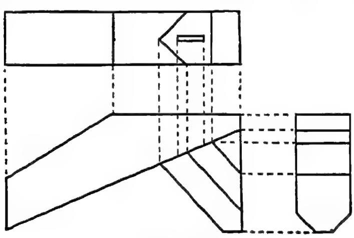

FIG. 20.

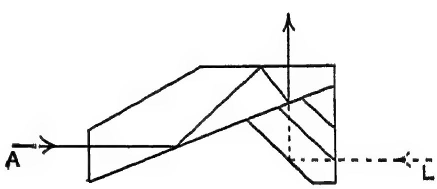

FIG. 21.

astigmatising systems are interposed in the ray paths on both sides of the instrument. This system may consist of a pair of negative cylindrical lenses, with axes horizontal, which can be thrown at will into the ray paths. The action of these lenses is to draw out the image in the eyepiece into vertical streaks across the separating line, when coincidence can be effected in the usual way.

§ (12) SEPARATING PRISMS.—The separating prism combination is perhaps the most important optical element in the range-finder It is situated between the object-glass of each of the telescopes and its focal plane; its function being to deflect the imaging cones of rays, which it receives from the ends of the range-finder, at right angles into the common focal plane of the eyepiece and the two objectives, with fine and sharp boundary lines between the partial fields, and at the same time giving to the images in these fields the desired orientation. An ideal separating prism would give a field of view with an invisible dividing line when directed to a clear sky. In early forms of range-finders the separating prism consisted simply of two rectangular prisms superposed as shown by *Fig.* 18, the light from the left window producing an image in the upper part of the field, and the light from the right window producing similarly the image in the lower part of the field. Another simple arrangement is shown by *Fig.* 19. The two prisms are placed edge to edge as shown, with the result that the field is divided by a vertical line instead of a horizontal one. In both these cases, however carefully the prisms may be made, the dividing line is shown to be very rough and badly illuminated when viewed, as it is, in the range-finder, with an eyepiece magnifying from 10 to 12 times.

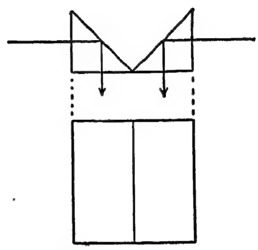

FIG. 19.

In the separating prism system employed in some forms of the Zeiss range-finder (see *Figs.* 20, 21, and 22), two prisms are cemented together with the surface of contact silvered, except for a small rectangular opening shown in plan view (*Fig.* 20). This rectangular opening in the silvering occurs in the common focal plane of the eyepiece and the telescope object-glasses. Light from the right eye of the range-finder is totally reflected from two faces of one of the component prisms, as shown by *Fig.* 21, and then from the silvered inter-face into the eye of the observer. Any light, how-

[1] For information on the calibration of the range-scales for instruments of different types see below, § (16), etc.

ever, which falls upon the unsilvered rectangular opening passes through it and away. Light from the left eye of the range-finder, after being reflected from the roof faces of the second component prism (see *Fig.* 21), passes vertically upward until it reaches the inner face, at which part is stopped by the silvering and part passes through the rectangular opening to the eye of the observer. The picture in the field of view, therefore, is for the most part produced by light from the right eye of the range-finder, but the narrow rectangular opening seen in the middle of this field of view frames a picture due to light from the left eye only of the range-finder. A small subsidiary prism cemented into the angle on the right, between the two main component prisms already referred to, serves to reflect the range-scale reading into the field of view. It will be seen that since the small rectangular opening in which one of the partial pictures appears is formed on a prism face, which is not at right angles to the optical axis of the eyepiece, it cannot be

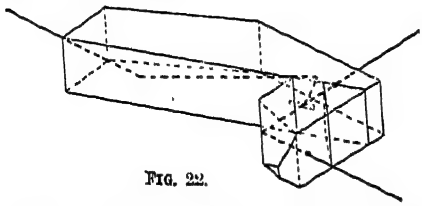

Fig. 22.

focussed up simultaneously throughout its entire length. This is a defect.

Fig. 23 shows, in side elevation and plan respectively, one of the various forms of eyepiece prism systems used by Messrs. Barr & Stroud in their range-finders. The top prism receives the light from the left eye of the range-finder, and the bottom prism acts similarly for the right eye of the range-finder. The ray L, shown as a full line, enters the top prism and is reflected at 1, at right angles in a forward direction—that is, away from the observer—and in the horizontal plane. It is again reflected at right angles into a downward direction at 2, ultimately being reflected at 3 to the separating prism A; the horizontal dihedral edge of which, formed by the meeting of the two prism faces at an obtuse angle, is in the common focal plane of the eyepiece and of the telescope objective, and forms the fine separating line in the field of view. All rays from the left eye of the range-finder fall upon the two faces of the separating prism, but it is only those falling upon the lower face which are refracted through the opening in the diaphragm to the eye of the observer. Those rays which fall upon the upper face are refracted as shown by the long-and-short dotted line so as to be stopped by the diaphragm. Rays reaching the separating prisms from the right eye of the range-finder are dealt with in a similar way, but, in this case, the rays falling upon the upper face of the prism are the only ones which ultimately reach the eye of the observer—those falling upon the lower face are refracted so as to be stopped by the diaphragm. In this way the separating prism acts to divide the field of view into two parts, the upper one of which receives light from the right eye only, whilst the lower part of the field receives light from the left eye only, the two partial fields of view being separated by a fine sharp line. A compound cylindrical lens B can be thrown

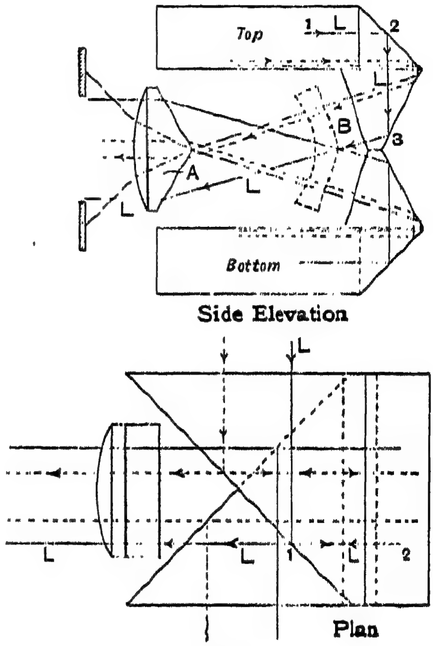

Fig. 23.

into the ray paths at will to astigmatise the final observed image.

§ (13) Stereoscopic Graticules.—In the Zeiss instruments, each graticule of the pair used in instruments of the fixed-scale type has a number of range-marks, which are numbered at intervals and arranged along a zigzag line. When these scales are combined visually, a single stereoscopic range-scale is seen, which, starting in the foreground of the picture, extends away from the observer indefinitely.

For the wandering-mark type a pair of similar marks, one in each graticule, is employed. In later instruments, however, especially those of the wandering-picture type, each of the graticules bears a number of range-marks (arrow-heads pointing downwards) arranged in two straight lines, approximately horizontal, but crossing one another at the

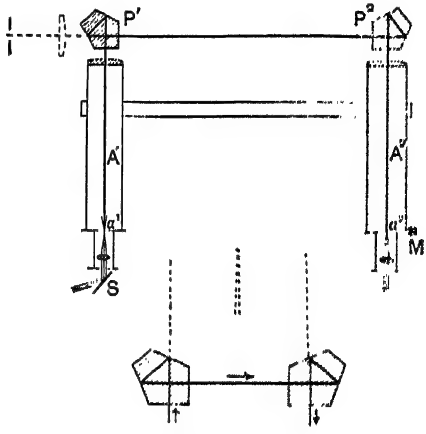
middle, at an angle of about 10°. These scales, when visually combined, present to the eye two overhead linear range-scales, each starting near at hand and receding into the distance; but whilst one is seen bearing away to the right, the other appears to bear away to the left, so that at a mean distance they appear to cross, the crossing point having a common range-mark. In observing with this type of range-finder, the deflecting prism is adjusted until the object being observed is seen to be at the same distance away as the range-mark common to the two scales at their crossing point. This design of graticule was invented by Zeiss about 1908. Greater accuracy when ranging on isolated objects is claimed for it over that obtained by the use of two single marks only.

§ (14) Range-scale Adjusting Apparatus for Range-finders.—In an instrument like the range-finder, which, under the severe conditions of use, is called upon to work at such a high order of accuracy, it will be readily understood that the maintenance of the various parts of the instrument in correct adjustment is a very severe problem for the designer and manufacturer. So far as the range-scale is concerned, the instrument can always be tested and adjusted when very distant or celestial objects are available. It is then only necessary to direct the instrument to a distant object—the moon, say—and operate the working head to effect coincidence of the two images. The range-scale should then read "infinity." If it does not do so, then the range-scale is set to indicate "infinity" and the adjusting prism forming one of the windows, above referred to, is rotated until coincidence is effected.

(i.) *Lath Adjuster.*—In the simplest form of apparatus for effecting this infinity adjustment, apart from ranging on real and distant objects, two vertical lines are drawn upon a lath or board at a distance apart equal to the base length of the range-finder with which it is to be used. When this board is fixed up at a distance of some hundreds of yards from the range-finder, and parallel to it, then one line is projected into one partial field of the eyepiece and the other line is similarly projected into the other. If the range-finder be in correct adjustment the range indicated will be "infinity" when coincidence has been effected. Quite early, however, in the history of the range-finder, it was felt that this method was too crude and cumbersome.

(ii.) *Abbe's Method.*—In the year 1893 Professor Abbe devised apparatus for correcting and adjusting telemeters or range-finders, which was based upon optical means which have practically been common to all the later and more developed apparatus for securing the same end.

Abbe's apparatus was particularly applicable to range-finders of the type (stereoscopic) in which two independent telescopes are employed. In *Figs.* 24 and 24A, for example, the invention is shown diagrammatically as applied to a stereoscopic range-finder of the wandering-mark type, that is, the range is determined by the adjustment of the micrometer M, which is necessary to give to the observer the impression that the wandering stereoscopic mark seen in the field of view is at the same distance as the object being ranged upon. The adjusting apparatus consists of a pair of pentagonal prisms P′ and P², mounted in front of the two telescope object-glasses as shown. The left eye of the observer



Figs. 24 and 24A

is then taken away from the telescope A′, and a mirror S is positioned to illuminate the fixed stereoscopic scale mark a'. Light from this mark, therefore, issues from the object glass as a collimated beam and enters the prism P′, by which it is reflected at right angles to the prism P², and then similarly into the second telescope A², by which it is brought to a focus in the same plane as the wandering-mark a^2. If the range-finder is in correct adjustment, and the prisms P′ and P² reflect the beam of collimated rays accurately through 180°, then it follows that the image of a' will be projected on to the wandering-mark a^2, when the micrometer M is set to infinity. Should this not be the case, the instrument is adjusted until it is so. The great advantage of this arrangement is that each of the pentagonal prisms acts as an optical square, that is, the deviation produced by it is practically constant and, further, independent of any small rotation of the prism about an axis normal to the plane of the diagram. When the base length of the range-finder is small, the pair of optical squares may be made from a single piece of glass.

The prisms P′ and P^2 may together produce a deviation of the collimated rays something less than 180°. Let this angular defect from $180° = \theta$, then the rays will enter the telescope A^2, as they would from a real object on the axis of the telescope A′, and at a distance equal to that at which the base of the instrument subtends the angle θ. If this angle θ and its corresponding range are known, then the testing operation consists as before in projecting the mark a' on to the mark a^2, but the micrometer M should, when this adjustment has been made, indicate the corresponding range.

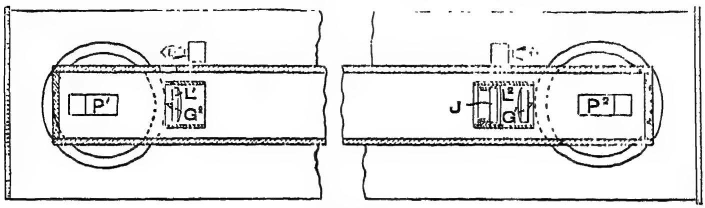


FIG. 25.

In a later modification of Abbe's apparatus, invented by König in 1904–1908, the necessity for using one of the telescopes of the instrument as a collimator is avoided by fitting a collimator independently.

(iii.) *Barr & Stroud's Method.*—An important instrument for adjusting range-finders was brought out by Messrs. Barr & Stroud in 1906. The optical principle upon which this instrument was constructed is shown by *Fig.* 25. Fiducial marks G′ and G^2 are borne by lenses L^2 and L′ respectively, of equal focal length and separated by a distance equal to that focal length. Each lens as shown, therefore, acts as a collimator to the fiducial mark on the other lens, with the result that the emergent beams are collinear, a property which is independent of any small lateral displacement of either of the lenses L′ and L^2, provided that the marks G′ and G^2 are mounted at the principal points of the two lenses. These collinear beams enter prisms P^2 and P′ respectively, from which they are reflected parallel to one another, and are therefore in a condition to enter the range-finder and give images of the lines G′ and G^2, equivalent to the images of a single object at infinity.

Fig. 26 shows in plan the application of this instrument to a range-finder, and in addition an adjusting prism J, which is adapted to rotate about an axis coincident with that of the two lenses G′ and G^2. By the rotation of this prism, therefore, the two issuing beams of light can be made either parallel to one another, or to diverge at the angle corresponding to that between beams of light entering the range-finder from an object at a known distance. The adjusting apparatus may, as shown, be made separate from the range-finder, or it may be attached to the framework of the range-finder itself.

§ (15) HALVING ADJUSTMENT.—In general the picture seen in one of the fields-of-view of a range-finder is duplicated and inverted in the second field, but it may happen that corresponding image points do not occur at equal distances from the separating line, so that when the infinity adjustment has been made, the image in the upper field is not a simple reflection of that in the lower field, with the line of separation as a line of symmetry.

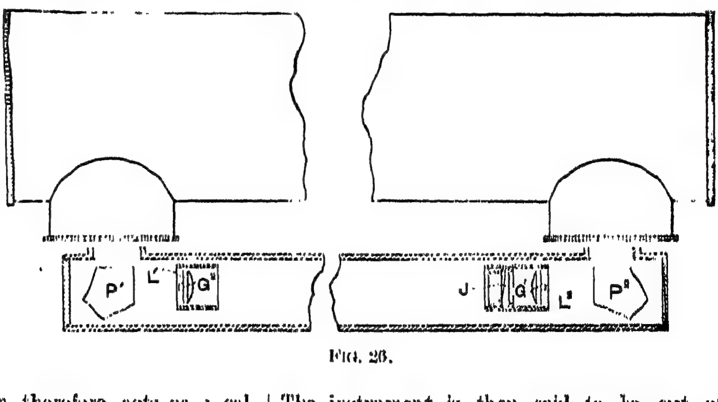

FIG. 26.

The instrument is then said to be out of halving adjustment. This want of adjustment, so long as straight edges at right angles to the separating line are being ranged upon, is not of great importance, but when a line inclined to the separating line is used for ranging purposes a very serious error is introduced by this want of adjustment. To effect the necessary adjustment it is clear that one picture must be displaced in the field-of-view vertically with respect to the other one. This may be carried out in the range-finder

by (1) tilting one of the pentagonal reflectors about a horizontal axis inclined at an angle of 45 degrees to the axis of the tube and parallel to the path of the normally incident ray as it passes from one reflecting surface to the other; (2) by displacing one of the telescope object-glasses in a vertical direction; (3) by the rotation in its own plane of a weak prism originally mounted with its edge vertical; or (4) by tilting a thick plane-parallel plate in a convergent beam of light.

The halving adjustment having been made, the correction of the infinity adjustment is made by shifting the upper field in a direction parallel to the dividing line as already described.

III. Calibration of Range-scales

§ (16) Coincidence Range-finders. (i.) *Sliding-prism Type.*—The relations which must exist in a coincidence range-finder between the length of its base b, the focal length f of its objectives, the deviating power δ in circular measure of its sliding deflecting prism, and the length L of its range-scale between the infinity mark and the mark for the minimum range R_m required, can be obtained as follows:

Imagine a range-finder adjusted on an object at infinity, and that the object then moves up along the straight line joining it with the left eye of the range-finder till its distance from the range-finder is equal to the minimum range R_m which it is desired to indicate on the range-scale. As the object thus moves, the parallax angle changes from 0 at infinity to b/R_m at the minimum range, and the image projected by the right half of the range-finder into the focal plane of the eyepiece moves out of coincidence through a distance d such that

$$\frac{d}{f}=\frac{b}{R_m}. \quad . \quad . \quad . \quad . \quad \text{(A)}$$

The image projected by the left half of the range-finder under the conditions named would remain stationary. To re-establish coincidence of the images the sliding prism with angular deviating power δ must be moved through a distance L, along the axis of the beam of light, such that $d=L\delta$; so that substituting this value of d, in equation (A) above, we obtain

$$L\delta=\frac{f.b}{R_m}. \quad . \quad . \quad . \quad \text{(B)}$$

To apply this formula, suppose it is required to find the length L, when the base length of the range-finder is 1 metre (39·37 inches), the focal length f is 11 inches, the minimum range required is 250 yards, and the deviating power of the prism is one unit in a distance of 170 units (equivalent to 20 minutes of arc). Then reducing the linear dimensions to inches in equation (B) we find that

$$L=\frac{11\times1\times39{\cdot}37\times170}{250\times36}=8{\cdot}18 \text{ in.}$$

(ii.) *Rotating-prism Type.*—In range-finders, such as the Zeiss, in which coincidence is effected by imparting equal rotations in opposite directions to a pair of similar prisms mounted in the parallel beam between the end reflector and the telescope O.G., it is desirable to secure the maximum possible openness of the range-scale by giving to each of the prisms an angular deviating power δ, such that a rotation of these prisms through 180°, *i.e.* from the position shown in plan by *Fig.* 27 to the position shown by *Fig.* 28, should allow of coincidence for all ranges between infinity and the desired minimum range R_m.

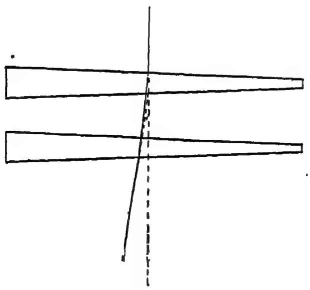

Fig. 27.

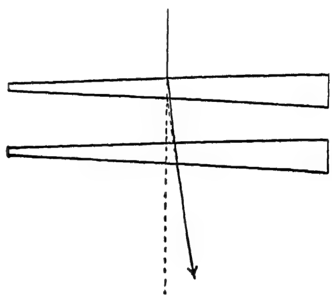

Fig. 28.

The angular deviating power of each prism being δ, a rotation through 180° will effect a deviation of any ray in the horizontal plane through an angle equal to 4δ, and the deviation δ_1, produced by a rotation through any angle α less than 180°, as shown by *Fig.* 29, is obtained from the equation

$$\delta_1=2\delta(1-\cos\alpha), \quad . \quad . \quad . \quad \text{(C)}$$

it being remembered that when α is between 90° and 180° the cosine is negative in value.

Thus for rotations of 0°, 90°, and 180° the deviations are 0, 2δ, and 4δ respectively. The angle 4δ must therefore be made equal to the

maximum angle of parallax b/R_m to be measured, or

$$\delta = \frac{b}{4R_m}. \quad . \quad . \quad . \quad . \quad (D)$$

Thus when $b=1$ metre and $R_m = 250$ m.,

$$\delta = \frac{1}{1000},$$

approximately $3\frac{1}{2}$ minutes of arc. It will be noticed that the focal length of the O.G. does

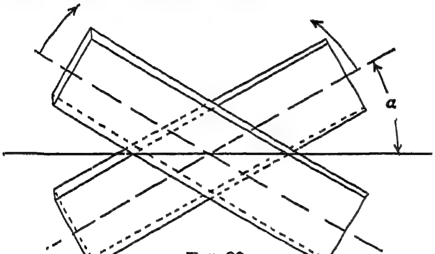

FIG. 29.

not enter into equation (D), for the reason that the deviation is effected in the parallel beam and not in the convergent beam, as in the case of the sliding-prism type of range-finder.

For any given range R the parallax angle $\theta = b/R$, and since δ must be equal to θ we have, by substituting in equation (C) above,

$$\frac{b}{R} = 2\delta(1 - \cos\alpha),$$

or

$$\cos\alpha = 1 - \frac{b}{2\delta R}, \quad . \quad . \quad . \quad (E)$$

where α is the angle of rotation of one of the deviating prisms from its infinity position necessary for bringing about coincidence. By giving to R in the above equation the successive numerical values it is desired to indicate on the range-scale, the corresponding angle α can be found.

Thus in the case of the range-finder considered above, with a base length of 1 metre and deflecting prisms each with an angular deflecting power of one in a thousand, equation (E) becomes

$$\cos\alpha = 1 - \frac{500}{R},$$

from which the following table has been calculated as an example:

Range (metres).	Angle.	Range (metres).	Angle.
20,000	12° 50′	800	67° 59′
10,000	18° 11′	700	73° 23′
5,000	25° 50′	600	80° 22′
4,000	28° 58′	500	90°
3,000	33° 35′	400	104° 29′
2,000	41° 25′	300	131° 49′
1,000	60°	250	180°
900	63° 38′	..	..

These angles must, of course, be multiplied by the gearing ratio adopted—usually two.

(iii.) *Two-magnification Type.*—In this type of range-finder an eyepiece range-scale, extending along the lower side of the coincidence line, is graduated so that when the instrument is in adjustment the coincidence of the two differently magnified images of an infinitely distant object can only be obtained at the place along the coincidence line at which the infinity mark of the scale occurs. Let *Fig.* 30 represent the field-of-view of such a range-finder, and suppose that the images of an infinitely distant object have been brought into coincidence on the line marked "∞." Now suppose the object to move up along the straight line, joining it with the left eye

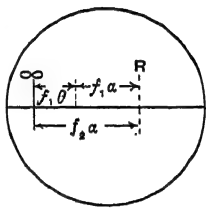

FIG. 30.

of the range-finder, to a distance at which the base length b of the range-finder subtends an angle θ. Then the partial image, in the upper part of the field-of-view, produced by light passing through the right eye of the range-finder, will, during the supposed movement of the object, move from left to right through a distance $f_1\theta$, where f_1 equals the focal length of the corresponding telescope objective, whilst the partial image due to the left eye, in the lower part of the field, remains on the infinity mark. Now suppose the range-finder to be rotated through a small angle α about a vertical axis, in the counter-clockwise direction as seen from above, both the images will then move to the right, but the more magnified image, in the lower part of the field, will move more quickly than the one in the upper part of the field, and eventually catch it up at a distance d from the "∞" mark, such that $d = f_2\alpha$, where f_2 is the focal length of the telescope objective on the left. Since the image in the lower field is more magnified than the image in the upper field, it follows that $f_2 > f_1$, and that in consequence, whilst the lower image moves through the distance $f_2\alpha$, the upper image will move through a shorter distance $f_1\alpha$. Thus

$$d = f_1\theta + f_1\alpha, \quad . \quad . \quad . \quad . \quad (1)$$

but

$$d = f_2\alpha, \text{ i.e. } \alpha = \frac{d}{f_2}, \quad . \quad . \quad . \quad (2)$$

and

$$\theta = \frac{b}{R}. \quad . \quad . \quad . \quad . \quad (3)$$

Substituting these values of α and θ in equation (1) we get

$$d = \frac{f_1 b}{R} + \frac{f_1 d}{f_2},$$

and solving for d we obtain

$$d = \frac{b f_2 f_1}{R(f_2 - f_1)} \quad . \quad . \quad . \quad (4)$$

which shows that the eyepiece range-scale is a reciprocal one, since b, f_1, and f_2 are constants for the range-finder. Equation (4) may be written

$$\frac{1}{f_1}-\frac{1}{f_2}=\frac{b}{d\,.\,R}\text{ (a constant)}, \qquad (5)$$

i.e. the difference in the focal powers of the two objective systems must be made equal to the base length divided by the product of the length of the range-scale, and the range corresponding to that length.

In practice the total length of the range-scale is limited to about 1 cm., and the minimum range required is, say, 250 metres, so that if the base length equals 1 metre, then

$$\frac{1}{f_1}-\frac{1}{f_2}=0{\cdot}4,$$

the focal lengths being expressed in metres. From this equation, one focal length being assumed, the other can be found. Thus when $f_1=25$ cm., f_2 must be made equal to 27·7 cm. In a range-finder of this type, made by Bausch and Lomb, $f_1=16{\cdot}26$ cm., $f_2=16{\cdot}78$ cm., $b=0{\cdot}8$ m., and $d=0{\cdot}95$ cm. for the minimum range of 450 m.

§ (17) Stereoscopic Range-finders: Fixed Scale and Wandering-mark.—In these types of range-finders (see *Fig.* 8) the parallactic displacement D, in the common focal plane of the two objectives, is obtained from $d=bf/R$, where, as before, B is the base length of the range-finder, f the focal length of the telescope objectives, and R the range. The distance between the two infinity marks —marks upon which the two images of a star would be simultaneously projected—in the common focal plane of the objectives may, by suitable disposition of the reflectors, be given any value, usually that of the average interpupillary distance of the men likely to use the range-finder. This distance, once determined and adjusted, remains fixed, that is, it is not affected by any adjustment of the interocular distance necessary for individual observers. A fixed scale might consist simply of a single mark in one ocular field and a number of marks in the other field, corresponding to the series of ranges for which the instrument is to be graduated. With such an arrangement as this the image of the single mark, in the use of the instrument, would be fused stereoscopically in succession with each of the marks in the other ocular field. In practice, however, it has been found better to provide for each of the ranges to be indicated a separate pair of marks, one in each ocular field, but the principle of the calibration is the same. Thus for a range-finder in which the product bf is equal to k, say, and in which the distance between the infinity marks is equal to A, say, the distance apart of the pair of marks for any finite range R_1 must be made equal to $A-k/R_1$.

The same principles apply in the case of the wandering-mark. Here one ocular field contains a fixed mark, whilst in the second field a second mark is adjusted transversely to the line of sight by means of a micrometer screw, the drum of which is calibrated for the ranges corresponding to the parallactic displacements required for the given ranges according to the equation above.

§ (18) Conclusion.—From the story now told, it will be seen that whilst the English naval and military authorities accept the coincidence type of range-finder as the most efficient service instrument, the German authorities on the other hand, under the guiding and compelling genius of Carl Zeiss, have favoured the stereoscopic type. Now in the case of a coincidence instrument there is no question but that a comparatively large percentage of service men can be trained to work it efficiently, whilst in the case of the stereoscopic instrument the conditions are very different. English military opinion tends to the conclusion that only about 5 per cent of men tried ever become efficient range-takers with the stereoscopic instrument, and this conclusion is supported by German experience. In the German training-schools we believe that, of the total number of the men tried, only about 15 per cent are finally selected for training. It is claimed that of these men a certain very small number, after an extended period of trial, attain a stereoscopic differentiating power of 4 seconds of arc. This compares favourably with the standard reached by the best range-takers with the coincidence type. The average, however, claimed by the Germans is about 10 seconds—should a man not be able to attain an accuracy of 20 seconds or less, he is rejected.

It must be remembered that the remarkable accuracy which has been claimed for both types of range-finder has only been secured by tests made under the most favourable conditions—laboratory conditions, in fact—and it may be that, as regards their best performances under those conditions, the one type can claim no decided advantage over the other. Tests under service conditions, however, are the only ones which have any useful discriminating value, and these are not so easily carried out. A range-taker, under the intense nerve strain brought about by a modern battle, may find that he can obtain very much better results with one type of range-finder than the other, and, so far as evidence is available, there can be little doubt that under the severest service conditions the coincidence has a very decided advantage over the stereoscopic type.

Now the battle of Jutland was fought with 9-feet Barr & Stroud coincidence range-finders on the one side, and 3-metre Zeiss stereoscopic range-finders on the other. Very few instruments of greater dimensions than these were used by either side. It is, however, strange to say, very difficult to arrive at a just conclusion as to the relative merits of the work done with these instruments. Each side has shown a desire to give full credit to the work of the other. When, however, everything is taken into consideration, there appears to be very little doubt that the days of the stereoscopic range-finder, as a chief service range-finder, are numbered. This is not to be wondered at when it is remembered that, before the war, Germany had held out against the world in adopting the type. No doubt it will still be made and used for special work, possibly against air-craft. Any one who has experienced the ease and precision with which a stereoscopic range-finder can be directed to and ranged on a mere wisp of floating cloud will readily realise that for work of this kind it stands out unrivalled.

SACCHARIMETER: a term applied to polarimeters, used to measure the strength of sugar solutions, in which the quartz wedge compensation system is employed. See "Saccharimetry," § (2).

SACCHARIMETER SCALES. See "Saccharimetry," § (4).

SACCHARIMETERS, conditions governing the accuracy and sensitiveness of. See "Saccharimetry," § (7).

Mechanical construction and design of. See *ibid.* § (6).

SACCHARIMETRY

§ (1) INTRODUCTORY.—The optical rotation of a sugar solution can be measured by means of the polarimeter,[1] and if the rotation of a *pure* sugar solution of the same concentration be known, the percentage purity of the first sample can then be calculated. Owing to the rotatory dispersion (variation of rotatory power with wave-length) of all active substances, a monochromatic light source is necessary in all polarimetric measurements. The half-shadow angle of the polariser must be small in order to obtain accurate results. But even with a half-shadow angle of 6°, only a small fraction of the incident light enters the eye of the observer at the matching point. The usual monochromatic light source (sodium light) was therefore too feeble for accurate measurements even when the optically active substance was highly transparent, and this is by no means the case with the average raw sugar solution.

Biot had observed that the rotatory dispersion of quartz was approximately the same as that of a sugar solution, and in response to a prize of 2000 francs offered by the "Société d'Encouragement" for a means of determining the strength of sugar solutions correct to 2 per cent, Soleil[2] ingeniously evolved the quartz compensator system, in which he utilised the rotatory power of quartz, to neutralise that of the sugar solution. With this arrangement, the polariser and analyser are *fixed and crossed*, and the rotation of a sugar solution is given by the distance a quartz wedge has to be moved in order to neutralise the rotation of the solution. Since the rotatory dispersions of quartz and of sugar solutions are approximately equal, this system permits the use of white light with its relatively great intensity and convenience.

§ (2) SACCHARIMETERS.—The term "saccharimeter" is now generally applied only to polarimeters in which this quartz wedge compensation system is used.

The optical arrangement in a standard polarimeter is shown in *Fig.* 1. The polarising prisms CD form the Lippich[3] polariser. The wedges K and L are made of left-rotating quartz and have their bases on opposite sides, so that a beam of light will pass through undeviated. The analysor M is "crossed" with the polariser CD before the quartz wedges are mounted. A compensating disc J of

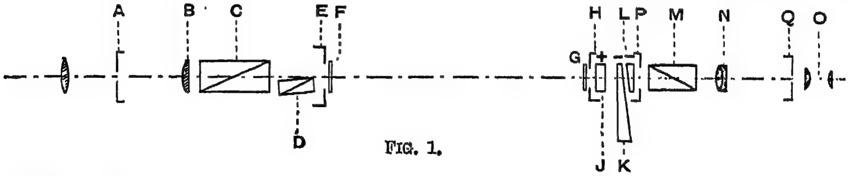

FIG. 1.

[1] See "Polarimetry."

[2] Soleil, *Compt. Rend.*, 1845, xx. 1805; 1845, xxi. 426; 1847, xxiv. 973; *Mém. Inst.*, 1845, xiii. 214.

[3] See "Polarimetry," § (6).

right rotating quartz is introduced. Its thickness is such that it equals that of the left rotating wedges K and L when the movable wedge K has been moved approximately one-fifth of its total path (as measured from the position when the *thinner* end of K is nearer the centre). The objective N is achromatic and the eyepiece O is focussed on the sharp dividing line of the prism D.

The light source is focussed on the diaphragm A of the polariser by a lens (shown in the diagram). A can therefore be regarded as

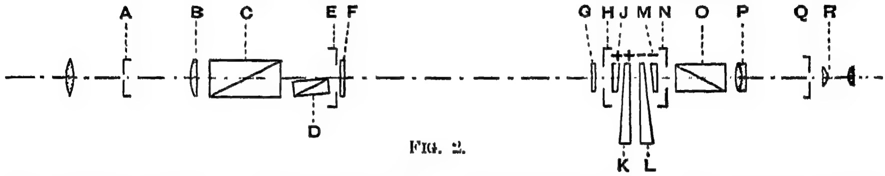

FIG. 2.

the virtual light source. An image of this is brought to a focus, in turn, at the objective N of the observing telescope, by means of the condenser lens B. Cover glasses F and G serve to protect the polarising and analysing systems from dust and damp.

When an observation tube containing a liquid is placed in the path between F and G, a halo is usually seen surrounding the usual field of view. This is caused by reflections at the inner walls of the tube; if a diaphragm is placed at Q (the focal plane of the eyepiece) so that its aperture is equal to, or only slightly greater than the size of the image of E formed by the lens N at Q, then this effect is avoided. The apertures H and P serve to cut off scattered light from outside and multiple back reflections.

In the double wedge instrument shown in *Fig.* 2 the optical arrangement is the same, only that now the quartz compensating disc (in the case of the single wedge instrument) is replaced by two wedges J and K of opposite rotation to the other pair L and M. The long

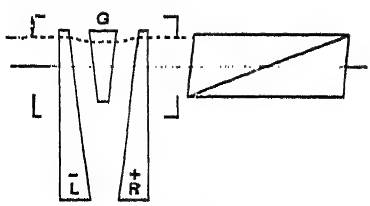

FIG. 3.

wedges K and L are movable, whilst the short wedges J and M are fixed. The special advantages of having two movable wedges of opposite rotations will be discussed later. Martens[1] suggested that the same result may be obtained as shown in *Fig.* 3. The one long wedge is right rotating while the other is left rotating. The deviation of the beam is compensated by means of the glass wedge G. Although this method means a considerable saving owing to the scarcity of optically pure quartz, it has not come into general use. There are possibly two reasons for this—first, the double refraction almost always present in a thick glass wedge with the decrease in sensitiveness that follows; and, second, the fact that the dispersion of glass being different from that of quartz a coloured fringe would be seen at each side of the field of view, since the light source is approximately white.

The standard instruments of Frič, Schmidt and Haensch, Goerz, Peters, Bausch and Lomb, and Hilger, are all optically identical with either *Fig.* 1 or *Fig.* 2. The saccharimeter of Pellin embodies a Laurent polariser, while in that of Bellingham and Stanley the modified Jellet prism described on p. 483 is employed. When a separate light source is used, another

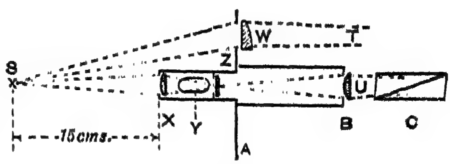

FIG. 4.

short focussed convex lens is mounted in front of the diaphragm A (*Figs.* 1 and 2), so that it forms an image of the source at A, when the latter is placed a particular distance (15 cm. in the Schmidt and Haensch instruments) in front of this auxiliary lens X (in *Fig.* 4). In order to secure a uniformly illuminated field of view a diffusing screen is placed at Z, and the image of S can be accurately focussed on it by looking sideways through the elongated observation hole Y at the side of the tube carrying the lens X. The diaphragm at A is extended outwards, as shown, to screen off the extraneous light from the observer. A deviation prism W is mounted in an aperture in this extended diaphragm so that a beam of light is obtained to illuminate the scales of the instrument. When electrical illumination is used, the large diaphragm at A and the deviating prism can be dispensed with, the illuminating beam T being obtained by placing a small mirror at the requisite angle above the source.

[1] Martens, *Zeitschr. für Instkde.*, 1900, xx. 82.

It must be noted that, as in the polarimeter, the beam emerging from the condenser B is not strictly parallel, but is made to converge on the objective of the observing telescope. This secures that the maximum permissible amount of light enters the eye of the observer, simultaneously with uniform illumination of the field of view.

§ (3) BATES'S SACCHARIMETER.—It is not possible to vary the half shadow angle of an ordinary saccharimeter, because it would entail a removal of the quartz wedges, etc., in order to set the analysing nicol at the new position of matching. If the polariser and analyser are not accurately crossed, a match cannot be made at any position of the wedge when the quartz compensating system is inserted, because, approximately white light being employed, the rotatory dispersion of quartz will cause considerable colour differences in the two halves of the field of view.

Bates [1] has constructed a saccharimeter in which the adjustment of the analyser is automatically made as the half shadow angle is varied by rotating the whole Lippich prism of the polariser.

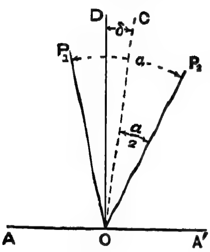

FIG. 5.

Let OP_1 in *Fig.* 5 represent the plane of polarisation of the light emerging from the whole Lippich prism, OP_2 the plane of polarisation of the half Lippich, and AOA′ that of the analysing nicol. OD is drawn perpendicular to AOA′, and OC bisects the angle P_1OP_2. Let δ be the angle that the normal to the plane of the analyser makes with OC, the bisector of the half shadow angle.

$$\angle P_1OA=\frac{\pi}{2}-\frac{\alpha}{2}+\delta,\quad \angle P_2OA'=\frac{\pi}{2}-\frac{\alpha}{2}-\delta.$$

If I is the intrinsic intensity of illumination of the light emerging from the whole Lippich, its intensity after transmission through the analyser will be given by

$$I\cos^2 P_1OA=I\sin^2\left(\frac{\alpha}{2}-\delta\right).$$

The intensity of the light leaving the half Lippich will be appreciably less. A portion is lost by reflection at the two ends of the prism, by absorption in the spar and by reflection at the balsam film; suppose this fraction to be $1-\kappa$; the fraction transmitted will be κ. Another portion is cut off because the half Lippich is not parallel to the whole Lippich, and the fraction transmitted will be given by $\cos^2\alpha$ according to the law of Malus.

The resultant intensity of the light from the half Lippich will therefore be $I\times\kappa\cos^2\alpha$, and this after transmission through the analyser becomes

$$I\times\kappa\cos^2\alpha\cos^2 P_2OA'=I\kappa\cos^2\alpha\sin^2\left(\frac{\alpha}{2}+\delta\right).$$

When a match of the fields is obtained, then

$$I\sin^2\left(\frac{\alpha}{2}-\delta\right)=I\kappa\cos^2\alpha\sin^2\left(\frac{\alpha}{2}+\delta\right),$$

$$\therefore \sin\frac{\alpha}{2}\cos\delta-\cos\frac{\alpha}{2}\sin\delta=\sqrt{\kappa}\cos\alpha\sin\frac{\alpha}{2}\cos\delta + \sqrt{\kappa}\cos\alpha\cos\frac{\alpha}{2}\sin\delta;$$

$$\sin\frac{\alpha}{2}\cos\delta(1-\sqrt{\kappa}\cos\alpha) =\cos\alpha\sin\delta(1+\sqrt{\kappa}\cos\alpha),$$

$$\therefore \tan\delta=\frac{1-\sqrt{\kappa}\cos\alpha}{1+\sqrt{\kappa}\cos\alpha}\tan\frac{\alpha}{2}.$$

If the loss of light by absorption and reflection at the half Lippich is neglected, then $\kappa=1$ and $\tan\delta=\tan^3\alpha/2$ as was shown by Bates in his first paper. But this factor κ is important, as was realised by Schönrock [2] and Wright [3] independently. The latter assumed that the loss of light in the half Lippich was approximately 10 per cent, the value of the constant κ in the above equation being therefore ·9. The following table, due to Wright, shows the difference introduced by considering this factor.

Half Shadow Angle in Degrees.	Value of δ from Bates's Formula.	Value of δ from Wright (κ =·9).	Half Shadow Angle in Degrees.	Value of δ from Bates's Formula.	Value of δ from Wright (κ =·9).
0	0	0	8°	1′	7′
2°	0	2′	10°	2′	10′
4°	0	3′	12°	4′	14′
6°	1′	4′	14°	6′	18′

Schönrock calculated the loss of light from the well-known equation of Fresnel. For perpendicular incidence the percentage loss is given by $(n-1)^2/(n+1)^2\times 100$. Taking n as 1·486 (refractive index of Iceland spar) the percentage loss is 7·5. A further allowance of ·5 per cent is arbitrarily made for absorption inside the small Lippich, thus making the constant κ in the above equation ·92. The effect of considering the absorption is, as Bates [4] pointed out, to make the variation of δ with α more approximately linear. If the analysing nicol is therefore made to rotate with an

[4] Bates, *Bull. Bur. Stand.*, 1908, v. 193.

angular velocity slightly greater than half of that of the whole Lippich, the variation of the zero point of the analyser can in Bates's construction be reduced to $\pm\cdot14°$ (or $\pm\cdot05°$ S.) from the true matching position as given above, even when the half-shadow angle is altered from 3° to 15°. But it appears that, where the highest accuracy is required in measuring a rotation, a small allowance must be made for the change of the zero position with the particular half-shadow angle employed.

§ (4) SACCHARIMETER SCALES.—The amount of the rotation of a substance is proportional to the distance that the movable wedge has to be displaced in order to neutralise the rotation. A scale is therefore fixed to the movable wedge, and a vernier mounted on the fixed one as shown in *Fig.* 6. The scale and vernier (S and V of *Fig.* 6) are illuminated by the beam from the deviating prism (T in *Fig.* 4). This falls on a grey glass screen W (*Fig.* 6)

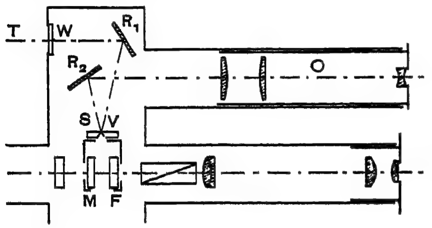

FIG. 6.

and is reflected by the mirror R_1 on to the scale and vernier. The reflected image of the latter in the mirror R_2 is observed by the telescope O.

It will be realised that the scales of all saccharimeters are arbitrary, depending on the angle of the wedge and on the length of a scale division, the rotation in a particular position being $nl \tan \theta(\kappa)$ where n denotes the number of divisions the wedge has been moved from its zero position, l the length in millimetres of a single scale division, θ the angle of wedge, and κ the rotatory power of quartz per millimetre for a particular wave-length.

The wedge angle and length of scale division adopted by Soleil were such that the rotation of the plane of polarisation of sodium light was 21·67° when the wedge was moved 100 divisions. This was supposed to be the amount by which the plane of polarisation of sodium light was rotated when passed through a quartz plate exactly 1 mm. thick, the faces of the plate being cut normally to the optic axis.

The value of the rotation given above is that of Broch (1846). Later determinations have shown that the specific rotation of quartz is appreciably greater than the above value; nevertheless, the 100° point on the scale has been standardised for the rotation as given by Broch, so that all French saccharimeters give almost identical readings—which is by no means the case with the other continental saccharimeters.

§ (5) ROTATION CONSTANTS OF SUGAR.—The specification of the normal sucrose solution which, when placed in a 200 mm. tube, would have a rotation of 21·67° for the sodium D lines at 20° C., has been the subject of a large number of determinations. The normal weight is defined as the number of grams of pure sucrose that is contained in 100 c.c. of the normal solution at 20° C., and values ranging from 16·0 grm. (Dubrunfaut) to 16·51 grm. (Clerget) have been given. In 1875, the value of 16·19 grm. (Girad, and de Luynes) was adopted as the official normal weight. The International Congress of Applied Chemistry (Paris, 1896) suggested that a redetermination should be made. The French Finance Ministry, acting on the report of Mascart and Benard,[1] adopted the value 16·29 grm., which remains up to the present the official French normal weight.

Ventzke[2] in 1842 proposed that the rotation of a standard sugar solution should be used to determine the 100° point on a saccharimeter scale. Originally, a 25 per cent solution of cane sugar was suggested as the normal solution; he afterwards proposed that the specific gravity of such a solution could be used for determining the concentration (that the normal solution should have a specific gravity of 1·1 at 17·5° C.). It was found impossible to make determinations of the specific gravity with sufficient accuracy, so that the normal solution was defined as one containing 26·048 grm. of sucrose in 100 c.c. of the solution at 17·5° C.[3]

In 1855 the Mohr c.c. came into general use (1 Mohr c.c. = volume occupied by 1 grm. of water weighed in air with brass weights at 17·5° C., 100 Mohr c.c. = 100·234 metric c.c.), and, until 1900, saccharimeters were standardised with a normal solution based on the Mohr c.c. whilst the normal weight remained unaltered. Thus the scale usually recognised as that of Ventzke has a normal weight 1·00234 times greater than that proposed by him.

Owing to the confusion and errors resulting from the two standards of volume, the International Commission for uniform methods of sugar analysis[4] recommended a new definition based upon the metric c.c. and a standard temperature of 20° C., as 17·5° C. is generally below the average temperature of a sugar laboratory. After correcting for the change

[1] Mascart et Bénard, *Ann. Chim. Physique*, 1899, (7), xvii. 127.

[4] *Zeitschr. Ver. Deut. Zuckerind.*, 1900 (I.) l. 357.

in the specific rotation of the sugar solution with temperature, and allowing for the temperature coefficient of the saccharimeter and tube, a normal weight of 26·01 grm. is obtained for an instrument standardised at 17·5° C. with the Mohr flask.

The International Commission decided to make the new normal weight exactly 26·000 grm. The following definition was formulated, and has since been accepted in all countries with the exception of France and the French colonies.

"One dissolves (for instruments arranged for the German normal weight) 26·00 grm. of pure sugar in a 100 metric cubic centimeter flask, weighing to be made in air with brass weights, and 'polarises' the solution in a room the temperature of which is 20° C. Under these conditions the instrument must indicate exactly 100·00.

"The temperature of all sugar solutions to be tested is always to be kept at 20° C., while they are being prepared and while they are being 'polarised.'"

By "polarising" is understood in this connection the measurement of the number of scale divisions that the wedge has to be moved in order to secure a match of the fields of the Lippich polariser when a column of the normal solution 200 mm. long is placed in the path, the point of reference being the reading on the scale when the fields are of equal intensity, *without* any active solution in the path.

Owing to difficulty of making a solution of pure sucrose of the required concentration, a secondary standard has to be made for both the manufacturer in the primary graduation of the instrument, and the user of the instrument for checking purposes.

The subsidiary standard is a quartz plate which when measured with a saccharimeter gives the same reading as that of a normal solution with the same instrument. The angular rotation of such a plate at 20° C. for sodium light was determined by Schönrock[1] in co-operation with Herzfeld,[2] the value given by him being 34·657°. Practically all saccharimeters employing the scale of the International Sugar Commission have, until recently (1917), been standardised on this basis. The above figure is commonly called the "conversion factor," and its accurate determination is of great importance in saccharimetry.

It had been noted at the Bureau of Standards that all normal sugar solutions, however carefully prepared, gave a reading below 100·00° when polarised in saccharimeters standardised on the basis of the conversion factor given by Herzfeld and Schönrock.

[1] Schönrock, *Zeitschr. Ver. Deut. Zuckerind.* (Techn. Teil), 1904, liv. 521, abst. in *Ann. d. Phys.*, 1904 (4), xiv. 406.

[2] Herzfeld, *Zeitschr. Ver. Deut. Zuckerind.* (Techn. Teil), 1900, l. 826.

A preliminary series of measurements were undertaken by Bates and Jackson[3] in 1912, when they found that the normal solution read 99·90° S. This was subsequently verified by Walker,[4] who prepared sucrose by the alcohol method and obtained 99·88° S. This led Bates and Jackson[5] to undertake an exhaustive investigation of the whole problem.

The absolute rotation of a normal solution of sucrose in a 200 mm. tube was measured by means of the spectro-polarimeter, using the green mercury radiation. This was found to be 40·763°. The absolute rotation of a quartz plate that gave the same reading on a saccharimeter as the normal solution was 40·690°, the difference being due to the slightly different rotatory dispersions of the two substances.

The ratio of the angular rotations of a quartz plate for sodium light (λ = 5892·5 Å.) and the green mercury radiation (5461 Å.) had been previously measured by Bates[6]; this constant was re-determined and the mean value found to be

$$\frac{\phi^{20^\circ \text{C.}}_{\lambda=5892\cdot5\,\text{Å}}}{\phi^{20^\circ \text{C.}}_{\lambda=5461\,\text{Å}}} = \cdot85085.$$

This ratio for the normal sugar solution was also measured and found to be ·84922.

The value of the conversion factor is therefore 40·690 × ·85085 = 34·620° for sodium light (λ = 5892·5 Å.) as against the value 34·657° from the Herzfeld-Schönrock determination.

Herzfeld[7] has criticised this result on the ground that Bates and Jackson have omitted to guard against the presence of micro-organisms in their standard solutions, and that the solutions from which the pure sucrose was crystallised were not kept slightly alkaline during evaporation to avoid slight hydrolysis. As Bates and Jackson have pointed out in their paper, the value for the specific rotation of sugar for the normal solution obtained from the Herzfeld-Schönrock conversion factor is very much higher than the average value determined from the formulae of Tollens and of Nasini and Villavecchia as combined by Landolt.[8] According to the latter, $[\alpha]_D^{20^\circ \text{C.}} = 66\cdot502$, whilst the value given by Schönrock[9] is 66·627. The value obtained from the redeterminations of Bates and Jackson is 66·529, which serves to corroborate the

value that they have obtained for the conversion factor.[1]

This modification of the Herzfeld-Schönrock values for the scale of the International Commission has been accepted at the National Physical Laboratory (England) and at the Bureau of Standards (America). Apparently pending international confirmation it has not yet been accepted by other bodies.

Sidersky and Pellet (1896) suggested that 20 grm. should be used as the normal weight instead of the 16 grm. (French) and the 26 grm. (German). The proposal was rejected by the International Commission[2] in 1906. A strong movement for its adoption was started in America[3] in 1918. The reasons in favour of, and against, this scale are considered by Saillard.[4]

Up to the present, however, no reliable data of sufficient accuracy are available to justify its adoption for high-precision saccharimeters.

§ (6) Construction and Design of Saccharimeters.—The polariser and analyser (with quartz compensating arrangement) are usually mounted on rigid trestle supports fastened to a heavy base. The polariser is similar to the types used on polarimeters (*q.v.*) with fixed half-shadow angle (with the exception of the Bates-Frič instrument). The movable wedge of the compensating system is moved along close-fitting ways by means of a rack-and-pinion movement. The scale is mounted on the carriage holding the movable wedge. While the other wedge is fixed, in the sense that it is not moved when an observation is being made, it can be moved laterally by means of a screw and key when necessary in order to arrange that at zero point of matching, the lengths of the movable wedge on each side of the optic axis of the instrument should be in the proportion of 30 : 115. This is needed so that the full length of the wedge and scale can be utilised. The vernier scale can be moved independently in a similar manner to correct for the zero error of the scale. The method of illuminating and observing the scale is indicated in *Fig.* 6. When two sets of wedges are employed as in *Fig.* 2, two separate observing telescopes are used in the Frič instruments, while in those of Goerz, and Schmidt and Haensch, the two sets of scale and vernier are brought into the field of view of the one observing telescope.

The range covered by single wedge (movable) saccharimeters generally extends from − 30° S. to + 110° S. or 115° S., the verniers reading directly to ·1° S. (in the case of the Hilger saccharimeter the vernier reads directly to ·05° S.). Generally it is possible to estimate to within a half of the vernier division. The scales and vernier are made of nickeline having a coefficient of expansion of ·000018, or of glass (·000008). A sensitive thermometer is often mounted in the compensator head, so that the temperature of the wedges and scales can be accurately known.

The movable wedge of the Bellingham and Stanley saccharimeter is only one quarter of the length of the usual wedge, and therefore the scale is correspondingly shorter. The latter is engraved by means of a photoceramic process and is observed by transmitted light, by means of a low-power microscope. The vernier is similarly engraved on a glass plate and is mounted in the focal plane of the microscope ocular.

As the above-named process admits of only one definite size for the scale and vernier, the variations in the angle of the wedge are compensated for by a slow motion to rotate the wedge in the plane perpendicular to the optic axis of the instrument, since it is the angle of the wedge in the direction of its motion that is the effective factor in determining the length of the scale.

The external features and other details of mechanical construction are best obtained from the makers named.

§ (7) Conditions governing the Accuracy and Sensitiveness of Saccharimeters.—The optical purity of the quartz in the compensating system to a great measure controls the accuracy and sensitiveness of a saccharimeter. Apart from regular twin crystals, which can often be detected by an examination of the crystal faces,[5] it is generally found that a parallel plate of quartz cut perpendicular to the optic axis contains a number of spike-shaped crystals of opposite rotation irregularly distributed, usually around the outside of the plate and pointing towards the centre.

These can be conveniently detected by the method of Buisson,[6] where interference bands are produced by the quartz plate in a parallel beam of polarised light. When green mercury light is employed the interpenetrating crystals show up as sharp discontinuities in the otherwise uniform interference bands.

If a quartz plate is examined in a powerful polarised beam of white light (say from a point-o-lite lamp) and the rotation of the plate be compensated for by adjustment of a pair of quartz wedges placed directly in front of the analysing nicol (method due to Twyman) a series of bands are seen of a hexagonal shape parallel to the natural edges of the plate.

[1] An independent determination of the 100° point of the Herzfeld-Schönrock scale has been made recently by Stanek. His results confirm the values obtained by Bates and Jackson. *Listy cukrovarnicke*, 1920-21, No. 45; *Zeitsch. Zuckerind. cechoslovak Republik*, 1921, xlv. 417, 425.

[2] *Inter. Sugar Journ.*, 1907, lx. 5.

[3] Cf. Browne, *Louisiana Planter*, Dec. 7, 1918; Jan. 5, 1919.

[4] Saillard, *Journ. des Fabricants de Sucre*, 1919, lx., No. 13.

[5] Cf. Lewis, *Crystallography*, p. 519.

[6] Buisson, *Journ. d. Phys.*, 5 série, 1919, ix. 25.

These apparently indicate that the rotatory power of quartz is to some extent influenced by conditions at the time of its growth. As these bands are invariably present, even when the above-mentioned interpenetrating crystals are absent, it is important to cut the wedges in a direction *along* the band.

It is owing to the lack of homogeneity of quartz that the double wedge system (*Fig.* 2) is of considerable advantage. Not only can the scale of working wedge be calibrated with reference to that of the "control" wedge at all points along its path, but also by placing the latter at different points, the rotation of a sugar solution can be measured with different portions of the working wedge, thereby eliminating errors due to local imperfections in the wedge.

These local errors in saccharimeter wedges can also be determined by means of the "control tube" of Schmidt and Haensch.[1] This consists of a telescopic observation tube of metal which can be adjusted by means of a rack-and-pinion movement, to give a column of solution of any length between 225 and 410 mm. By means of a vernier the exact length of a column of solution within this range can be read upon a scale, to within 0·1 mm. If an approximate half-normal solution is used, the 100° S. point on the saccharimeter will be given by a column about 400 mm. long. If the length of column required to neutralise the wedge at each scale division is determined, a calibration curve is obtained that allows for the faults of the wedge and also for any inequalities in the scale divisions. It is of course important that the scale of the telescopic tube be accurately calibrated independently. Browne[2] has given the curves of errors of a Schmidt-Haensch and a Bates-Frič saccharimeter taken annually over a period of seven years. It is interesting to note that while local imperfections persist, there seems to be a small progressive decrease, from year to year, in the average error of the scale.

If the optic axes of the quartz wedges and compensating disc do not accurately coincide with the direction of the optical axis of the instrument, the incident plane-polarised beam becomes elliptically polarised after transmission through the quartz, to an extent dependent on the amount of "axis error" and the thickness of quartz traversed. The methods of Gumlich[3] and Walker[4] seem only satisfactory for comparatively thick plates. Schönrock[5] has investigated the interference bands (in convergent polarised light) of a plate of quartz the optic axis of which makes a small angle with the normal to the plate. In conjunction with Brodhun[6] he has evolved a method of accurately determining the axis error of a parallel plate of quartz. The quartz plate is mounted on the table of a small spectrometer, and is mounted at an angle of about 40° to the optical axis of the collimator and telescope, which are in alignment. Nicol prisms are placed in both the telescope and collimator, and on illuminating the slit with sodium light the dark interference bands are seen. The plate is rotated in its own plane, until the displacement of the bands in either direction is a maximum. The plate is turned (about a vertical axis) until any one band is central with the cross wires in the telescope (or to the slit image). The plate is now rotated through 180° in its own plane, the plate being simultaneously turned (by rotating the table) so as to keep the band in the same position. The axis error of the plate is given by one-third of the angle that the plate has to be rotated. By employing a slow-motion movement for turning the spectrometer table Brodhun and Schönrock find that axis error can be determined to within a few seconds of arc.

The object of correcting for axis error in the quartz is to avoid elliptic polarisation of the plane-polarised beam after transmission through the quartz. The same effect is caused by accidental double refraction at any point between the polariser and analyser. It is therefore equally important that all the wedges, etc., be mounted as free from strain as possible. This is particularly applicable to the quartz control plates used for standardising and checking the 100° point of the saccharimeter, as the temperature variations are more pronounced in this case, as Weichman[7] and others have observed. Williams[8] has devised a mount for the control plate, in which the latter is held freely in a guard ring of steel, ·0025 mm. thicker than the quartz plate.

The glass plates protecting the polariser analyser should be made of well-annealed optical glass, as should also the end plate or cover glasses of the observation tube. The latter are often made of plate glass, this being the origin of some of the perplexing differences in rotation values obtained for one and the same solution examined in different tubes.

Owing to the difference between the rotatory dispersions of sugar solution and quartz (which though small is not negligible), the colour difference between the two halves of the field at the matching point is quite appreciable when a white light source is used, and an accurate matching is very difficult. The difference in

[4] Walker, *Phil. Mag.*
[5] Schönrock, *Zeitsch. Instkde.*, 1902, xxii. 1.
[6] Brodhun und Schönrock, *Zeitsch. Instkde.*, 1902, xxii. 364.
[7] Weichman, *School of Mines Quarterly*, 1899, xx.
[8] Williams, *Inter. Sugar Journ.*, 1919, xxi. 330.

the values of the rotation of a normal solution when the saccharimeter is illuminated with green mercury light ($\lambda=5461$ Å.) and sodium ($\lambda=5892{\cdot}5$ Å.) is ·188° S. (Schönrock [1]) or ·185° S. (Bates and Jackson [2]), the value for the green mercury radiation being the higher.

Schönrock [3] therefore suggested that one of the sodium light filters of Lippich [4] should be used. The latter used a 10 cm. column of a 6 per cent solution of potassium bichromate, but Schönrock found that a 1·5 cm. layer was sufficient. The International Sugar Commission in 1912 adopted the resolution that whenever white light is used in saccharimetric observations it must be filtered through a solution of potassium dichromate of such concentration that the product length of column in cm. and percentage concentration =9.

The evaporation of the water and the instability of the colour necessitates that the solution be periodically renewed. To obviate this difficulty Adam Hilger, Ltd., have evolved an aniline dye filter that is more permanent and gives on a saccharimeter readings identical with those of the standard bichromate filter. *Fig.* 7 gives the percentage transmission curves

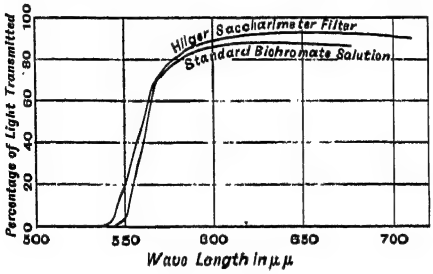

FIG. 7.

for the two filters, the data being obtained by means of a Hilger-Nutting spectro-photometer.

It will be noticed that these filters only exclude the lower portion of the spectrum, all wave-lengths above about 5700 Å. being transmitted freely. It is only to be expected therefore that different observers should obtain slightly different results owing to their varying spectral sensibility curves. An interesting observation has been made by Browne.[5] Three observers adjusted the length of control tube required to equalise the intensities in the fields of two saccharimeters the wedges of which were set at 100° S. Dividing the mean value of each observer (for each instrument) by the general average length of column, the following values, in terms of the saccharimeter scale, were obtained.

Observer.	Schmidt and Haensch Saccharimeter.	Bates-Frič Saccharimeter.	Average.
	° S.	° S.	° S.
A	100·020	99·971	99·9955
B	99·992	100·013	100·0025
C	99·987	100·017	100·0020
Average .	99·9997	100·0003	100·0000

It will be noticed that there is a difference of about ·04° S. between the results of A and C on the one instrument, while with the other instrument this difference has an approximately equal negative value. On examination it was found that the half-Lippich prism of the Bates-Frič saccharimeter is on the right, while in the Schmidt and Haensch instrument it is on the left. This indicates that the partial absorption of the light by the half-Lippich prism is an appreciable factor in the complex problem.[6]

§ (8) CORRECTIONS FOR TEMPERATURE.—As the temperature corrections in saccharimetry are unusually complicated, it is desirable to work at a temperature as near to 20° C. as possible.

The linear coefficients of expansion of quartz parallel and perpendicular to the optic axis are ·000007 and ·000013 respectively, so with a change of temperature the angle of the wedge is altered, the coefficient of the change being −·000006. The specific rotation of quartz has a temperature coefficient of ·000136 (Schönrock [7]), whilst that of the metal scale is about ·000018 (or ·000008 for glass).

The total temperature coefficient of a saccharimeter is ·000007 − ·000013 + ·000136 + ·000018 = ·000148 in the case of the metal scale, and ·000138 when the glass scale is used.

The true reading of the instrument at 20° C. is given by

$$R_{20} = R_t + R_t(t - 20°\text{ C.})\cdot 000148 \text{ (metal scale)},$$

or

$$R_{20} = R_t + R_t(t - 20°\text{ C.})\cdot 000138 \text{ (glass scale)},$$

where R_t is the reading of the saccharimeter at the temperature t.

The temperature coefficient of a quartz plate is ·000136 + ·000007 = ·000143. So that if P_t is the rotation in sugar degrees of the plate at $t°$ C. its rotation at 20° C. is $P_{20} = P_t + P_t(\cdot 000148 - \cdot 000143)(t - 20)$ for the

[6] According to a footnote to the above paper, Browne mentions that Horne has experienced a similar reversal of the "personal equation" by looking at the image of the field in a plane mirror, or by observing the field with the head bent downward.
[7] Schönrock, *Zeitschr. Ver. Deut. Zuckerind.*, 1904, liv. 521.

metal scale, and $P_{20} = P_t + P_t(\cdot000005)(20 - t)$ for the glass scale saccharimeter.

Schönrock[1] has determined the temperature coefficient of sucrose between 9° C. and 31° C., and in the neighbourhood of 20° C. it is ·000184, the coefficient of expansion of the solution is ·000285, and that of the glass observation tube ·000008, hence the total coefficient for the sucrose solution in the tube is ·000461. If we neglect the effect of temperature on the reading of the quartz plate, we can express the rotation of a sucrose solution at 20° C. (W_{20}) in terms of polarisation carried out at t° C., as

$$W_{20} = W_t + W_t\{\cdot000461 + \kappa\}\{t - 20\},$$

where κ is the temperature coefficient of the saccharimeter itself.

The temperature coefficients of other sugars are given by Browne.[2]

§ (9) Technical Methods of Saccharimetry.—The saccharimeter is most generally used in the analysis of the products of the cane- and beet-sugar industries. Owing to the similarity in their rotatory dispersions, nearly all the sugars can be quantitatively estimated by means of the saccharimeter, although in certain instances, *e.g.* commercial glucose, dextrin, etc., it is advisable to use a bichromate filter of double strength (*i.e.* percentage concentration × length in cm. = 18), as the rotatory dispersion of these substances is greater than with sucrose.

For full details of the chemistry and technique of sugar analysis, reference must be made to the standard text-books of Lippman,[3] Browne,[4] Weichman,[5] and others, and to the Circular (No. 44) of the Bureau of Standards. The following is the usual method of carrying out a direct polarisation, *i.e.* the determination of sucrose, in the absence of any other optically active substance.

Dissolve the normal weight (26 grm.) of the substance (assumed to be chiefly sucrose) in a 100 c.c. flask containing some water. In general the solution will be dark, and a clarifying agent must be added, usually 1-3 c.c. of basic lead acetate solution followed by 1-2 c.c. of alumina cream. (The amount of clarifying agent should be as small as possible.) The volume is then completed to the 100 c.c. mark, any foam accumulating on the meniscus and preventing accurate reading being dispersed by blowing on it a little alcohol or ether from an atomiser.

The solution is shaken thoroughly and filtered, the first portion of the filtrate being rejected, the remainder being well shaken up again. A 200 mm. tube is well rinsed in the solution and filled. The reading observed on the saccharimeter (after correction for zero error of instrument) will give directly the percentage purity of the sample. If the whole operation has been carried out at a temperature other than 20° C. a correction of ·03° S. per 1° C. difference can be used for high grades of sugars.

§ (10) Invert or Double Polarisation Method.—The method of direct polarisation, as explained above, gives the percentage of sucrose only in the absence of other optically active substances. The double polarisation method depends upon the principle that when sucrose is hydrolysed the reaction is expressed by the following equation:

$$\underset{\text{Sucrose.}}{C_{12}H_{22}O_{11}} + \underset{\text{Water.}}{H_2O} = \underset{\text{Glucose.}}{C_6H_{12}O_6} + \underset{\text{Fructose.}}{C_6H_{12}O_6}.$$

This resulting mixture of glucose and fructose in equal quantities is termed Invert Sugar, which has a specific rotation $[\alpha]_D^{20} = -20$. It will be seen that one part of sucrose is converted to $(360/342) = 1{\cdot}05263$ parts of invert sugar.

If the specific rotation of sucrose be taken as 66·5, then the ratio of optical activity before and after inversion will be

$$\frac{66{\cdot}5}{1{\cdot}05263(-20)} = \frac{-66{\cdot}5}{21{\cdot}0526},$$

which is a *decrease* of 87·5526 in the specific rotation, and the decrease for a normal sucrose solution would be $(100 \times 87{\cdot}5526)/66{\cdot}5 = 131{\cdot}66$, so that the scale reading of a normal solution of pure sucrose would after inversion read −31·66° S.

It follows, therefore, that the decrease in the saccharimeter reading on inversion when divided by the factor 1·3166 gives the percentage of sugar originally present. This of course is only the case when no other optically active substance present is hydrolysed, and when the agent used for inversion does not influence the specific rotation of the other substances. The inversion method of determining sucrose was discovered by Clerget[6] in 1849, the inversion agent being a few c.c. of hydrochloric acid. It is necessary to warm the solution to a temperature of 68° C., and on cooling again allowance must be made for the dilution of the invert sugar by the acid. When the solution after inversion is too dark to be measured on the saccharimeter, it may be decolorised by means of filtration through animal charcoal, or by the addition of reducing agents such as zinc dust, etc., the destruction of colouring matter being due to the nascent hydrogen liberated by the action of the hydrochloric acid present on the zinc.

Unfortunately, the hydrochloric acid considerably influences the specific rotations of

fructose, raffinose, amino compounds, etc., that may be present, and the Clerget method is modified by either equalising the conditions before and after inversion with hydrochloric acid, or to use other inverting agents that do not have the objections of hydrochloric acid. Numerous organic acids have been tried, but as a whole have not been satisfactory. Kjeldahl[1] in 1881 employed yeast as the inverting agent, the active part of which is the enzyme invertase, which can be prepared by the method given by Hudson.[2]

This invertase method is probably the best of the Clerget modifications, as it has no effect on the specific rotations of substances usually present with sucrose except in the special cases where raffinose or gentianose is present.

As the temperature of a solution of invert sugar is raised, the specific rotation of the fructose is gradually decreased, whilst that of the other constituent (glucose) is not affected. Those two substances being present in equal quantities, a temperature can be reached at which the rotatory power of the one substance will exactly neutralise that of the other. This temperature is usually taken to be 87° C., and forms the basis of the method of Chandler and Ricketts,[3] originally employed for estimating the amount of commercial glucose present in cane-sugar, molasses, and honey. The saccharimeter reading is obtained by placing the solution in a water-jacketed observation tube (as described in "Polarimeter," § (17)), and circulating water from a thermostat until the reading of a thermometer placed at the central opening is steady, at 87° C.

SCATTERING OF LIGHT BY GASES, WITH SPECIAL REFERENCE TO THE BLUE SKY

§ (1) Light from the Sky.—The fact that the sky is luminous at all calls for explanation. Its light is evidently derived from the sun, as the sky becomes dark whenever the sun is far below the horizon. But why do we receive sunlight from directions away from the sun, and why is the light modified to a blue colour?

If the sky in a direction at right angles to the sun is examined with a Nicol prism, it will be found that the light is strongly polarised. The direction of vibration is at right angles to the line joining the sun to the point examined. The polarisation, though by no means complete, is very conspicuous, and could not be missed by the most casual observer.[4] Capacity to explain this effect must be a crucial test of the merits of any proposed theory of the blue sky.

All the explanations which have from time to time been given postulate some material substance which intercepts part of the incident sunlight and scatters it laterally towards the observer on the earth's surface.

This lateral scattering has always been connected with the earth's atmosphere. The blue colour seen against the dark background of a distant mountain is obviously to be attributed to the same general causes as the blue of the zenith; thus we cannot assign the latter to anything that occurs in outer space.

From many points of view fluorescence of air would seem to afford an explanation. The ultra-violet light of the sun might give rise to a lateral scattering of blue light of lower refrangibility than its own. This theory, however, is negatived by the fact that the Fraunhofer lines are present in the light of the blue sky, just as in the direct light of the sun. A fluorescence spectrum has on the other hand no connection with, or at least no detailed resemblance to, that of the exciting light. Moreover, this view leaves the polarisation unexplained. Another theory was attempted by Clausius.[5] He assumed that bubbles of water were present in the upper atmosphere, and he regarded the blue colour as an example of the colours of thin plates, produced by reflexion from the bubbles. If these are sufficiently thin the colour will be the blue of the first order. This theory, however, fails to account for the richness of

[4] The phenomenon may be used to bring the moon in its earlier phases into view at an earlier hour of the day than would otherwise be possible: the masking light of the sky being partially quenched with the Nicol.
[5] *Pogg. Ann.* lxxii., lxxvi., lxxxviii.

sky blue, nor does it meet the requirements as regards polarisation very satisfactorily. Moreover, the presence of bubbles of the required thickness is a purely *ad hoc* supposition.

The true direction in which to look for an explanation was pointed out by the experiments of Brücke.[1] He poured a small quantity of a solution of gum mastic in alcohol into an excess of water, which has the effect of producing a precipitate of the gum, in a fine state of division, and capable of remaining in suspension for a long period. If this liquid is illuminated by a horizontal beam of sunlight, the light scattered laterally will show a marked blue colour. When this is examined with a Nicol prism at right angles to the primary beam, it is found to be polarised almost completely, the vibrations of the laterally emitted, or *scattered*, light being executed in the vertical plane. If, keeping in the horizontal plane, we pass away from the rectangular direction, the percentage of polarisation becomes less, tending to vanish as the original direction of propagation is approached. The conditions of symmetry round the original beam allow us to anticipate this, since there is nothing to distinguish vertical and horizontal directions of vibration in the limiting case.

An alternative method of producing the effects was employed by Tyndall,[2] who took advantage of a peculiar property of certain organic vapours. Butyl nitrite vapour, for instance, when mixed with a little hydrochloric acid, gives a fine cloud as the result of chemical decomposition when illuminated by a powerful beam from the sun or from the electric arc, and this cloud, for a minute or two after its formation, shows the blue lateral emission to good advantage: though the present writer has never been able to get so good an approach to a pure blue sky as Tyndall's descriptions would lead one to expect. As the action proceeds the particles become larger, and the scattered light tends to whiteness. At the same time the polarisation becomes less marked. The condition for a good blue, and for nearly complete polarisation, is that the particles should be small.

§ (2) LORD RAYLEIGH'S THEORY.—Small compared to what? The answer was given by the third Lord Rayleigh.[3] They must be small compared with the wave-length of light, so that at any given moment nearly the same phase of the incident vibration prevails at all parts of the particle.

Rayleigh entered on a full theoretical discussion of the subject.[4] He showed that if the particles are regarded as small independent vibrators, with their phases at random, simple considerations of symmetry indicated that the polarisation must be as observed. The case was essentially different from that of polarisation by reflexion from a glass surface, in that the phases of the elementary vibrators in that case were not at random. It was also simply shown from the theory of dimensions that the intensity of the scattered light must be inversely proportional to the fourth power of the wave-length: thus the short waves have a great predominance, which accounts for the blue colour. From a consideration of the analogy of waves on water, it will readily be seen that a small obstacle is more effective in breaking up and scattering short waves than long ones. For a more detailed treatment of the subject, Rayleigh made use of the elastic solid theory of light. Although this theory is now obsolete, it has sufficient formal analogy with the electromagnetic theory to form a trustworthy guide. Later, the subject was rediscussed by him in terms of the electromagnetic theory.[5]

The blue colour of the sky, then, is to be attributed to the scattering of light by small particles. But of what nature are these particles? The earlier writers appealed to atmospheric dust, and Rayleigh in his earlier papers took the same view, favouring especially particles of common salt. Later,[6] he showed theoretically that the molecules of the air itself would account for the greater part of the effect. The calculation was based on the values obtained by Bouguer, who examined the transmission of sunlight to the atmosphere, for various altitudes of the sun. The light scattered laterally is missing from the transmitted beam, and hence a measurement of the absorption gives a means of estimating the amount of, or at least a superior limit to, the scattering. In the calculation referred to, it was connected with the refractive index of air, and with the number of molecules in a cubic centimetre.

Later and much more accurate results for atmospheric transmission have been obtained by Abbot working on Mt. Wilson, and knowledge of the number of molecules in a c.c. is now much more definite. Using these improved data, Schuster[7] shows that the formula gives results within 1 or 2 per cent of those observed.

It is to be remarked that this accurate agreement is only got when the observations are taken at a high altitude. The lower part

[7] *Theory of Optics*, 2nd ed. p. 329.

of the atmosphere—say the lowest mile—contains dust which adds considerably to the scattering due to the molecules themselves.

§ (3) Dust-free Air: Experimental Verification.—Thus far the investigation was carried by indirect methods. The direct observation of scattering by dust-free air followed considerably later. It was made independently by Cabannes,[1] by Schmoluchowski,[2] and by the present writer.[3] Previous workers (*e.g.* Tyndall) who had attempted the problem were discouraged by observing that the track of a powerful beam through air became apparently dark when means were taken to remove the dust by filtration. It must be remembered, however, that the effect to be expected is very faint. The thickness of air illuminated in any laboratory experiment can only be a small fraction of the height of the homogeneous atmosphere. Thus if a beam of sunlight 5 in. square were used, the intensity seen laterally should be only about $\frac{1}{50000}$th of the brightness of the sky.

Success depends not so much on increasing the intensity of illumination, or using a beam of large diameter, for the limit of what is practicable in these directions is soon reached. The point to be attended to is rather to design the apparatus in such a way that no false light interferes with the observation. If this can be achieved, then the great sensitiveness of the eye or the cumulative action of the photographic plate can be brought to bear. The principle to be used is to examine the beam, whether visually or photographically, as it passes across the mouth of a black cave. If the cave is deep enough it gives an incomparably darker background than black velvet or any other blackened surface. The arrangement used by the writer in his earlier experiments is illustrated in *Fig.* 1. The beam enters by the window A. It is delimited by the diaphragm B. It passes out at C, and is viewed laterally by means of the window D. E is the black cave which forms the background. F (diagrammatic only) is a photographic lens.

When the apparatus is filled with the ordinary dusty air of the room, the track of the (horizontal) beam is strongly marked out by the illuminated dust. On drawing a current of filtered air through the apparatus the beam appears to casual observation to become invisible. But closer examination with a well-rested eye shows its track still marked out in a faint blue luminosity.[4] Moderate filtration with cotton-wool suffices to remove all dust from the air. The use of

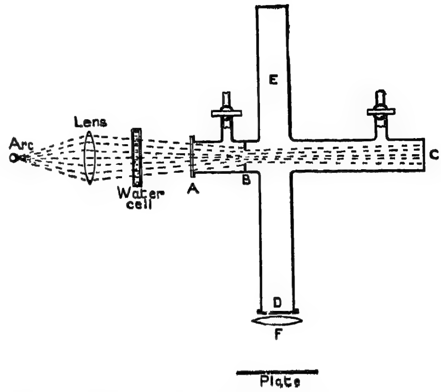

Fig. 1.—Diagram showing Arrangement of Apparatus.

a much longer and more tightly packed filter induces no further change.

§ (4) Polarisation and Intensity of the Scattered Light.—If a Nicol or double-image prism is held in front of the eye or the camera, it can readily be verified that the scattered light is almost completely polarised, the vibrations being vertical (beam horizontal) (see Plate, Nos. 5 and 6). A closer examination, however, shows that there is a slight residual defect of polarisation. The horizontal vibrations are too faint for visual detection, but can be brought out by prolonged photography. Experiments made in this way show that with air this faint component polarisation has about 4 per cent of the intensity of the strong one.

This result indicates much more complete polarisation than is found in the sky. It must be remembered, however, that that part of the sky which is at right angles to the sun is not illuminated by the sun only, but also by other parts of the sky. Moreover, the air usually contains dust particles which are not small compared with the wave-length of light. Both these causes tend to make the polarisation less complete.

As regards the slight defect of polarisation found in dust-free air, this is to be attributed to the non-spherical symmetry of the scattering molecules.

Similar incompleteness of polarisation is observed in other gases; the extreme cases

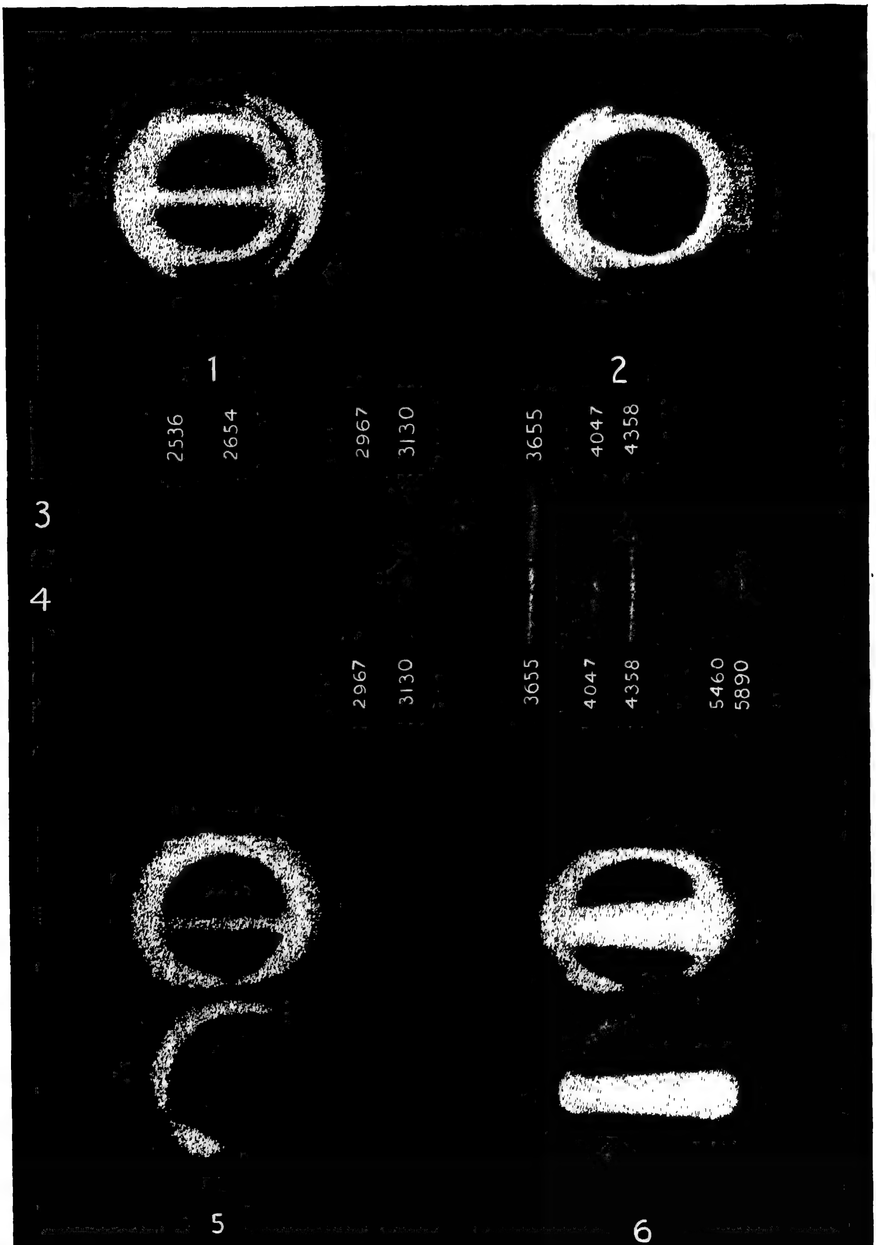
[4] Owing to a peculiarity of colour vision with faint lights, some persons are not able to recognise the colour as blue, though others feel no doubt about it. The use of colour-filters or a spectrographic examination, however, leaves no doubt that the scattered light is bluer than the incident (see description of Plate, Nos. 1, 2, 3, 4).



1. Beam in dust-free air viewed transversely. Ultra-violet filter. The oval outline is light diffused by walls of vessel. The beam is seen passing across this oval.
2. Similar conditions, except that a yellow filter is substituted. Beam very much fainter relative to light diffused by walls of vesse.
3. Spectrum of light from mercury lamp scattered by dust-free air and showing ultra-violet lines 2536 and 2654, but not the yellow and green lines.
4. Spectrum of mercury lamp direct, showing yellow line 5890 and green line 5460, but not the far ultra violet lines.
5. Beam in pure air through a double image prism. Vibrations in upper image vertical, in lower horizontal. The beam is invisible in the lower image, showing that polarisation of the scattered light is nearly complete.
6. Similar photograph with dusty air. The beams are very strong, and comparable in intensity

hitherto found are nitrous oxide, giving a weak component polarisation 15 per cent of the strong one, and argon, giving ·5 per cent for the same number. The nearly complete polarisation in argon will naturally be connected with the monatomic molecule. It is probable that data of this kind will afford a valuable clue in unlocking the secret of molecular and atomic structure. J. J. Thomson has discussed the subject from this point of view. The total intensity of scattering in a given gas is proportional to the density, and this relation has been tested in carbon dioxide at ordinary temperature up to the point of liquefaction. There is no evidence of molecular aggregation, which would result in increased scattering, up to this point. The proportionality to density affords an experimental proof that the intensities due to the separate molecules are additive, and consequently have their phases distributed at random.

The total intensity of scattering in different gases has been compared, with the result that it is nearly proportional to the square of the refractivity. This is in accordance with theoretical anticipation for a spherical molecule, an assumption which for this particular purpose seems to represent the main features of the case.

§ (5) Resonance Effects.—All that has been said so far applies to cases where the period of the incident light is very different from the free period of the gaseous molecules or atoms. With ordinary gases this condition is fulfilled, since the free periods are in the remote infra-red or ultra-violet. But in certain cases of metallic vapours it is possible to examine phenomena of resonance. R. W. Wood [1] has shown that when mercury vapour at the ordinary temperature is illuminated by light of the ultra-violet line in the emission spectrum of mercury at $\lambda 2536$, a copious scattering occurs. The scattered light is but slightly polarised, and the transition between this case and the ordinary scattering, in the absence of resonance, has not been fully traced on account of experimental difficulties.

Wood has also observed resonance in sodium vapour illuminated by D light.[2] The present writer extended the observation to the light of the ultra-violet line $\lambda 3303$, which is the member of the principal series next to the D line.[3] He also showed that illumination by $\lambda 3303$ gave rise to a secondary emission of the D line. This observation, however, belongs more properly to the subject of fluorescence.

SHUTTERS, TESTING OF PHOTOGRAPHIC

§ (1) INTRODUCTION.—The problem of accurately measuring the speeds of camera shutters has engaged the attention of a great number of investigators, but the methods evolved, though differing greatly as regards the nature and complexity of apparatus employed, are all based on the measurement of small intervals of time.

The term "speed" really denotes the total duration of exposure at any point of the plate. In the case of between-lens sector shutters this is equivalent to the total time during which the shutter leaves are open. In the case of focal plane shutters the speed is usually specified as the time taken for the opening of the blind to pass a point in its own plane opposite the centre of the plate. The duration of exposure at any other point usually has a somewhat different value owing to the variable velocity with which the blind moves. These durations in the plane of the blind differ from the intervals for which the corresponding points of the plate itself are exposed.

The speeds of ordinary shutters vary from about 1 to 1/1000 second, though some types of shutter are designed to give speeds of the order of 1 to 5 seconds. In order, therefore, that a method should give accurate results over the ordinary range of speeds it should be capable of measuring intervals of time to an accuracy of from 1/1000 to 1/10000 second. It should be noted in this connection that for most purposes it is not necessary to obtain an accuracy of, say, one per cent, since in most shutters the speed corresponding to any given setting varies considerably in successive exposures.

§ (2) MEASUREMENT OF SPEED. (i.) *Simple Methods.*—Before describing the more accurate methods of measuring shutter speeds it may be of interest to refer to one or two simple methods which do not involve very complicated apparatus. One method consists of forming an image of an illuminated pinhole by means of a lens and placing the shutter to be tested in the path of the beam of light. If, now, a photographic plate or a piece of sensitive paper is made to move with a constant definite velocity in the plane which is normal to the optical axis of the lens system and passes through the point image, a line is formed on the plate or paper, when the shutter is released. The length of the line gives a measure of the speed, provided that the velocity of the plate or paper is known. Instead of causing the plate to move in a plane it is perhaps more convenient to use a piece of sensitive paper wound round a drum, which is made to rotate at a constant rate, the axis of the drum being normal to the optical axis of the illuminating system. The accuracy of this method depends, of course, on the constancy with which the sensitive surface is moved and on the accuracy with which the motion can be determined.

A method employed some years ago consisted in photographing a bright ball forming the bob of a pendulum,[1] the ball being released from a known height and photographed in its first oscillation. A black background, with white lines drawn at distances representing equal intervals of time, was used for determining the speed of the shutter, this being given by the length of the trace of the bob image.

A simple instrument for testing shutters has recently been put on the market by a German firm under the name "Columbus."[2] It consists of a tuning-fork, giving 50 complete vibrations per second, between the prongs of which there is a small electric bulb. A sharp image of the lamp filament is formed by a microscope objective attached to one of the prongs of the tuning-fork. The instrument is set up in front of the camera whose shutter is to be tested, so that, when the fork is at rest, the image of the filament is focussed on the ground glass. A horizontal slit is inserted in front of the camera objective; when the fork is caused to vibrate, the illuminated point image is drawn out into a horizontal line. If, now, an exposure is made while the dark slide is moved downwards in the camera, a wavy line is obtained. The speed of the shutter is then determined from the number of waves formed. The instrument enables one to measure the speed for the central rays and also the difference in speed for the central and marginal rays.

Useful information on simple methods of shutter testing is to be found in recent volumes of the *British Journal of Photography*, in the German work L. David's *Praktikum*, 3rd edition, and in a paper by P. Schrott in the *Photographische Korrespondenz*, Oct. 1919.

(ii.) *More accurate Methods.*—

For more accurate determinations of shutter speeds a number of devices, such as rotating discs provided with spokes, vibrating singing flames, and tuning-forks, have been employed for giving the necessary short intervals of time. The first-named arrange-

[1] For discussions on pendulum methods of measuring shutter speeds see *Brit. Journ. of Photography*, 1906, liii.

[2] *Zeits. f. Feinmechanik*, 1920, xxviii. 58.

ment was used by Abney,[1] the spokes which project from a rotating disc being made to interrupt the beam of light which passes through the shutter. The speed of rotation of the disc is determined by means of the note given out by a siren arrangement.

Methods of measuring shutter speeds by utilising the motion of a revolving disc, containing a slit or slits, across a stationary illuminated slit, have been described by A. Kershaw[2] and J. de G. Hunter.[3] The former varies the speed of rotation of the disc until, on looking through the aperture of a shutter, the stationary slit appears to have no dark portion, indicating that the speed of the shutter is the same as the period of the rotating slit. In the case of focal plane shutters the stationary slit is arranged perpendicular to the direction of motion of the blind. Hunter's method is somewhat similar, except that he measured the length of the trace transmitted by the stationary and rotating slits. As the positions of the first and last points of the trace have to be determined, a number of exposures are necessary at each speed, and in order to keep the trace at the same position an automatic releasing device is used so that the exposure is made when one of the slits in the rotating disc comes to a certain position. The method has the advantage that photographic records can be made at the different exposures. The shutter speed is determined from the length of the trace and the speed of rotation of the disc.

Benoist[4] has utilised the vibrations of an acetylene gas flame to give equally spaced short intervals of time. An image of the flame is formed on the plate of a camera. When this is swung round during the exposures, a series of images is formed and the speed of the shutter can be determined if the frequency of the vibrations of the flame is known. One form of apparatus employed in this method is as follows. A box is provided on one face with a small burner, at the extremity of which the acetylene led into the box is lighted. The opposite face, which is formed by a rubber membrane, is fixed against an opening arranged at a convenient height in the wall of an organ pipe of known frequency. When the organ pipe vibrates under the action of suitable bellows, the flame vibrates with the same frequency. A somewhat simpler arrangement is to use a flame of acetylene emitted from the end of a pointed tube which is surrounded by a glass chimney. Such a flame "sings" and the note can be varied by altering the length of the chimney. The frequency of vibration of the flame can be determined by means of the note. One disadvantage of the singing flame method is that the trace obtained is a discontinuous one, so that the shutter speed can only be determined with an accuracy equal to the time interval of one vibration of the flame. Benoist[5] also suggests the employment of the vibrations of an electric arc run on alternating current of known frequency.

A method employed by the Eastman Kodak Company[6] consists in taking a number of photographs of the shutter during its period of operation, the time of exposure of each photograph being small in comparison with the rate of movement of the shutter. A beam of light from an arc lamp in a small projection lantern is reflected from a lightly mounted aluminium crown on which are placed 20 small plane mirrors held vertically on the face of the crown; the lantern condenser focusses an image of the arc crater at the mirror surface. The crown of mirrors is rotated about a vertical axis at a speed of 50 revolutions per second by means of a motor controlled by a centrifugal governor. The beam of light is thus interrupted 1000 times per second, a frequency which has been found most suitable for general testing. The beam is limited at the condenser by a vertical slit 2 mm. wide, the width of the beam as it flashes by reflection past the shutter opening being about 1/30 of the distance between the flashes; thus each exposure is about 1/30000 second. The reflected beam falls on a simple lens behind which the shutter to be tested is held, and a small camera lens of 90 mm. focal length forms an image of the shutter on the rim of an aluminium wheel 12 inches in diameter, around which a band of negative cinematograph film is fastened. This wheel is then rotated about a vertical axis by means of a crank and gearing at such a speed as to separate the different images of the shutter. Both the speeds and the efficiencies of a shutter may be determined by this method. For recording shutter speeds of 1/10, 1/5, and 1/2 second, the image of the shutter opening is restricted to a narrow band by inserting a 1 mm. slit in front of the box in which the moving film is enclosed. In order to save counting the hundreds of images obtained at these speeds one of the twenty mirrors may be painted black.

A very accurate method of testing shutter speeds, depending on the use of tuning-forks and vibration galvanometers, has been described by Campbell and Smith.[7] A plan of the general arrangement of apparatus employed in a modified form of the experiment is shown diagrammatically in *Fig.* 1. The light from a "Pointolite" tungsten arc

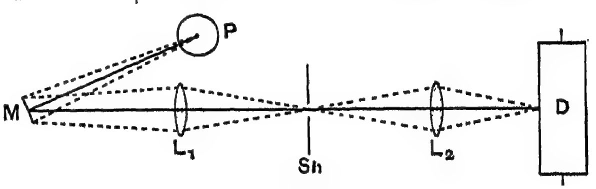

FIG. 1.

P is reflected from the mirror M of a vibration galvanometer and then passes through two lenses L_1 and L_2. A diminished point image of the incandescent tungsten ball is thus formed on the surface of a drum D which

can be rotated about a horizontal axis at any convenient speed by means of a small-power motor with variable gearing. The shutter *Sh*, whose speed is to be measured, is placed in the position where an image of the tungsten ball is formed by the first lens L_1. A piece of sensitive bromide paper is wound round the drum. When the vibration galvanometer, which is in tune with an electrically driven

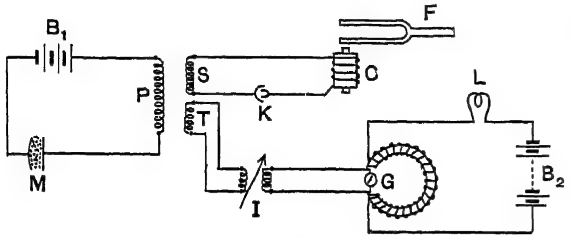

FIG. 2.

tuning-fork of known frequency, is set in action, the mirror M vibrates about a vertical axis, so that the point image on the surface of the drum is caused to vibrate in a horizontal plane. A wavy image is thus imprinted on the bromide paper when the drum is rotated. The number of waves formed depends on the total duration of exposure of the shutter and the frequency of the tuning-fork employed. When measuring the time trace which is obtained, it is most convenient to count the number of complete half-waves and estimate the end portions in terms of their projections on a line parallel to the axis of rotation of the drum. In order to get the greatest possible accuracy in determining the time intervals corresponding to these portions, it is necessary to remember that the motion of the point image is simple harmonic. By means of an easily calculated conversion table the lengths of the above-mentioned projections, expressed as fractions of the amplitude of the wave, may be obtained in terms of time intervals. In measuring the speed of a focal plane shutter a fine horizontal slit is mounted at the centre of the shutter and as near to the blind as possible; it is placed at the position where an image of the tungsten ball is formed by the lens L_1 (*Fig.* 1). In the case of speeds where the width of the slit is not small compared with the width of the blind opening, a small correction has to be applied to the result obtained, if great accuracy is required.

For testing speeds over the whole range commonly met with, it is convenient to use a number of tuning-forks giving, say, 50, 250, and 1000 vibrations per second respectively.[1] Each of these is electrically maintained in vibration and is in tune with a vibration galvanometer of corresponding frequency.

The electrical circuits employed are indicated diagrammatically in *Fig.* 2.

The primary coil P of a transformer is connected through a microphone hummer [2] M to a battery B_1 of from 6 to 8 volts. The microphone is mounted on or near the tuning-fork (or bar) so as to be set in vibration with it. The current, which is induced in the secondary coil S of the transformer by the intermittent current in the primary circuit, passes through a condenser K and a coil C which attracts one of the prongs of the tuning-fork F. A tertiary coil T of the transformer is connected through a variable mutual inductance I to the moving coil of the vibration galvanometer G; [3] the amplitude of vibration of the galvanometer mirror can be varied by altering the mutual inductance. The field of the galvanometer is maintained by the current from a battery B_2 of 100 volts, a lamp resistance L being included in the circuit. In order to get the best results the following condition should be satisfied as nearly as possible:

$$LK\omega^2=1,$$

where $\omega=2\pi n$,
L=coefficient of self induction of the secondary circuit,
K=capacity of condenser,
and n=frequency.

The method of maintaining tuning-forks in vibration by means of microphone hummers gives a good deal of trouble in practice. It is being superseded

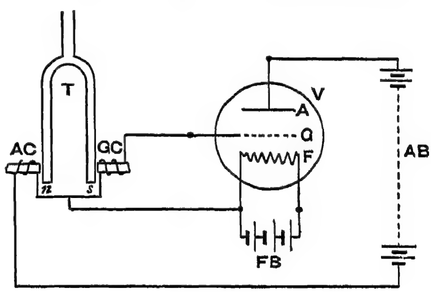

FIG. 3.

by a method which has been made possible by the recent development of triode valves in connection with wireless telegraphy.[4] The method is shown in *Fig.* 3.

[1] A vibrating cylindrical bar having a frequency of 1000 per second may be used.

[2] For information *re* microphone hummers see A. Campbell, *Roy. Soc. Proc.* A, 1906, lxxviii. 208; *N.P.L. Collected Researches*, ii. 268.

[3] A. Campbell, *Phys. Soc. Proc.*, 1905 7, xx. 626; *Phil. Mag.*, 1907, xiv. 494; *N.P.L. Collected Researches*, 1908, iv. 201.

[4] W. H. Eccles, *Phys. Soc. Proc.*, 1919, xxxi. 269; W. H. Eccles and F. W. Jordan, *Electrician*, 1919, lxxxii. 704; for theory, see S. Butterworth, *Phys. Soc. Proc.*, 1920, xxxii. 345.

The filament F of the triode valve V is heated by the battery FB. The anode A is connected through the anode battery AB and the coil AC to one terminal of the filament, and the grid G is connected to the filament through the coil GC. The tuning-fork T is permanently magnetised by an auxiliary magnet, on whose pole-pieces the coils AC and GC are wound, the poles of the fork being indicated by *n* and *s*. Suppose the fork to have been set in vibration, and consider the moment when the two prongs are moving away from their respective coils. The motion of the pole *s* will induce an E.M.F. in the coil GC which will raise the potential of the grid and so increase the current flowing into the valve at the anode. This current leaving by the filament completes its circuit through the coil AC, round which it passes in such a direction as to repel the pole *n*, and thus assist its motion. The energy necessary for keeping the vibration galvanometer in action may be tapped off from a coil placed near AC.

§ (3) Measurement of Efficiency.—In addition to the determination of speed it is sometimes necessary to measure the efficiency of a shutter at its different speeds. The method employed in the case of sector shutters is shown in *Fig.* 4. A time trace is formed on sensitive bromide paper, wound round a rotating drum D, by means of a system of lenses L_1 and L_2, as in the case of the speed test. In addition a horizontal slit S is placed in a diametral plane of the shutter *Sh* and as close to the shutter leaves as possible. This slit is illuminated by light from the same "Pointolite" lamp P as is used for the time trace, a cylindrical lens L_3 being employed to give a drawn-out image of the tungsten ball. An image of the slit is formed on the surface of the drum by means of a lens L_4; it is advisable to arrange that the images of the slit and the tungsten ball should lie on the same horizontal line. If, now, the shutter is released while the drum is rotating, a record is obtained, giving at each instant a measure of the length of slit uncovered. Such a record for a sector shutter is shown diagrammatically in *Fig.* 5.[1] The time trace may be limited to one complete revolution of the drum by inserting an auxiliary shutter, set at the necessary speed, between the lenses L_1 and L_2; the two shutters can then be released at practically the same instant. A series of measurements of the area of the shutter aperture, corresponding to different lengths of the slit opening, is then made by projecting an image of the former on to a piece of sensitive bromide paper, a fine thread being stretched across the shutter at the position occupied by the slit. Such a series of images is illustrated in *Fig.* 6, the white line in each case representing the position of the thread. From records like those shown in *Figs.* 5 and 6 a curve is constructed, giving at each instant of the exposures the area of the shutter aperture through which light passes.

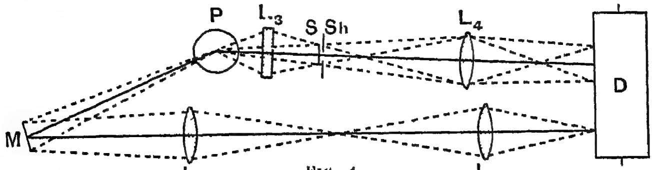

Fig. 4.

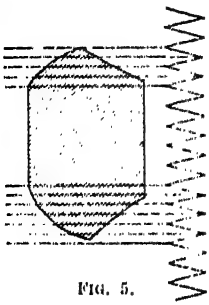

Fig. 5.

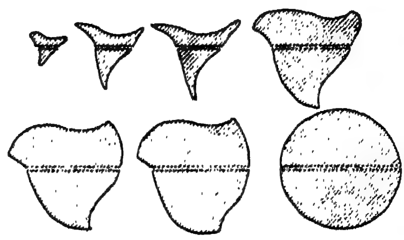

Fig. 6.

Now, if τ = total duration of exposure,
T = equivalent exposure,
a = area of shutter aperture at time t,
and A = maximum area of shutter opening,
it follows that

$$AT = \int_0^\tau a\,dt.$$

Thus the efficiency $= \dfrac{T}{\tau} = \dfrac{\int_0^\tau a\,dt}{A\tau}$.

[1] It is sometimes preferable to form the time trace across the centre of the efficiency record.

The value of the numerator is obtained by measuring the area bounded by the above-mentioned curve and the time axis. Hence the efficiency may be determined.

The efficiency of a focal plane shutter may be obtained theoretically from a consideration

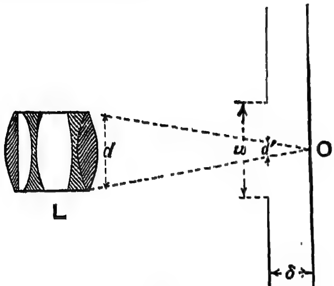

FIG. 7.

of *Fig.* 7. Let L be the lens and P the plate of a camera, B representing the roller blind. Let

w=width of opening in blind,
v=velocity of blind,
δ=distance between blind and plate,
f=focal length of lens,
d=diameter of lens aperture.

Then, using the same notation as before, the total duration of exposure τ at a point O is given by

$$\tau=\frac{w+d'}{v},$$

where d' is the diameter of the beam of light which the lens focusses at O, measured in the plane of the blind.

But $$d'=\frac{\delta}{f}\cdot d,$$

therefore $$\tau=\frac{w+\frac{d}{f}\delta}{v}.$$

On the other hand, the equivalent exposure T at O is given by

$$T=\frac{w}{v}.$$

Thus the efficiency $=\frac{T}{\tau}=\frac{w}{w+\frac{d}{f}\delta}$.

In focal plane work with moving objects the user is interested in τ, while the maker reckons to give T when he does not rely on his imagination.

By way of example we may take $v=100$ inches per sec. (a higher value than usual), for $T=1/1000$ sec., in which case $w=\cdot 1$ inch. Then, if $d=f/4$ and $\delta=\cdot 5$ inch, $\tau=9/4000$ sec.

With a more usual value of v, say 50 inches per second, $T=1/1000$ sec. corresponds to $\tau=7/2000$ sec. Thus the nominal superiority of the focal plane shutter for high speed work is largely one of nomenclature, and the difference between such shutters and good between lens shutters is less than the figures would indicate.

The method of measuring the efficiencies of sector shutters has been employed by the writer for obtaining information with regard to the motion of the blind in focal plane shutters. The shutter to be tested is mounted at S*h* (*Fig.* 4) in such a way that the length of the blind opening is at right angles to the length of the slit S. When the shutter is released, two traces are obtained on a piece of sensitive bromide paper wound round the drum D. *Fig.* 8 represents diagrammatically

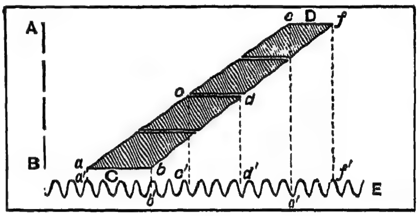

FIG. 8.

the type of record that would be obtained, on unwinding and developing the paper, in the case of a blind moving with uniform acceleration. AB is the image of the slit when the drum is at rest and the shutter is fully open; the clear spaces represent the images of fine wires stretched across the slit at certain points for the purpose of reference. A number of interesting data can be obtained from a study of the trace (CD). Let lines be drawn through the points a, b, c, d, e, and f parallel to AB, so as to cut the time trace E in the points a', b', c', d', e', and f'. Then, if we neglect the finite width of the slit image and also the distance of the slit from the shutter blind, we obtain the following results:

(i.) a' b', c' d', e' f' represent the times taken by the blind opening to pass certain points such as the top, middle, and bottom of the plate.

(ii.) a' e' and b' f' give the total times taken by the edges of the blind opening to traverse the plate.

(iii.) The slopes of the edges of the trace (CD) at any point give measures of the velocities with which the edges of the blind opening pass that point.

SILICA, as used in the manufacture of glass. See "Glass," § (4).

SILVERED MIRRORS AND SILVERING

§ (1) Historical.—Polished silver surfaces have long been used as mirrors on account of their great reflecting power. Looking-glasses made of polished silver were used by the ancients, and in more recent times similar surfaces were given parabolic forms for use as reflectors in lighthouses. Such polished surfaces were capable of reflecting about 60 per cent of the incident light, but on account of the rapid loss in reflective power, due to tarnishing, it was more common to use polished surfaces of speculum metal, which does not tarnish readily and reflects about 63 per cent of light.

The advantages of a combination of transparent glass backed by a highly reflective medium are so great that mirrors were made by pressing mercury between glass and tin foil, the two metals forming an amalgam which adhered to the glass and in time hardened. This process is in use to-day and is fairly satisfactory for flat surfaces, but it requires considerable skill to secure a surface free from blemishes; and, moreover, it is not suitable for surfaces with curvature. The process is often called "soft silvering."

The chemical deposition of metallic silver on glass as now practised probably owes its origin to Liebig,[1] who found in 1835 that a brilliant deposit of metallic silver resulted from heating an aldehyde with an ammoniacal solution of nitrate of silver in a glass vessel.

It seems, however, that a process of silvering glass without quicksilver was practised by Thomas Rogers of London as early as 1750, but no details of the method are available.[2]

Silvered glass spherical mirrors, for lighthouses, were made by Letourneaux before 1840, and the idea of silvering glass mirrors on the *face* for use in telescopes appears to have occurred to both Steinheil and Foucault independently.

Steinheil first silvered telescope mirrors in 1856, and refers to the "Liebig process," whilst Foucault's account, given in the *Comptes Rendus* of February 1857, refers to the "Drayton process." Drayton's are the first British patents on chemically deposited silver, being patents 9968/1843 and 12358/1848. Drayton used oil of cloves and grape sugar as reducing agents of an ammoniacal solution of nitrate of silver.

§ (2) Modern Methods.—From that time the records of the Patent Office show that there is scarcely an interval in which patents have not been taken out for new methods of chemically depositing silver on glass. Nevertheless, all the processes so far known are empirical ones, and there are so many conditions affecting the reaction that no hard-and-fast rules can be laid down. The most successful methods are given below.

The Rochelle salt process, introduced by Cimeg in 1861 (Patent No. 619), is almost universally used when the work is required to be silvered on the back; the "Brashear" or "Sugar" process is employed when the deposit is required on the face, as in telescope mirrors, and where the glass can be suspended face downwards in the silvering solution.

In silvering large areas of plate glass, the sheets are first washed with a solution of proto-chloride of tin and then levelled up on a warm table; the silvering solution is then poured over the prepared glass (being retained in position at the edges by capillary action) and allowed to stand until the deposit is sufficiently dense. Further applications of the solution can be applied to increase the density if necessary. The effect of the proto-chloride of tin solution is to produce a darker and more uniform deposit, and at the same time a deposit that is more adhesive and does not flake off. To procure a uniform and adherent deposit of silver it is necessary that the glass surface should be fresh. Surfaces of old standing, however chemically cleaned, do not silver well and have often to be reground and polished before a satisfactory deposit can be secured.

Plate glass known as "silvering quality," having received an extra finish, makes the best looking-glasses. *Sheet* glass usually makes mirrors exhibiting a yellow tinge, due to sulphiding from traces of sulphur acquired in the flattening *lier*; and, moreover, the deposit on a fine surface is rarely as adhesive as that on a worked one.

(i.) *Rochelle Salt Method.*—Two stock solutions are required—A and B.

Solution A: Silver nitrate, 10 grams; water, 80 c.c. When dissolved, add ammonia very slowly until precipitate is nearly redissolved. Dilute to 1000 c.c. with distilled water, and filter. Care must be taken to avoid an excess of ammonia, as on this the success of the silvering depends. Thus, before filtering, the solution should exhibit a faint brown coloration.

Solution B: Silver nitrate, 2 grams; dissolve in as little water as possible, and add 1000 c.c. of boiling water. To this, whilst boiling, add 1·66 grams of Rochelle salt (sodium potassium tartrate), and continue boiling for twenty minutes or more until the liquid is nearly clear, leaving a grey precipitate. Filter hot.

Equal parts of A and B are mixed, when silver immediately begins to deposit. Thus no time should be lost in pouring it over the surface to be silvered.

[1] *Annalen der Chemie und Pharmacie*, xcviii. 132.
[2] *Lighthouses*, Alan Stevenson, 1850, Part ii. 103.

In practice on a large scale the temperature is kept at 40° C., when a good film is deposited in about twenty minutes.

(ii.) *Brashear's or Sugar Method.*—In Brashear's process the most important thing is the sugar solution. This improves by keeping, a solution some months old being more effective than a new one. The composition of the reducing solution is as follows: 1000 c.c. distilled water, 100 grams loaf sugar; dissolve, add 100 c.c. alcohol and 5 c.c. nitric acid.

Solutions of 10 per cent of silver nitrate and of caustic potash are prepared separately, the latter one as wanted. A supply of ammonia and some very dilute ammonia are also required, the latter in order to obtain the pale brown colour of the ammoniated solution of silver nitrate that is necessary before adding the reducing agent.

Having selected a suitable dish to contain the liquid, in which the mirror can be placed face downwards with about ½ or ¾ in. of liquid underneath, find, on the basis of 1 of silver nitrate solution to 4 of the total required, the amount of silver solution needed. To this add ammonia till the first precipitate is dissolved; then add one-half of this quantity of the potash solution (this is a variation from Brashear's formula that works well); and again add ammonia till the mixed solution is quite clear, taking care to put only sufficient ammonia for that purpose; then add a weak solution of nitrate of silver till a clear brown colour is obtained. Should this become a dark brown, some of the weak solution of ammonia will bring it to a pale brown colour, which must persist.

The mirror, previously cleaned, is suspended in the dish in distilled water of sufficient amount to make up, on the addition of the solutions, the total liquid required; it is lifted out and the prepared solution mixed with the distilled water and an amount of the reducing solution equal to about one-half that of the nitrate of silver solution, more or less as the temperature is under or over 60° F.; the mirror is then immersed, beginning by dipping the edges first and lowering so as to prevent the formation of air-bubbles under the glass. The solution changes from pink to black, and in about thirty minutes sufficient silver is deposited.[1]

The thickness of the silver film suitable for telescopes has been found by Dr. Draper and Dr. Common to be about 0·0001 mm.

(iii.) *Alternative Methods.* — An alternative method to that of immersion for the application of the silvering solutions is one of spraying.[2] This is an economical process, as the two solutions are mixed almost at the moment of application. Usually the solutions are fed separately along the arms of a Y-tube, uniting in the third arm, which is under air pressure, the mixture issuing as a nebulous spray.

This method was tried, without much success, by Dr. Common in silvering large telescope mirrors, but in its modern application to searchlight mirrors silvered on the back, where the spraying is done much in the same way as paint is applied by the aerograph, and where the mirror can be rotated at about 100 revolutions per minute at the same time as it is sprayed, the process[3] has been quite successful in securing uniform films.

Mirrors silvered on the face become tarnished rather quickly unless protected from the action of traces of sulphides in the air; even then it is frequently necessary to re-polish or re-silver. With mirrors silvered on the back, protection may be given by coating the silver in various ways according to the subsequent treatment it is expected to receive. In ordinary looking-glasses the silver is first coated with shellac varnish or gold size, and subsequently given a backing of red oxide of iron paint. Other backings, containing bitumen or gutta-percha, are also used. With such protections the silver remains good almost indefinitely, defects only appearing through action of the glass on the silver, impurities left before silvering, or on exposure to the air by fracture of the backing.

§ (3) Electrical Deposition. (i.) *Searchlight Mirrors.*—Searchlight mirrors have metallic backings to protect the silver. First a coating of copper is deposited electrolytically on the silver, and frequently this receives a further backing of electro-deposited lead, which may be of sufficient thickness to form a support for the mirror in case of fracture. Such a series of layers, glass, silver, copper, and lead, is, on account of differences in coefficients of expansion, attended with disadvantages if suddenly heated, for the metallic backings expand beyond the elasticity limits of the glass and tear the silver from the glass surface, causing "blisters" to appear in the silver film. In some cases the silver adheres to the glass so intimately that a surface layer of the glass itself is torn away, producing a frosted appearance.

(ii.) *Metallic Mirrors.*—Advantage has been taken of the difference in the coefficients of expansion of metals and glass to produce metallic mirrors by electro-deposition.[4]

A glass surface accurately worked to the figure required receives a deposit of silver; this

[1] Further details of silvering glass are to be found in *The Observatory*, No. 193, 1892; *Ast. Phy. Jour.*, 1895, i. 252; *Nature*, Sept. 23, 1897, p. 505; *English Mechanic*, Feb. 3, 1911, Nov. 10 and 24, 1916; *Knowledge*, Nov. 1914, p. 402; *Conjoint Report on Silvering by the Physical and Optical Societies*, 1921.

[2] Patent 9977/1898, Barnes and another.
[3] Patent 127316/1917, Barnes.
[4] Patents 22730/1891, Lake, and 5600/1859, Cowper-Coles, 12005/1907, Cowper-Coles.

is then used as the cathode, and by electro-deposition of the required metal the mirror is built up to the necessary thickness. The whole is then subject to a sudden temperature change and the metal part sprung from the glass.

Silver cannot be electro-deposited on glass, except by first roughing the glass and preparing it with plumbago or making it conductive by other processes, *e.g.* burning gold or other metal into its surface and then using the prepared surface as the cathode.

(iii.) *Cathode Rays.*—A more recent application of the deposition of silver by electric means is by the use of cathode rays. In vacuum tubes provided with electrodes—*e.g.* X-ray tubes—prolonged discharge produces a blackening of the tube due to the deposit of a metallic film on the interior walls. In a similar way small glass surfaces have been coated with silver by this method of cathodic deposition or cathodic sputtering. The body to be coated is placed just outside the dark space surrounding the cathode and is connected to the anode. The cathode is disc-shaped or formed of a brush of fine wires, and the tube is hydrogen filled at a pressure less than 0·1 mm. mercury. Almost any metal is readily deposited on glass by this method of sputtering, and almost any degree of opaqueness can be secured.

(iv.) *Thermal Deposition.*—Thermal deposition of silver is practised by heating the metal in a small electric furnace in an exhausted vessel. The receiving surface is kept cool and brought close to the heated metal, when, as volatilisation takes place, it receives a deposit of the metal.

Mention should also be made of the method of spraying surfaces with silver. The surface to be coated is placed below an oxy-acetylene flame, into which is inserted silver wire. The glass travels to and fro under the wire or *vice versa*, and the force of the jet carries the volatilised metal on to the surface, where it condenses.[1]

§ (4) Dental Application.—One of the latest applications of silvering is in dentistry. Infected dental tissue is sterilised by treating with an ammoniacal solution of silver nitrate, which it readily absorbs. Healthy tissue is unaffected. The infected area is then isolated by a further application of formalin, which reduces the silver solution and deposits metallic silver. This fills up minute cavities, inaccessible by other means, and thus prevents further infection.

§ (5) Half-silvered Mirrors.—"Half-silvered" glass mirrors having a thin film of deposited silver have been applied to many kinds of optical instruments. Usually the film of silver is of such a density that half of the incident light is reflected and half transmitted. Such an arrangement is found in the Michelson interferometer[2] and also in a form of binocular microscope, where the light, after passing through the objective, falls on a half-silvered surface, the reflected and transmitted beams then being directed to the right and left eye respectively. Another application of the "half-silvered" surface is made in some forms of collimating gun-sights,[3] where the line of sight passes through the film to the target, whilst at the same time the eye sees, in the same optical direction, the reflection of a fiducial point contained in an attached collimator.

§ (6) Miscellaneous Applications.—To prevent loss of light in certain optical instruments it is often necessary to silver glass faces, as in prisms on which the light is incident at less than the critical angle; of these may be cited the end reflectors or pentagonal prisms, also the compound central prisms in use in many rangefinders.

A deposit of silver acting as an opaque screen has been made use of in the Abbe test plate, where a silver film on glass is ruled in such a manner as entirely to remove the metal along the rulings. The result, when seen under the microscope, is a coarse grating, with alternating opaque and transparent bars suitable for testing microscope objectives.

Next to the use of deposited silver for looking-glasses, probably the greatest commercial application is the silvering of the interior walls of vacuum flasks in order further to diminish the rate at which radiation occurs.

Glass and quartz fibres are silvered not for use as reflecting surfaces but to make them electrically conductive. In the Einthoven string galvanometer a silvered glass or quartz fibre is stretched in a strong magnetic field, the silvered fibre acting as a conductor and forming the moving system of the instrument.

§ (7) Amount of Reflection.—Steinheil, as long ago as 1857, found that freshly deposited silver reflected 91 per cent of the incident light at 45° incidence and reflection. More recently Hagen and Rubens[4] have determined the coefficient of reflection for perpendicular incidence and reflection all along the spectrum, from $\lambda 140000$ in the infra-red to $\lambda 2500$ in the ultra-violet, and find

[1] For fuller particulars see "Electrical and Thermal Disintegration of Metals," *The Chemical World*, ii. 140 *et seq.*

[4] *Ann. der Phys.*, 1900, i. 352, 1902, viii. 1, 1903, xi. 873.

that a face-silvered mirror reflects almost equally well all rays in the visible spectrum, the coefficients at λ7000 and λ4000 being 95 per cent and 85 per cent respectively. For values of reflectivity at varying angles of incidence see "Reflecting Power of Mirrors" by C. A. Chant.[1]

In the infra-red the coefficient of reflection rises to a steady 98 per cent, but there is a rapid falling off in the ultra-violet, where it diminishes to 4 per cent at λ3160, but rises to 34 per cent at λ2510. The trend of the curve, according to Hagen and Rubens, is upwards at this point, though Minor[2] finds a decreasing reflecting power beyond λ2500.

In consequence of this transmission of ultra-violet rays, silver reflectors are inadmissible in spectrographs and other instruments used for investigating the Schumann and extreme region of the ultra-violet.

Advantage has, however, been taken of this transmission band to use the silver deposit as a light filter for taking photographs in the almost monochromatic light around λ3000. (See "The Moon in Ultra-violet Light,"[3] and "Nickelled Glass Reflectors for Celestial Photography,"[4] by R. W. Wood.)

When we come to the reflectivity of glass mirrors silvered on the back—*e.g.* searchlight mirrors—there is a slight loss due to absorption and internal reflection in the glass. Measurements of the mean coefficient of reflection made at the N.P.L. in 1918 give a mean value of 88 per cent, whilst one of ten specimens attained the high figure of 94 per cent. The claim for the superiority of the gilded mirror over that of a silvered one has now been abandoned. The mean reflectivity of two such mirrors is about 70 per cent and 86 per cent respectively, but there are conditions of landscape which, under illumination from a gilded mirror, give greater contrast than when illuminated by a searchlight with a silvered mirror, owing to diminished reflection of the green rays by the gilded mirror. The same contrast effect, however, can be produced with the silvered mirror by making the observations through suitable light filters.

§ (8) Reflection of Polarised Light.—The phase change, when light is reflected in glass from a silver surface, depends upon the thickness of the silver, but for a thick film it appears to be three-quarters of a wave-length retardation.[5]

Circularly polarised light is changed to elliptically polarised by reflection from silver surfaces. Details of the change in position of the axis of the ellipse due to changes of incidence are given in a "Note on the Polarising Effect of Coelostat Mirrors."[6]

Simmance-Abady Flicker Photometer. See "Photometry and Illumination," § (98).

Sine Condition: a relationship which must be fulfilled for rays passing through different zones of an optical system in order that the defect known as coma may be eliminated. See "Microscope, Optics of the," § (12); also "Telescope," § (3), and "Optical Calculations."

Single-ray Velocity, Axis of: a direction in a biaxial crystal in which a ray undergoes no double refraction; also known as a secondary optic axis. See "Polarised Light and its Applications," § (7) (ii.).

Siren: a device for producing a musical note of given frequency, in which a disc, with a circle of holes in it, spins so that the holes are alternately opened and closed by passing a similar set of holes in a fixed plate, an air-blast giving the sound; this provides a suitable method for evaluating the frequency of an organ-pipe. See "Sound," § (53) (ix.).

"Smashing" Point of a Lamp. See "Photometry and Illumination," § (78).

Sodium Oxide, Use of, in Glass Manufacture. See "Glass," § (5) (i.).

Solids, Specific Heats of, application of quantum theory to. See "Quantum Theory," § (5); also "Calorimetry, Quantum Theory," Vol. I.

Soprano, E♭: a brass wind-instrument of high compass. See "Sound," § (44).

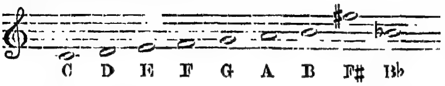
SOUND

1. Pitch, Scales, and Temperament

§ (1) Pitch and Frequency.—As the keys of a piano are struck in order from left to right, the various notes of the instrument are heard, and we pass, by a gradual transition, from the deep tones of the bass to the shriller tones of the treble. The sounds successively heard are said to be higher and *higher in pitch*, and pitch is that property of the note which determines its *position* in this musical range. It is found to depend solely on the number of vibrations per second occurring in that sound. This number of vibrations per second, or *frequency*, is accordingly adopted as a precise physical measure of the pitch. Musically, the pitch of a sound is denoted conventionally on the staff notation by the place of a certain symbol on a staff consisting of five horizontal lines and their associated spaces. The place of any staff among the pitches it is wished to

[6] *Ast. Phy. Jour.*, 1909, xxix 300.

denote is expressed by the clef at its commencement. Each such sound or note is called by one of the following letters, C, D, E, F, G, A, B. Further niceties are then expressed by the presence of a sharp (♯) or flat (♭), denoting a certain sharpening or flattening of that pitch indicated by the given position on the staff or its corresponding letter.[1]



§ (2) Interval.—When the above letters are used up the next musical sound to the right (higher in pitch) is called C again, sometimes distinguished by an accent (C′) to show that it occupies a higher place on the staff and in the sequence of possible notes. The frequency of this C′, when recognised by the musical ear as sustaining the true octave relation to C, may be shown experimentally to be just double that of C. Further, any two sounds, for which the ratio of their frequencies equals *two*, are found to have the same musical relation. They are accordingly said to be an octave apart. Or, in other words, the *interval* between them is said to be an octave. Similarly, with any other pairs of sounds which are recognised as sustaining some one definite musical relation, the *ratio* of their frequencies is a constant characteristic of and invariably associated with that relation and that only. Thus, the interval or range between any two musical sounds may be measured physically by the ratio of their frequencies, or by some other method closely linked with and dependent on this ratio. It thus follows that a large interval is measured by a ratio which is the product of those ratios which measure the small intervals of which the large one is composed. For, if three notes have frequencies in the relation 2, 3, and 4, the ratios of the small intervals are 3 : 2 and 4 : 3, while that of the whole or extreme interval is 4 : 2; and this is obviously the product of the other two. But this multiplication of ratios of component intervals to obtain that of the larger is sometimes inconvenient. For example, it does not lend itself to plotting intervals to scale, on a diagram, where the measure of the extreme interval must be the sum of those of the component intervals. To meet this need we take the logarithms of the ratios instead of the ratios themselves. Then, in the above numerical case, we have

$$\log 3/2 + \log 4/3 = (\log 3 - \log 2) + (\log 4 - \log 3) = \log 4/2.$$

That is, the logarithms *add* where the ratios multiply.

Musically, the intervals between pairs of notes are expressed by such terms as *second*, *third*, *fourth*, *fifth*, etc., corresponding to CD, CE, CF, CG, etc. To these terms various prefixes are used, such as *major*, *minor*, *diminished*, etc., to indicate the varieties possible in certain intervals though named by the same ordinal number. An alternative method for naming small intervals is the use of the terms tone (or whole tone) and semitone. Thus, the intervals CD, DE are tones, while EF is a semitone. It must not be taken to follow that CD is always exactly equal to DE, nor that EF is precisely the half of either of the above. The intervals EF, BC, AB♭ are called *diatonic* semitones; the intervals CC♯, FF♯, BB♭ being called *chromatic* semitones.

§ (3) Scales.—A scale is a series of notes proceeding up or down at certain specified intervals. These usually consist of tones and semitones, or of semitones only. Thus the following are examples of scales: (1) C, D, E, F, G, A, B, C; (2) C, D, E♭, F, G, A, B, C; (3) C, C♯, D, D♯, E, F, F♯, G, G♯, A, B♭, B, C. The first and second are diatonic scales, *i.e.* they include tones in their intervals. The third is a chromatic scale, *i.e.* it is coloured or affected by using notes not belonging to the diatonic scale. Further all the above are scales of C since they begin and finish on C, called the *keynote* of the scale, and have the notes appropriate to that scale. In the chromatic scale (3) all the intervals are called semitones (though not necessarily all equal). In the diatonic scales, (1) and (2), the intervals are either tones or semitones, but the order of their occurrence differs in the two scales. Thus in the first the order of intervals is: tone, tone, semitone, tone, tone, tone, semitone; while in the second we have as the order: tone, semitone, tone, tone, tone, tone, semitone. In the former case, the third from the keynote, CE, is called a major third and the scale a *major* scale. In the latter case, the third from the keynote, CE♭, is called a minor third and the scale a *minor* scale. These two forms of the diatonic scale are often referred to as the major and minor modes. The minor scale (2) is the ascending form of the melodic minor. The descending form would have B♭ and A♭ instead of B and A. There is also the harmonic minor which has the same notes in descending and ascending, viz.: C, D, E♭, F, G, A♭, B, C. Its intervals in ascending sequence are, therefore, tone, semitone, tone, tone, semitone, tone and half, semitone.

§ (4) Modulation.—Suppose that a piece of music began with the notes shown in scale (1) above and after a time the F was always replaced by F♯. It may then be found that the sequence of intervals is changed so that the scale in use is really that of G. For, on passing up from G, we have: tone, tone, semitone, tone, tone, tone, semitone; and this

[1] For production of sounds of various desired pitches see section "Sound Producers."

sequence is characteristic of the major diatonic scale. The piece of music is then said to have changed in key from C to G. If, on the other hand, when originally in the key of C major, after a time the E should be always replaced by E♭, the music will then have changed from the major to the minor mode, the key now being C minor. Such changes, either of key or mode, are called *modulations*.

§ (5) Intonation and Temperament.—By intonation is meant any precisely specified system of tuning the intervals in the various scales. A temperament is an intonation which, for the sake of simplicity, deliberately sacrifices some desirable exactness. The question naturally arises as to why this should become necessary. Let us examine this point carefully, having in view a keyboard instrument with notes of fixed pitches. An ideal intonation would secure three signal advantages, namely: (1) pure concords; (2) free modulation; (3) practical convenience. The first is needed to express truly the intentions of the composer and to satisfy critical ears, at any rate in slow music. The second is needed to enable the singers or players to take a piece in any desirable key and to allow of any unrestricted changes of key or mode which may occur within the piece itself. The third advantage is usually construed as being a limitation to twelve notes to the octave, though a few more may be allowable if arranged with studied simplicity. It must be remembered that the limitation of the number of notes in the octave is desirable for various reasons. Thus, if too great intricacy is entered upon, there is difficulty not only in tuning and retuning, but in playing and also in writing and reading the music.

Is there any inherent difficulty in simultaneously satisfying the above three requirements? To answer that we must find what they severally involve.

It is found by experiment that pure concords necessitate simple ratios of frequencies; that is, ratios expressible by small whole numbers. This has led to what is called *just* intonation, in which the frequencies of the notes are as follows. Any departure from these precise relations impairs the purity of the concords.

Relative frequencies	24	27	30	32	36	40	45	48
Notes	C	D	E	F	G	A	B	C′
Intervals as ratios	9/8	10/9	16/15	9/8	10/9	9/8	16/15	

In estimating the intervals by their ratios, that of the higher note to the lower is taken. The logarithms of these three sizes of intervals (which may be called the *large* tone, *small* tone, and semitone) are respectively 0·0511525, 0·0457575, and 0·0280287. Or, if we take numbers of four figures proportional to the logarithms, we have for the relative sizes of the three intervals of the just scale 5115, 4576, and 2803. Now, if we repeated these intervals throughout the scale as given above, we should have the large tone occurring three times, the small tone twice, and the semitone twice. This would give by addition a total number 30,103, to represent the interval of the whole octave from C to C′. Hence, if the notes in the scale which give concords with C are to occur at certain of the natural equal steps in a ladder throughout the octave, such a ladder would need over thirty thousand steps. And yet this, as we have seen, would be only an approximation to absolute truth.

But, for free modulation, we need to be able from any note to proceed by any interval of the scale. Further, all possible modulations must be linked up so that sharpened notes at some point or other coalesce with other flattened notes. Hence, for exactness, every step in the 30,103 would have to be provided, for no smaller numbers express the same ratios.

Thus, in the inevitable nature of things, the intonation which satisfies the first and second requirements fails utterly at the third requirement of practical convenience. Or we might equally say that what satisfies the first when limited to twelve notes in the octave, fails utterly to comply with the second.

Another and more practical way of regarding the matter is from the point of view of the violinist or violoncello player. Let two such players tune a certain string of each instrument to unison, and let one player sound that whole string while the other plays upon such a portion of that string as to give pure concords with the other. Thus, one might hold the keynote of a scale while the other in turn sounds the other notes of the scale. Let the exact *stops* (or positions of finger) on the string be marked. Then it would be found that they do not fall in with any simple subdivision of the octave into any small number of steps corresponding to equal intervals. Such equal intervals would be obtained on shortening the string by the same *fraction of its then sounding length* when proceeding to each new stop. Here lies the *root difficulty* of the whole problem. And it is *impossible* to remove it. We can but bow to it and do the best that is possible under the circumstances.

Yet another way of emphasising the difficulty and illustrating its inevitableness is as follows: Pass up from a given note, say 100 per second, in three ways, namely, by octaves, by fifths, and by major thirds. Then we obtain the following three series:

By octaves . .	100, 200, 400, 800, 1600, etc.
By fifths . .	100, 150, 225, 337½, etc.
By major thirds .	100, 125, 156¼, etc.

This at once shows that, in just intonation, no number of ascents by fifths or by major thirds will ever equal any other number of ascents by octaves, for the last immediately brings us to even hundreds, while the former two lead to odd numbers and fractions. In other words, the numbers concerned in these ratios (2, 3, and 5) are *prime* to one another.

It is therefore clear that every practical solution of the problem must be a compromise, some desirable exactness of concord being sacrificed for the sake of simplicity and convenience. And the way to find such practical solutions or temperaments is to seek some smaller number of steps in the octave such that certain exact numbers of them will give for each note of the scale a tolerable approximation to the concord sought. In all such cases the octave relation must be retained inviolate: for it is more sensitive to mistuning than any other interval (except the unison).

§ (6) THE CHIEF TEMPERAMENTS.—Such a system as described above is called a *temperament*, because in it certain intervals are purposely tempered or made to lose some accuracy of tuning in order to meet the requirements of practical convenience and allow of free modulation with fewer notes.

The only temperaments that have enjoyed any great vogue hitherto are the mean-tone and the equal temperament. But it seems desirable to notice briefly two others, viz. Bosanquet's Cycle of Fifty-three and Woolhouse's Cycle of Nineteen, as the comparison of the four places the whole subject in a clearer light.

(i.) *Bosanquet's Cycle of Fifty-three.*—This temperament is as near an approach to just intonation as could be demanded from any instrument with fixed keys. It retains a diatonic semitone exceeding the half of a tone, and even distinguishes between the large and small tones of the diatonic scale. As its name implies, it divides the octave into 53 equal parts or steps. It allots 9 of them to the large tone, 8 to the small tone, and 5 to the diatonic semitone. Its departures from the just intonation do not reach the hundredth of a tone, hence all the concords may be regarded as true. Its great fault lies here, *two* new notes are needed for each change of key to the next sharp or flat remove. This is due to the retention of the large and small tones (9 steps and 8 steps). Now from C to D the interval must be 9 steps for the key of C, but from G to A (for the key of C) the interval must be *8 steps*. Thus, when passing to the key of G, we require *9 steps* from G to A (in order to reproduce here the old interval C to D, between the keynote of a scale and its second note). Hence the first sharp remove from C to G involves *a slightly-sharpened A* as well as the usual F♯. Hence the first step towards simplicity is to drop the distinction between large and small tones as in the temperament to be noticed next.

(ii.) *Mean-tone.*—The *mean-tone*, as its name implies, uses one size of tone only, but makes it the *mean* of the large and small tones required by the just intonation. Thus, the interval C to E is made *quite true* on the mean-tone temperament, but is divided into two *equal* mean-tones. This puts the fifths (and fourths) slightly out of tune. For, as we have already seen, just major thirds never repeat so as to build up any number of just fifths. Also, since the fourth is the difference of an octave and a fifth, it is disturbed also. Still the harmony of the mean-tone was found to be wonderfully good and was preserved on organs for many years. It presented the signal advantage that only *one* new note was needed for each remove. The objection that drove it out of use was the fact that it still required so many notes to the octave for free modulation into any and every key. This was due to the retention of a diatonic semitone about three-fifths of the tone. Thus, a sharpened note really differed from that derived by flattening the note above. Hence to hear the mean-tone properly all these separate sharps and flats must be provided. But this was never done, its necessity being apparently only imperfectly understood. To realise the number of notes needed to render the mean-tone, we may note that Huygens's Cycle of Thirty-one is practically in agreement with it. Thus 31 notes to the octave are needed to give free modulation in the mean-tone, or in what is practically equivalent to it. This cycle allots 5 steps to each tone and 3 steps to the diatonic semitone, leaving 2 steps for a chromatic semitone. When organs with only five black digitals to the octave were tuned to mean-tone, only five keys could be played in beside the natural key of C. When the attempt to play in other keys was insisted upon, then notes tuned as sharps were used when flats were really needed, or *vice versa*, and disaster followed. But thirty-one notes to the octave are too many to expect on an organ and were probably never provided. Hence the mean-tone has not been really offered along with free modulation.

(iii.) *Woolhouse's Cycle of Nineteen.*—The next thing is obviously to reduce the number of steps in the octave while retaining, if possible, the diatonic semitone greater than half a tone as it should be. This was done in the proposal of Woolhouse to divide the octave into 19 steps, allotting 3 steps to each tone and 2 steps to each diatonic semitone. The first question to be asked is as to the approximation to just intonation which this cycle offers as regards the thirds and fifths. It is found to be nearly as good as the mean-tone, having true minor thirds and major

sixths, the fifths and fourths being a little out of tune. It is to be specially noticed that the sharps and flats of this temperament differ not in name only but in tuning. Further, that with nineteen notes in the octave modulation is quite unrestricted. The notes are

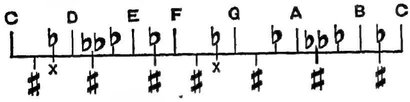


FIG. 1.—Woolhouse's Cycle of Nineteen.

shown to scale in *Fig.* 1. With this cycle it would be possible to play in the extreme keys B♭♭, F♭, G♯, and D♯ beside the usual 15 keys. For slow sustained music it should be easy enough to play on a keyboard arranged to sound this cycle. The present black digitals could be made with a front half (dull red, say) for the sharps and a back half (dull green, say) for the flats, then two shorter black digitals could be placed between E and F and between B and C. They would be the sharp of the lower note and the flat of the upper.

(iv.) *Equal Temperament.*—This familiar temperament makes the maximum sacrifice of harmony for the sake of free modulation with the minimum number of notes to the octave, viz. 12. The semitones, whether diatonic or chromatic, are just half the tones, hence only 12 steps are needed. This temperament makes the intervals of the major third and major sixth much too large, those of the minor third and minor sixth much too small. Hence the common chords in either mode are far from ideal.

(v.) *Comparison of Various Temperaments with Just Intonation.*—Much of what has preceded on the different temperaments is compactly exhibited in the accompanying Table I.

TABLE I

CHIEF MUSICAL TEMPERAMENTS AND JUST INTONATION

Names and Steps.	Scales, Intervals, Steps, and Errors.								Concords.	Keys.	Notes.
	C.	D.	E.	F.	G.	A	B.	C.			
Just—										1	7
Vibrations	24	27	30	32	36	40	45	48	All true	3	11
Intervals	0	1·02	1·93	2·40	3·51	4·42	5·44	6·00		12	20
										Free modulation	Unlimited number
Bosanquet's	0	1·02	1·925	2·49	3·51	4·415	5·434	6·00	All practically true	3	11
9, 8, 5, 9, 8, 9, 5 =53 steps	0	9	17	22	31	39	48	53		6	17
Errors	..	..	0·5♭	..	..	0·5♭	0·6♭	..		12	25*
										23	31* (51 in name)
										53*	53
Huygens's (mean-tone nearly)	0	0·965	1·93	2·52	3·48	4·45	5·41	6·00	True major third	6	12
5, 5, 3, 5, 5, 5, 3 =31 steps	0	5	10	13	18	23	28	31	Very good minor third	11	17
Errors	..	5♭	..	3♯	3♭	3♯	2♭	..		24	30
										31*	31*
	..	..	..	..	..	..	..	..	Rather flat major third and fifth	6	12
										11	17
Woolhouse's	0	0·95	1·895	2·526	3·474	4·42	5·37	6	True minor third	12	18
3, 3, 2, 3, 3, 3, 2 =19 steps	0	3	6	8	11	14	17	19	Second between D and 'D	19*	19
Errors	..	7	3·5♭	3·6♯	3·6♭	..	7♭	..			
Equal	0	1	2	2·5	3·5	4·5	5·5	6	Very sharp major third sixth, and seventh	12	12
										or 15*	12
2, 2, 1, 2, 2, 2, 1 =12 steps	0	2	4	5	7	9	11	12		or 20*	12
Errors	..	2♭	7♯	1♯	1♭	8♯	6♯	..			

* Fewer notes required for given number of keys than might have been expected. This is because in the full number of notes by *name* some are identical in pitch.

For the just intonation the numbers of vibrations in the same time are given for the various notes of the scale. Then below follow the intervals up from C expressed to the nearest hundredths of the equal temperament tones. For the four temperaments which follow, the vibrations are not given, but the intervals up from C are expressed both in equal tones and in the steps characteristic of the temperament in question. In a third line occur the errors of the temperament from just intonation expressed in hundredths of an equal tone. To give an idea what sort of interval this hundredth of a tone is, it may be noted it is that between lengths 870 and 869 of a given stretched string. This may be realised in millimetres on a monochord. Again, to make clear what the errors of a temperament mean when expressed as a change of stop on an instrument of the violin family, take Woolhouse's cycle and consider a violin string of vibrating length 13 inches (from bridge to nut). Then, if the open G string be taken as the keynote of a scale which is to be played on that string alone, the lengths of vibrating parts of string for just intonation and for Woolhouse's temperament are as follows:

	Notes	G.	A.	B.	C.	D.	E.	F♯.	G.	
Lengths	Just	13	11·56	10·40	9·75	8·67	7·80	6·93	6·50	inches
	Woolhouse . . .	13	11·65	10·44	9·71	8·70	7·80	6·99	6·50	„
	Differences . . .	0	0·09 flat	0·04 flat	0·04 sharp	0·03 flat	0	0·06 flat	0	„

(As may be seen from the foregoing table of temperaments, violin players already depart more than this when adapting themselves to the equal temperament.)

(vi.) *Chief Intervals within an Octave.*—In the accompanying Table II. are exhibited the chief intervals within an octave. The first column gives the names of the intervals, the other four columns give their values classified under the various systems of tuning, viz. just intonation, mean-tone, Woolhouse's Cycle of Nineteen, and equal temperament. In the column for just intonation the values of the intervals are expressed both in *cents* (or *hundredths* of the *semitone* of equal temperament) and in the ratio of frequencies of the higher to the lower tone of the interval. Thus, for the major third, between the notes C and E, we have the interval expressed as 386 cents and also as 5 : 4. In the other columns the ratios are not given, as they would usually be cumbrous and of very little value. In the column for mean-tone, after the values of the intervals in cents, are inserted in round brackets the values for Huygens's Cycle of Thirty-one, which are very nearly the same. The reader may be here reminded that the various intervals in Bosanquet's Cycle of Fifty-three are practically indistinguishable from those of just intonation; they are accordingly omitted from the table entirely.

§ (7) Historical Pitches.—Widely different pitches have been adopted for the scales at various times and places and for distinct musical uses. A few typical pitches, ranging over five centuries, are given in chronological order in the accompanying Table III. It will be seen from this that the church and chamber pitch began very high, fell, rose, and fell again. The representative European pitches remained with but small fluctuations for more than a century. The orchestral pitch, after remaining fairly steady for some time, rose to a climax, but a tendency to revert to a lower value showed itself in 1896, and this low or flat pitch is still often used. The pitches are specified by the frequency of the note A in the treble staff and also by the intervals in cents above an imaginary lowest pitch. It will be seen from the column of cents that the whole range of church pitches in use covers seven semitones of the equal tempered scale! The old European pitches, on the other hand, varied less than a single semitone. The same remark applies to the modern orchestral pitches, but the lowest of these latter is above the highest of the former.

II. Propagation of Sound

§ (8) Source of Sound.—Sounds have their origin in a rapid to-and-fro motion of some body, solid or fluid, which is then said to be in vibration. This vibrating body may be the string of a harp, piano, or violin, the column of air in an organ-pipe, flute, clarinet, or trumpet, the skin of a drum, the prong of a tuning-fork, or the sides of a church bell. In any of these cases the rapid to-and-fro motion thus started may spread by a wave-motion in the atmosphere somewhat as ripples spread on the surface of still water on a pond round the spot where a stone fell in. But though there is a general resemblance between the two cases, some contrasts need to be noticed. Thus, on the surface of water the spreading occurs in all horizontal directions from the central source of disturbance. Hence the ripples are *circles*. In the atmosphere (if unobstructed) the spreading is in all directions,

up and down as well as horizontal. In consequence, we have a *spherical* sound wave spreading round its central source. Again, in the case of ripples on water, though the spreading is horizontal the to-and-fro motion of the water is *partly up and down.* But, in the case of sound in the air, while the waves of sound spread by advance along any and every straight line from the origin, the to-and-fro motion of the air at any point occurs *wholly in the line* along which the wave is there advancing. For this reason sound waves are said to be *longitudinal.* Thus, while the ripples in water show crests and troughs the sound waves in air have places of compression and rarefaction. Yet a third contrast may be referred to here. The ripples are started by the stone itself; the sound waves often need the intervention of something else between them and the origin. Thus the string of a violin needs the bridge and belly of the instrument, otherwise no appreciable sound would be heard.

TABLE II

CHIEF INTERVALS WITHIN AN OCTAVE

Names of Intervals.	Values of Intervals in various Systems.			
	Just Intonation.	Mean-tone.	Woolhouse's Cycle of 19.	Equal Temperament.
Ellis's cent . . .	1/1200 of octave	..	..	One hundredth of semitone of which 12 = an octave
Skhisma (2 cents nearly)	Excess of 8 fifths and 1 major third over 5 octaves = 1·953 cents	..	..	Practically = 1/100 tone

* Numbers in ( ) refer to Huygens's cycle of 31.

Sounds may also advance by a wave motion through any other gases, through liquids (as the water of lakes or the open ocean), and through solids (as the crust of the earth itself). The speeds of sound in these different substances will be different and will also vary slightly with the state of each substance.

For mathematical and physical treatment of these cases see E. H. Barton's text-book on *Sound* (London, 1922); J. W. Capstick's

Sound (Camb., 1913); or Alex. Wood's *Physical Basis of Music* (Camb., 1913). A general account of the more important results is given in the following articles.

§ (9) Theoretical Speeds of Sound in Gases.—It can be shown mathematically that the speed of a wave motion in any suitable elastic medium is the square root of the quotient—*elasticity concerned* divided by *density*. Thus, if v is the speed of sound in a gas whose appropriate elasticity is E and density D, we have the relation [1]

$$v=\sqrt{\left(\frac{E}{D}\right)}. \quad . \quad . \quad . \quad (1)$$

Further, in the case of sound in gases the elasticity in question is known to be its pressure (P) multiplied by a factor (k) greater than unity. This factor (k) is the ratio of the two specific heats of the gas under constant pressure and at constant volume respectively. Its exact value depends upon the number of atoms in the molecules of the gas. It approaches 5/3 for a monatomic gas or vapour (*e.g.* argon or mercury vapour), it is about $\sqrt{2}$ for a gas with diatomic molecules, and is about 5/4 for gases with triatomic molecules. Thus for air $k=1{\cdot}408$ and for steam $1{\cdot}26$ nearly.

Thus, if we now write U for the volume of the gas per unit mass (this quantity being the reciprocal of the density), equation (1) becomes

$$v=\sqrt{(kPU)}. \quad . \quad . \quad . \quad (2)$$

[1] See "Vibrations of Air."

In using these equations to obtain numerical values for any gas in a specified state, the units used must be in agreement and on some definite system. Thus, if the speed is required in centimetres per second, the pressure P must be in dynes [1] per square centimetre and the density D in grams per cubic centimetre (or its reciprocal U in cubic centimetres per gram). If the speed is required in feet per second, the change could be effected by dividing the previous result by 30·48 (the number of centimetres in a foot); or, one might begin by putting the pressure in poundals [2] per square foot and the density in lbs. per cubic foot and so get the result direct in feet per second. The ratio k is a *pure number* and has no units. It remains, therefore, the same whatever system of units is in use.

Example.—To find, in cm. per second, the speed of sound in dry air at 0° C. at a barometric pressure due to 76 cm. of mercury (of density 13·6), the density of the air then being 0·00129 gm. per c.c. and the value of k being 1·408. Then we have

$$v=\sqrt{(1{\cdot}408\times 76\times 13{\cdot}6\times 981\div 0{\cdot}00129)}$$
$$=33{,}265 \text{ cm. per sec. nearly.} \quad (2a)$$

Effect of Moisture.—The ratio of the specific heats in water vapour is about 1·26 and its density is 5/8 that of dry air at the same pressure and temperature. Hence kP/D for water vapour has a value 1·43 times that for air at same pressure and temperature. The speed of sound in air is accordingly increased by the presence of moisture. This increase depends on the amount of water vapour present, and may amount to about two-thirds of a metre per second.

§ (10) Speed affected by Temperature but not usually by Pressure.—By Boyle's law the product of pressure and constant volume of a given mass of gas is constant for temperature. Hence we see from the form of equation (2) that the speed of sound in a gas is *constant if the temperature be constant, whatever the pressure may be* within ordinary limits.[3] For if P increases U correspondingly decreases so as to keep the product PU constant. But if the temperature rises, then the value of PU increases by $\frac{1}{273}$ of its value at 0° C. for every 1° C. rise of temperature. Thus, if v is the speed of sound at t° C., v_0 that at 0° C., and $(\text{PU})_0$ is the value of the product at 0° C., we may rewrite (2) in the form

$$v^2=k(\text{PU})_0\left(1+\frac{t}{273}\right)=v_0{}^2\left(1+\frac{t}{273}\right). \quad (3)$$

[1] At the sea-level in London, one gram weighs about 981 *dynes*.

[2] At the sea-level in London, one pound weighs about 32·2 *poundals*.

[3] Koch in 1907 showed that in air at 0°, but under 25 atmospheres pressure, the speed of sound was 1·008 times that in air under atmospheric pressure.

For moderate changes of temperature this becomes

$$v=v_0\left(1+\frac{t}{546}\right) \text{ nearly.} \quad (4)$$

Thus for sound in air, if we take 33,200 cm./sec. for v_0, we have

$$v=(33{,}200+61t) \text{ cm./sec. nearly.} \quad (5)$$

The equivalent approximate formula in feet per second is

$$v=(1089+2t) \text{ ft./sec. nearly,} \quad (6)$$

if the temperature be measured in degrees Centigrade.

§ (11) Theoretical Speeds of Sound in Liquids.—In the case of liquids the wave motion of sound is still a longitudinal one, as in the case of gases. The elasticity called into play is also, as in gases, the volume elasticity or bulk modulus. But it is no longer easily obtained from the pressure, as for gases. On the contrary, the elasticity for a liquid must be found for each case from the experiments on it that have been made by recognised workers in this domain. Let the value of this elasticity be denoted by K for a given state of some liquid, and let M denote its reciprocal called the compressibility, then we have for the speed of sounds in the liquid the equation

$$v=\sqrt{\left(\frac{\text{K}}{\text{D}}\right)}=\sqrt{\left(\frac{1}{\text{MD}}\right)}, \quad (7)$$

where D is the density of the liquid.

Often, in tables on the subject, the *compressibility* of liquids is given. Thus for water at 1-25 atmospheres pressure and 15° C. Amagat found the compressibility to be $48{\cdot}9\times 10^{-12}$ for an increase of pressure of one dyne per sq. cm. The density of water at 15° C. is 0·99912 gm. per c.c. Thus the value of the speed of sound in it would be given by

$$v_{15}=\sqrt{\left(\frac{10^{12}}{48{\cdot}9\times 0{\cdot}99912}\right)}$$
$$=143{,}166 \text{ cm./sec. nearly.} \quad (7a)$$

If the density be taken at 8° C. as 0·9999 gm. per c.c. and the elasticity be supposed to remain practically constant, we should have

$$v=\sqrt{\left(\frac{10^{12}}{48{\cdot}9\times 0{\cdot}9999}\right)}$$
$$=143{,}000 \text{ cm./sec. nearly.} \quad (7b)$$

It may be seen that although the much greater density of water than air tends to lessen the speed of sound in it, the still greater disparity of their elasticities overcomes that drawback. Thus the speed of sound in water is over four times that in air.

§ (12) THEORETICAL SPEED OF SOUND IN SOLIDS.—Suppose first that the solid is only a *rod*, and therefore quite free to shrink laterally where stretched and to bulge where compressed lengthwise. Then if Y denotes the value of Young's modulus [1] for the material of the rod and D its density, we have the following expression for the speed of sound in it:

For a solid rod,

$$v=\sqrt{\left(\frac{Y}{D}\right)}. \qquad (8)$$

As an example consider brass, for which $Y=10^{12}$ dynes per sq. cm. and $D=8\cdot4$ gm. per c.c. nearly. Then

$$v=\sqrt{(10^{12}\div8\cdot4)}$$
$$=345{,}033 \text{ cm./sec. nearly,} \qquad (8a)$$

or over *ten* times the speed in air.

For an extended solid like the crust of the earth, where there is no freedom for bulging sideways at places compressed endwise, a quite different relation holds. In this case let K be the bulk modulus or volume elasticity and N the rigidity (or shape elasticity). Then the expression for the speed of sound takes the form:

For an extended solid,

$$v=\sqrt{\left(\frac{K+\frac{4}{3}N}{D}\right)}. \qquad (9)$$

Suppose an extended mass of brass existed, and let it be required to find the speed of sound in it. Then, taking the value of K to be $10\cdot65\times10^{11}$ and N to be $3\cdot5\times10^{11}$, each in dynes per sq. cm., we obtain

$$v=\sqrt{\{(10\cdot65+\tfrac{14}{3})10^{11}\div8\cdot4\}}$$
$$=427{,}061 \text{ cm./sec. nearly.} \qquad (9a)$$

It may be noticed that the value of the speed for the extended solid is in this case nearly 5/4 of that in a rod of the same material.

§ (13) EXPERIMENTAL DETERMINATIONS OF SPEED OF SOUND IN AIR. PARIS, 1738.—The earliest exact determination of the speed of sound in the open air seems to have been made in 1738 by members of the Paris Academy. The stations used were the observatory at Paris, Montmartre, Fontenay-aux-Roses, and Montlhéry, involving a total distance of about 18 miles. The experiments were made at night by firing cannons alternately at the two end stations. The calculations depended upon seeing the flash and hearing the report at the other stations. Then the distance in question divided by the time elapsed between the receipts of the flash and the report gave the first rough value for the speed sought.

The time required by light to cover this distance is justly neglected, since the speed of light is about 186,000 miles per second. The experiments were continued for some time under different conditions of the atmosphere as to wind, temperature, barometric and hygrometric states.

The conclusions arrived at from these investigations may be stated as follows:

(i.) The speed of sound is independent of air pressure.

(ii.) It increases with the temperature of the air.

(iii.) It appeared to be the same at each distance from the source.

(iv.) The speed of sound with the wind is the sum, and against it is the difference, of the speeds of sound and of the wind.

(v.) The speed of sound in still dry air at 0° C. (deduced by Le Roux from above experiments) is 332 metres per second.

Four of the above conclusions have been confirmed by other workers at various times and places and under very diverse conditions.

§ (14) SPEED OF SOUND IN AIR INCREASES WITH INTENSITY.—The one conclusion that cannot be accepted to-day for ordinary conditions is the third. This would make it appear that the speed of sound is independent of the intensity. It might not have varied appreciably in the experiments in question so far as the stations used permitted an analysis of the matter. But it is now known that with sufficiently great intensities the speed is appreciably increased. This was shown in 1864 by Regnault at Versailles by experiments in the open air, two distances, 1280 and 2445 metres, being used, and reciprocal firing of guns adopted. The instants of firing and of receipt of the sound were electrically recorded, and the following results were obtained:

For the distance of 1280 metres, $v_0=331\cdot37$ m. per sec.

For that of 2445 metres, $v_0=330\cdot7$ m. per sec.

Hence by these experiments it is shown that nearer the gun, where the sound is more intense, the speed is slightly greater. This is in accord with theory. For when the sounds are sufficiently intense the temperature in the compressions is appreciably raised, and the speed increased accordingly

This increase of speed with intensity of the sound is well shown by the photographs of bullets in flight, due to Professor C. V. Boys, taken in London in 1892 (see *Fig.* 2). If a projectile moves much quicker than the normal speed of sound, the air in front of its nose is highly compressed and so heated until the appropriate speed of sound is that of the bullet. So then the bullet has in front of it and round its sides a shell of compressed air like the breast wave round a swan when

[1] This is the quotient of stretching force per unit area divided by elongation per unit length. See also "Vibrations of a Rod."

advancing in still water. In each case, the quicker the motion of the object through the medium the sharper will be the advancing nose of the wave. Further, in each case, the relation of the speed of the moving object

FIG. 2.—Boys's Photograph of Bullet in Flight.

to that of the normal waves in the medium can be ascertained from the geometry of the breast wave.

§ (15) EXPERIMENTAL DETERMINATION OF SPEED OF SOUND IN WATER.—The classic experiments on the speed of sound in water are those by Colladon and Sturm carried out in 1826 in the Lake of Geneva. The stations were two boats moored at a measured distance apart. From one a bell hung in the lake and was sounded by a lever whose upper end by the same motion fired some gunpowder, thus signalling to the other boat the instant when the sound started. The sound travelling through the water was received at the other boat by a funnel whose mouth was below in the water and upper end applied to the observer's ear. The mean temperature was estimated as 8°·1 C., and the speed found was 1435 metres per second.

It may be noticed that the theoretical result calculated earlier is in fair agreement with this, especially when it is considered that the water in the open lake must be very different from that experimented upon in the laboratory for its compressibility.

§ (16) SPEED OF SOUND IN WATER INCREASES WITH INTENSITY.—Threlfall and Adair published in 1889 their experiments on the speeds of sound-waves from explosions under water in Port Jackson harbour, Australia. Charges of gun-cotton were used; the firing was electrical and gave a signal on a chronograph, on which also was recorded the instant when the sound reached an india-rubber diaphragm immersed at the far station 150 metres or more distant. The normal speed for feeble sounds in the water was calculated to be about 1500 metres per second; the observed speed of the explosion wave from 9 oz. of gun-cotton was 1732 m./sec., and from 64 oz. of gun-cotton was 2013 m./sec.

§ (17) EXPERIMENTAL DETERMINATION OF SPEED OF SOUND IN IRON.—For this purpose Biot used 376 cast-iron pipes with a total length exceeding 950 metres. A bell at one end was struck and its sound travelled through the iron walls of the pipes as well as through the air inside them. At the far end the sound through the iron was received first and that through the air arrived at a measurable time, t seconds, later. Hence, if the total length of the pipes is L cm., the speed of sound in cast-iron u cm./sec., and that in the air inside the pipes v cm./sec., we have for the times of travel through air and through iron L/v and L/u respectively. But their difference is t. Thus

$$\frac{L}{v}-\frac{L}{u}=t,$$

whence

$$u=\frac{Lv}{L-vt}.$$

The value thus found for cast-iron was about 350,000 cm./sec. or 3500 metres/sec.

§ (18) REGNAULT'S DETERMINATION WITH ROUGH PIPES.—This determination was the result of an elaborate set of experiments carried out with the water-pipes newly laid in Paris in 1862–63. A pistol, explosions, and musical instruments were used as sources of sound, the method of measuring time being electrical. The shot broke that part of an electrical circuit just in front of the pistol, thus causing a shift of the mark traced on a smoked rotating drum. This shift registered the start of the sound on its course along the air inside the pipes. The sound on reaching the far end of the pipe moved a very fine membrane. This made an electric contact and so completed a circuit, thus causing the reversed shift of the mark on the drum. Side by side with this mark were (1) a set of dots indicating seconds given by a pendulum, and (2) a wavy trace due to a tuning-fork. Thus the time elapsing between the start and arrival of the sound (corresponding to the length on the mark between the first and final shifts) was measured in seconds by the dots

and in thousandths of a second by the wavy trace. Regnault tried to allow for the time lag of the membrane, which was greater for feebler sounds. The length of the pipe divided by the correct time gave a quotient which represented the speed of the sound under the experimental conditions. The pistol was inserted at the beginning of the pipe, which was there closed by a disc, and the far end was closed by the membrane. Thus the sound could pass to and fro several times, suffering partial reflections at the ends. Pipes of three diameters were used and a number of lengths tested. The variations of speed with length and diameter are shown in the accompanying graphs of *Fig.* 3.

From these curves it may be seen (1) that the speed of sound tends to a lower limit when very feeble owing to the great distance traversed,

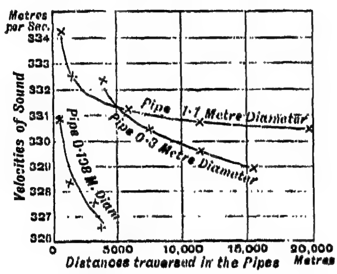

Fig. 3.—Regnault's Speeds in Pipes.

and (2) that this limiting speed is greater in wide pipes than in narrow ones. Regnault considered that in the pipe of 1·1 metre diameter its sides were practically without effect. He therefore gave 330·6 metres per second as the speed of sound in air at 0° C. in an infinitely wide pipe (or, by taking the sound in its feeblest state, 330·3 m./sec.). The humidity of the air in these experiments on pipes was observed and corrected for. Rink by a special analysis of Regnault's results deduced the value 330·5 m./sec. for the speed of sound through air in a pipe 1·1 metre diameter.

In other experiments Regnault failed to detect any difference in the speed of sound, although the pressure was increased to more than five times its first value (viz. from 247 to 1267 mm. of mercury).

Violle and Vautier, in 1905, by experiments on pipes, found that within the range of frequencies from about 32 to 640 vibrations per second the speed of sound in air does not change by one-tenth per cent.

§ (19) Blaikley's Determination with Smooth Pipes.—This account of researches in the speed of sound through air in smooth brass tubes was published by D. J. Blaikley in 1883–84. He felt that in any open-air experiments the results were usually vitiated by uncertainties as to mean temperature and hygrometric state of the air over the range in use. Further, he noticed that in Regnault's experiments with pipes the decrease of speed there found would, if extended to the diameters used in brass instruments (in which Blaikley was specially interested), lead to smaller values than those actually experienced. This discrepancy is attributed to the roughness of Regnault's pipes. Blaikley also feared that the membrane used by Regnault might lead him to an underestimation of the speed, and this surmise was then supported by special experiments. Dulong, in 1829, had estimated the speed of sound by experiments on organ-pipes specially chosen as giving a tone of good musical quality. To this Blaikley objected, because such a tone consists of the prime (or fundamental) accompanied by a retinue of fainter overtones of frequencies double, treble, quadruple, etc. that of the prime. Now these overtones, when elicited *separately*, have frequencies slightly different in value from the exact double, treble, etc. of the prime frequency. Then, on blowing the pipe, these naturally inharmonious overtones are forced into the strict relation to the prime expressed by the ratio numbers 2, 3, 4, etc. But this forcing into tune of the overtones and their prime does not operate solely by changing the overtones, but also may *slightly disturb the prime itself* in arriving at the requisite adjustment. The prime tone is in consequence slightly different in pitch from that which, without such constraint, corresponds to the true speed of sound and the wave-length under consideration. Hence, from the length of the pipe and this constrained pitch a vitiated speed of sound would be inferred.

In view of the above criticisms Blaikley preferred to experiment with a special form of pipe which resembled the glass chimney of an oil lamp instead of being parallel throughout as is an ordinary organ-pipe. That is to say, the pipe used has a bulb or pear-shaped portion in the first quarter wave-length near the mouth. Beyond the bulb there was a considerable length of parallel cylindrical pipe in which worked a sliding plug. This pipe, when blown, gave the fundamental or prime tone alone. Consequently its pitch was not disturbed by being blown into tune with any overtones, as these were entirely absent. The blast was obtained from a fan, the wind from which passed a regulating bellows. The bellows pressure was 2·5 inches of water column, and that in the mouth less than 0·1 inch of water, much under the lowest which Regnault had found to alter the speed. Both the temperature and humidity of the air were observed. The pitch was taken from

a Koenig fork of 256 vibrations per second and the pipes were set to give a beating rate of about four per second, the lengths being gauged by standard rods and a micrometer.

Experiments were made with smooth brass tubes of five sizes, the frequencies of the tones ranging from about 131 to 323 per second. The results are shown in Table IV.

Blaikley's values show that the diminution of speed is proportional to the reciprocal of the diameter of the pipe. They also favour the view that it is proportional to the reciprocal of the square root of the frequency of the tone sounded in the pipe.

Blaikley applied to the above mean values obtained in Paris (*a*) in the open air and (*b*) as deduced from pipes.

§ (20) Hebb's Telephone Method for Speed of Sound.—In 1904 T. C. Hebb made a very careful determination of the speed of sound in air by use of parabolic reflectors and telephones. No pipes were used, as they were regarded as introducing complications. All long-distance methods were objected to on the following grounds:

(*a*) Very loud sounds must be used, so possibly involving a different speed near the source.

(*b*) It is almost impossible to correct accurately for wind, temperature, and humidity over long ranges.

Table IV

Mean speeds for each diameter . . .	m./sec. 324·383	m./sec. 326·90	m./sec. 328·78	m./sec. 329·72	m./sec. 330·134
(Probable errors of mean speeds, added by writer in 1921).	..	m./sec. $\pm 0{\cdot}037$	m./sec. $\pm 0{\cdot}013$	m./sec. $\pm 0{\cdot}035$	m./sec. $\pm 0{\cdot}046$

(The probable errors were not given by Blaikley himself, but have been added for the present work to show how accurate this investigation is and how closely it may be trusted. If the probable error be both added to and taken from the mean value to which it applies, limits will be obtained between which the true value is as likely to lie as to be outside of them.)

of the speed for each sized pipe a modification of Helmholtz's formula in order to calculate the speed of sound in free air. He thus deduced the mean value

$$v_0 = 331{\cdot}676 \text{ metres per second}$$

as his final determination for the speed of sounds of feeble intensity in dry open air at 0° C. (To this we might now add a probable error of $\pm 0{\cdot}04$ m./sec.)

The corresponding value for the ratio of specific heats for dry air was $k = 1{\cdot}4036$.

For purposes of application to brass instruments this investigation must be regarded as the standard of appeal, since it was obtained by direct use of such tubes. Further, the speed deduced for the open air, though obtained indirectly, must be regarded as of extremely high value. It is seen to lie between the two values already quoted, as

(*c*) The *lag* (or *personal equation*), either of a human operator or of some recording device, is involved.

In accordance with these principles a novel method was adopted by which it was hoped all the above drawbacks could be obviated. The experiments were carried out in a room 120 feet long, with a whistle as the source of sound and blown so steadily as to maintain its frequency to an accuracy of 1 in 5000. This source was placed at the focus of a parabolic mirror made of plaster of Paris. From the mirror proceeded a parallel beam of sound waves along the room to a second similar mirror which converged them to its focus. At the source of sound was a telephone transmitter connected to a battery, and to *one of two primaries* of a special induction coil. At the focus of the second mirror was another similar telephone transmitter, also

connected to a battery and to the *other primary* of the induction coil. The *secondary* of this induction coil was connected to a telephone receiver. Suppose the whistle to be sounding and the mirrors to be such a distance apart that the sound heard from the telephone receiver is a maximum. Then the effects of the two primaries of the induction coil must be in such relation as to make their combination most powerful, *i.e.* their vibrations are in the same phase and so are mutually helpful. Now let the distance between the mirrors be changed till the sound from the telephone receiver is a minimum. Then the primaries must be just opposite in their effects now. If the separate effects, which could thus be made additive or subtractive for different distances, were practically equal, then the minima effects would be reduced almost to zero, and the corresponding positions could be accurately observed. Let the frequency of the whistle be N per second and its period, or time of one complete vibration, be T second. Then, if the speed of sound in air is v and the distance in air passed over by sound in one period is L cm., we may write

$$v = \frac{L}{T} = NL.$$

The length L is called the *wave-length* in air of the sound used. And it may be seen that it is on changing the distance between the mirrors by *half the wave-length* that we change the effects of the two primaries from the complete additive to the complete subtractive relation, and so change the result heard from maximum to minimum. Hence, by locating a number of successive maxima and minima the wave-length L was found. In this determination an accuracy of about one in a thousand was reached.

The determination of the pitch of the whistle was made by tuning it in unison with a fork which was itself compared with a 512 fork by wavy traces on a smoked disc. The 512 fork was compared in the same way with a pendulum, and then the pendulum with a clock.

Thus knowing L and N, their product gave v the speed of sound sought. The final determination for the speed of sound in dry air at 0° C. was

$$v_0 = 331.29 \text{ metres per second,}$$

with a probable error of ± 0·04 m./sec.

§ (21) Speeds of Sound in Various Media.—The foregoing, together with other determinations of the speeds of sound in

§ (22) Architectural Acoustics. (i.) *Sabine's Work.*—It is well known that some churches, halls, theatres, or other buildings are acoustically unsatisfactory. They prove trying to the speakers or musical performers, to the audience, or to both. Others are good for speech but bad for music, or *vice versa*, while yet others may be acceptable for both speech and music. The principles and problems underlying the successful design or remedial treatment of any auditorium to be used for a specific purpose for long failed to receive the attention which, from the importance of the subject, they deserved; but considerable progress in this direction has been made during the present century.

The sounds uttered by a speaker or musical instrument reach the auditor somewhat enfeebled by the distance passed over, but have, on the other hand, various echoes, reverberations or distortions added to them by the floor, walls, ceiling, furniture, and occupants of the room. Thus two questions accordingly present themselves for quantitative treatment: (*a*) What, if any, enfeeblement or additions are desirable in the case of speech, song, and instrumental music? (*b*) How may those desired effects be realised with approximately quantitative accuracy? The subject has been investigated along both these lines by the late W. C. Sabine, who states:[1] "In order that hearing may be good in any auditorium it is necessary that the sound should be *sufficiently loud*; that the simultaneous components of a complex sound should maintain their *relative intensities*, and that the *successive sounds* in rapidly moving articulation, either of speech or of music, should be *clear and distinct*, free from each other and from extraneous noises." These three are the necessary and sufficient conditions for good hearing. Scientifically, the problem involves the absence (*a*) of *prejudicial enfeeblement*, (*b*) of *distortion* of quality of sounds, and (*c*) of too *prolonged reverberation*. From the constructive point of view the problem involves the *size* and *shape* of the auditorium and the nature of the *materials* (including the audience itself) whose surfaces are exposed to the sounds.

(*Ibid.*) "Sound, being energy, once produced in a confined space, will continue until it is either transmitted by the boundary walls or is transformed into some other kind of energy, generally heat. This process of decay is called absorption. Thus, in the lecture-room of Harvard University, in which this investigation was begun, the rate of absorption was so small that a word spoken in an ordinary tone of voice was audible for 5·5 seconds afterwards. During this time even a very deliberate speaker would have uttered twelve or fifteen succeeding syllables. Thus the successive enunciations blended into a loud sound, through which and above which it was necessary to hear and distinguish the orderly progression of the speech. Across the room this could not be done, nor even near the speaker, except with an effort, wearisome in the extreme if long maintained. With an audience filling the room the conditions were not so bad but still intolerable."

"This may be regarded as a process of multiple reflection from walls, ceiling, and floor, losing a little at each reflection until ultimately inaudible. This phenomenon will be called reverberation, including as a special case the echo. In general, reverberation results in a mass of sound filling the whole room and incapable of analysis into its distinct reflections. It is thus difficult to recognise and locate. In the general case of reverberation we are concerned only with the rate of decay of the sound. This rate of decay was gauged by measuring what is inversely proportional to it the duration of audibility of the reverberation or residual sound.

"Broadly considered, there are two, and only two, variables in a room shape (including size), and materials (including furnishings). In designing an auditorium an architect can give consideration to both; in repair work for bad acoustic conditions it is generally impracticable to change the shape, and only variations in materials and furnishings are allowable."

To test the effects of absorption Sabine tested a lecture-room at Harvard empty, without and with cushions. With an organ-pipe as source of sound and a chronometer for timing the duration of audibility after the sound had ceased, he found a time of 5·62 seconds in the absence of cushions. With 8·2 metres of cushions this time fell to 5·33 seconds, and with 17 metres of cushions it fell to 4·94 seconds. With all the seats (436) covered with cushions the time of audibility was only 2·03 seconds. By covering the aisles and platform and placing other cushions on a scaffold till the whole number available (1500) were in use, the duration of audibility fell to 1·14 seconds.

Sabine found that the above duration of audibility of the sound in a room was directly proportional to the total volume of the room, and inversely as the total absorbing power of room empty plus that of audience. Or we may write

$$t = c\frac{V}{R+A},$$

[1] *Sci. Abs.* A, 1915, p. 194.

where t is the time, c is a constant (depending on the units in use), and may be taken as about 0·16 when the metre is the unit of length, or 0·05 when the foot is the unit of length, V the volume of the room, R its absorbing power when empty, A the absorbing power of the audience.

(ii.) *Halls in Paris.*—Marage tested the acoustic properties of six halls in Paris [1] and quoted Sabine's formula as applicable. "In the largest of these halls, the Trocadero, holding 4500, the mean time of resonance was 2 sec. when empty and 1·4 sec. when full. To make himself distinctly heard in this hall a speaker must use a slow utterance, pausing at each phrase. But it was not necessary to use more energy than in addressing 250 in the Physical Theatre of the Sorbonne. In the large theatre of the Sorbonne, holding 3000, the resonance extended almost to 3 sec. empty, but was only 1 sec. or less when full. The acoustic properties of this hall were considered very good."

Marage agreed with Sabine that this time of resonance serves to characterise the acoustic properties of a hall. He found that this duration of the sound varies with the quality, pitch, and intensity of the primary sound; hence a hall good for a speaker may be bad for an orchestra. For a hall to be good acoustically Marage considered that the duration of the resonance should be practically constant at all parts of the hall, for all vowels, and fall between half a second and a second. If the duration of the resonance much exceeds a second, the speaker can make himself understood only by speaking very slowly, articulating distinctly, and avoiding giving to the voice too much energy.

(iii.) *Jaeger's Treatment.*—G. Jaeger carried the treatment of the subject a step further by studying the growth, maximum, and decay of the intensity of sound in a room.[2] He showed that E, the intensity of sound per unit volume in a room, while the source was sustained constant, grew according to the law

$$E=\frac{4P}{vaS}(1-e^{-kt}),$$

where P is the power of the source, v the speed of sound in the air of the room, a the mean absorption coefficient (ratio of absorbed intensity of sound to that falling upon it) of the surfaces in the room (walls, floor, ceiling, audience, etc.), S the total area of these surfaces, $e=2·7183$, $k=vaS/(4$ volumes of room), and t is the time from commencement of sound at source.

Thus the maximum value of E would be $4P/vaS$. The decay of the sound when the source became silent would be given by

$$E=\frac{4P}{vaS}e^{-kt},$$

where t is now the time from cessation of sound at source.

The value of the product aS, occurring in these formulae, is the sum of a number of like products, say $a_1S_1+a_2S_2+a_3S_3$, where a_1, a_2, a_3, etc., are the absorption coefficients for surfaces of areas S_1, S_2, S_3, etc., respectively.

The formulae show that the greater the product aS, the *smaller* is the maximum energy that can be attained in the room by a source of fixed power P, but that the rise to this maximum is *quicker* and the decay *more sudden* also; though these times of rise and fall depend upon the *volume* of the room as well.

(iv.) *Watson's Investigations.*—In 1913 F. R. Watson published an account of a case in which the ventilating arrangements were held to assist the acoustics of the room under notice, namely, the Baltimore Academy of Music.[3] In this hall "the whole supply of fresh air was admitted at the back of the stage, was there warmed, then crossed the stage horizontally *above* the speakers, actors, or musicians, passed through the proscenium, and then, somewhat diagonally toward the roof, across the auditorium in one grand volume and with gentle motion so as almost entirely to prevent the formation of minor air-currents. It was exhausted partially by an outlet in the roof and partly by numerous registers in the ceilings of the galleries. The acoustics of this auditorium were considered excellent. The weakest voice was audible to every seat in the house; sounds such as a sigh, a kiss, or even the simulated breathing of the somnambulist, might be heard in the most distant parts; and all musical effects were exactly appreciated. All singers and speakers agreed in describing the facility with which the voice was used on this stage." It was stated that haphazard currents of air or those intervening between the speaker and the audience are detrimental, and should be avoided.

Later, F. R. Watson described his acoustic treatment of the faulty auditorium at Illinois.[4]

This room was dome-shaped and had many subordinate curved surfaces, which focussed the sounds in an objectionable manner. It seated 2200 and originally showed a reverberation of 9 seconds. After some treatment

[3] *Eng. Record*, 1913, lxvii. 265-268; *Science Abstracts*, A, 1913, xvi. 330.

[4] *Univ. of Illinois Bull.*, 1914, xi. No. 73, 3-29; *Science Abstracts*, A, 1914, xvii. 540.

the mean time of reverberation determined from 400 observations was 5·9 seconds, whereas, calculated by Sabine's formula (volume of room 11,800 cubic metres), this time came out as 6·4 seconds. Thick carpets were placed on the stage, a large canvas painting (400 square feet) was introduced, and the glass removed from the skylight in the ceiling. This reduced the time of reverberation of the hall when empty to 4·8 seconds. When quite full the hall showed a still shorter reverberation which was not troublesome. Pronounced echoes, however, still gave trouble. These were prevented by draperies hung in the dome. A sound-"board" was constructed of plaster in a paraboloidal form and acted well for a single speaker, but was objected to by some on account of its appearance. Further, it was useless for a chorus or band, and was accordingly discarded. The auditorium was finally corrected by installing a calculated amount of hair felt on walls that produced echoes. A decorative cloth was applied over the felt to give a pleasing appearance.

Watson afterwards treated the armoury at Illinois.[1] This room presented an unusual case of defective acoustics because of its huge volume and small absorbing power. It was built to fulfil the usual requirements of an armoury in regard to military drills; but, in addition, it had been used occasionally for other large assemblies. The acoustics proved impossible for speaking and music. The room is 400 feet by 212 feet by 93 feet high at the centre of the roof, which is almost semicircular (and thus forms a reminder of the roof of St. Pancras Station, London). Calculated by Sabine's formula the time of reverberation, when empty, was 24 seconds. It was now seen why attempts with a special megaphone, parabolic reflectors, and loud-speaking telephones had all failed.

The final and successful treatment lay in the introduction of canvas curtains to enclose a space 212 feet by 134 feet by 34 feet high. The time of reverberation in this enclosure for an audience of 4500 was then estimated to be 1·1 second. The arrangement was carried out and auditors in all parts of this space could hear and understand the various speakers.

(v.) *General.*—Large, bare, unbroken wall spaces of stone, brick, or plaster may produce objectionable *echoes* and are to be avoided whenever possible in a room intended for speaking or rapid music. Roughnesses or recesses in the walls only count when their size is comparable to the wave-length of the sounds in use. For the quiet speech of a lecturer with a bass voice in a room to hold, say, 100, the wave-length is of the order eight feet. Consequently, in such a case, window recesses two feet wide and six inches deep could scarcely be counted as roughnesses, but alcoves four feet wide and two feet deep might be so reckoned. The same remarks apply to the recessing of the ceilings by beams, coves, mouldings, etc.

If by reason of bare hard walls distinct echoes occur, their objectionable presence may be sometimes reduced by the use of a *sound-board* over the *speaker*. Thus if, by the meeting of the direct and reflected sounds at some one small region in the room, the hearing is there very defective, a *concave* sound-board may focus part of the sound directly to that "dead" place and so improve matters. In other cases it may be advisable to use a *plane* or *convex* sound-board to prevent the chief sound proceeding direct to that surface which produces the objectionable echo, or to cut the sound off entirely from the upper part of the space. Obviously the sound-board is not easily applicable to the case of musicians, so we consider it for the case of a single speaker only and when located at a definite place. Then, since the wave-length may be large, say 8 feet, the sound-board must be correspondingly large or the waves of sound will bend round it and the board will be useless. Again, if the sound-board is required (as usual) to reflect as much as possible, it is better made of plaster on a framework of wood and finished to the exact curvature needed for the purpose in view.

A careful examination of all the circumstances of the case is required before deciding what, if any, sound-board is desirable and might be expected to prove of service.

There are very few, if any, cases in which *wires* strung along or across a building can be expected to be of the slightest use.

It is to be noticed that a room considered to be right for speech may be just a little too *dead* for music. Such a room may be improved therefore by the removal, on musical occasions, of some carpets, curtains, or other deadening trappings which are needed for lectures.

(vi.) *Absorption Coefficients.*—In the accompanying table are given the values of the coefficients of absorption for a number of different materials as determined by W. C. Sabine, H. O. Taylor, and others. These will be found useful to insert in Sabine's formula, either when designing any auditorium, or when the endeavour is to remove the defective acoustics of some room already in use.

The absorption coefficient, a, is defined as the quotient, *intensity of sound absorbed* by a given surface divided by the *intensity of sound falling upon it.*

TABLE VI

ABSORPTIONS OF SOUND

Substance.	Coefficient of Absorption a.
Open window	1·000
Audience	0·96 to 0·44
Hair felt (1 inch thick)	0·78 to 0·50
Compressed cork (1½ inch thick)	0·32
Oriental rugs, extra heavy	0·29
Oil paintings and frame	0·28
Asbestos roll fire felt (¾-inch thick)	0·26
Heavy rugs	0·25
Brussels carpet	0·23
Carpet rugs	0·20
Cretonne cloth	0·15
Linoleum, loose on floor	0·12
Pine boards	0·06
Plaster on laths	0·034
Single glass	0·027
Bricks or plaster	0·025
Cheese cloth	0·019

Reference should also be made to the sound-proofing of buildings.[1]

The bulletin on "Sound-proof Partitions" gives a survey of the whole subject with a bibliography of published articles.

§ (23) LONG-RANGE TRANSIT OF SOUND.—When waves of sound are spreading from a powerful source in the open air a number of causes operate to diminish their intensity and may prevent their ever reaching the destination for which they were intended. A number of these cases will be noticed here. Much of our knowledge of such phenomena is due to Tyndall and to the late Lord Rayleigh.[2]

(i.) *Radiation.*—If sound issues from a small source, comparable to a point, and spreads equally in all directions in a still homogeneous atmosphere, then its intensity falls off inversely as the square of the distance from the source. Thus at double the distance the intensity is reduced to a quarter, at treble the distance to one-ninth, and so on.

(ii.) *Temperature Gradient.*—Kelvin has shown that, when undisturbed by winds and sunshine, the air tends to a state which he called *convective equilibrium.* In this state, if air be suddenly taken from one level to another, the expansion or compression consequent on the change of pressure, but *without any gain or loss of heat*, would just bring it to the temperature already possessed by that region. There is thus a lower temperature at greater heights since there the pressure must be less, and the air in ascending to it would suffer expansion and consequent cooling. It can be shown that in such a state, the temperature of the air falls steadily in proportion to the height ascended.

Where this state of things prevails it has been shown by the late Lord Rayleigh that the path of a ray of sound through the air is a catenary with vertex downwards and that if the ray were reversed the same catenary would be described. (A *catenary* is the shape assumed by a uniform and flexible chain or rope fixed at two points and hanging slack at rest under gravity, the vertex being the lowest point.)

(iii.) *Wind Gradient.*—If the wind is everywhere horizontal, and in the same direction, but increases uniformly from the ground upwards, the ray of sound may describe a catenary or something closely like it. But in this case the path is not reversible. Thus, if the direction of the sound is against the wind the catenary has its vertex downwards. But if the sound passes with the wind the catenary described has its vertex upwards. Hence, if cannons are fired at two stations, A and B, it may happen that those fired at A will be plainly heard at B, whereas those fired at B may be inaudible at A.

(iv.) *Regular Reflection.*—Any large solid surfaces, such as a hillside or a cliff, may produce regular reflection as in the case of the ordinary echo. Such reflection may also occur at invisible surfaces in the atmosphere, where its density suddenly changes owing to a change in temperature, or to a change in humidity, or to changes in both. These may be called aerial echoes. Tyndall considered they are probably concerned in the rolling of thunder.

(v.) *Scattering.*—Sometimes the atmosphere, although optically transparent, is partially opaque to sound. It has been found that this is due to the presence of patches or layers of alternately different densities owing to sudden changes in temperature, in humidity, or in both. In this state of things, no regular reflection occurs such as produces an echo. But, on the other hand, the sound is scattered from each such irregular surface, and so the intensity of the direct sound is, in consequence, distinctly diminished. This phenomenon is analogous to the reddening or partial obscuration of the sun when setting in a smoky atmosphere and to the scattering of light from the interior of a turbid liquid or of an opal glass. For in these latter cases the optical media cited, while failing to give a reflection in the regular manner needed to form a mirror image, yet stop and scatter so much of it that the quantity passing directly onwards is appreciably reduced.

This state of semi-opacity in the acoustic sense was carefully investigated by Tyndall, and illustrated by the following lecture

[1] See "Insulation of Sound," W. C. Sabine, *Brick-builder*, 1915, xxiv. 31. "Sound-proof Partitions," F. R. Watson, *Univ. of Illinois Bulletin*, No. 127, 1922.

[2] See Tyndall's *Sound*, London, 1895.

experiment. A number of alternate layers of carbon dioxide and coal gas were interposed between a bell and a sensitive flame. The flame then remained unaffected by the bell, though the region which was acoustically opaque was optically transparent. When the two gases were turned off and air had diffused into the space, the flame responded readily to the bell.

Suppose the atmosphere has many of these patches which scatter the sound, so that its acoustic action may be compared to the optical effects of a turbid liquid. Then, on this account alone, the law of diminution of the sound proceeding directly ahead would be as follows. On advancing equal distances the intensity of the sound would lose equal percentages of the values it had on beginning each such distance. In other words, the intensity of the direct sound would diminish in geometrical progression as the distance increased in arithmetical progression. This same law has been found recently to hold for sounds under water in which many small obstructive patches occur. (For the recent development of submarine signalling see the article on "Sound Ranging.")

(vi.) *Diffraction.*—The spreading of sound behind obstacles, which is one form of diffraction, must also slightly weaken the main or direct beam of sound, beyond that due to other causes.

(vii.) *Fog, etc.*—We may now notice other states of the atmosphere which have been supposed prejudicial to the free passage of sound, but which Tyndall by an elaborate series of experiments found are not so. These include the presence of rain, hail, snow, and fog, which, he asserted, have "no sensible power to obstruct sound." Kelvin has shown that the temperature gradient, which forms the limiting condition of equilibrium of the air in a warm fog, is about half that in the limiting condition for fog-free air. This state is, of course, one in which the temperature falls as we ascend. Thus on theoretical grounds it should be expected that sound would pass with less loss in a fog than when the air is clear. This inference is fully borne out by Tyndall's prolonged researches off Dover.

It must be pointed out that the above statements, though correct, may be easily misunderstood and a false impression received as to what is really meant. Sound will usually travel better in a fog than in clear air, provided that the path in question is *wholly* in the *same* continuous bank of fog. That is to say, the sound must *originate in and be heard in the same continuous bank of fog.* If a sound originates in clear air and is to be listened for in clear air on the far side of an intervening bank of fog, then there might be large reflections at the first and second faces of the fog, and the sound might be much weakened or inaudible at the place where it was intended that it should be heard. Again, if the sound originates in one bank of fog and the listener is in a second bank of fog with clear air intervening, the sound might again be very faint or inaudible at the listener's position owing to the two reflecting surfaces interposed. Thus, though it is rightly asserted that sound travels well while *entirely in one continuous portion of fog,* the presence of a *number of banks of fog with intervening clear spaces,* all between the source and its desired destination, may prove very detrimental to the long-range transit of sound.

(viii.) *Zones of Silence.*—Many notices have appeared of late years calling attention to exceptional cases of sound propagation in which some explosion is heard in the vicinity, following which is a zone or annular space of *silence,* this being succeeded by a still more distant region in which the sound is again audible. Various theories have been put forward to account for this, such as (*a*) wind gradient, (*b*) temperature gradient, (*c*) more complex meteorological states of the atmosphere. The first alone may suffice to bring sound down again by total reflection at a height where a certain critical state obtains. The difficulty in settling what has been the cause of such phenomena on any particular occasion usually lies in the absence of qualified observers expecting an explosion and listening for it. Thus evidence collected afterwards may be biassed or in other ways untrustworthy.

III. Sound Producers

§ (24) General Survey.—We shall treat here the various producers of sound whether devised for music, signals, or other purposes, the first class, however, greatly preponderating.

It is often convenient to think of a musical instrument with its accessories (and certain parts of the performer himself) as divisible into three main portions. These are: (*a*) the *exciter,* or means of producing vibrations; (*b*) *the vibrating system*; and (*c*) the manipulative *mechanism* for the production of the scale, for expression, etc. Sometimes the vibrating system may be subdivided into a *vibrator of definite pitch* and a *resonator* which reinforces and otherwise modifies the sounds originated by the vibrator. In other cases there is a vibrator, not possessing a definite pitch of its own, but only favouring certain pitches, some one of which is made actual and definite by the resonator (in addition to its function of modifying the quality of the tone). The subdivision gives, in all, four portions of the instrument. Take as an example the case of the violin. In this the bow in the player's right hand is the exciter, the strings are the vibrators of definite pitch, the sound box and contained

air form the resonator, while the finger-board and the fingers of the player's left hand furnish the mechanism for the scale. The second form of subdivision is illustrated by the flute. Similar analyses may be supplied by the reader for the other instruments, special intricacies being referred to as we proceed.

Having thus briefly glanced at how the sounds may be produced, we now pass on to notice what are the characteristics which serve to distinguish one musical instrument from another. The chief of these are as follows:

(*a*) The range of pitches possible, or the *compass* of the instrument.

(*b*) The interval relation of the notes, or *scale* in use.

(*c*) The *power and delicacy* of the sounds producible.

(*d*) The *noises* accompanying the beginning or finishing of the sounds.

(*e*) The possible or inevitable change of intensity of the sounds while they last.

(*f*) The quality of the sound when established, by musicians termed *tone*.

(*g*) The possibility of sounding a number of notes together or the restriction to one at a time, *i.e.* the capacity for *harmony* or the restriction to *melody*.

Taking each of these seven points in order, we may illustrate them by the following contrasted pairs of instruments, of which one of any pair may be distinguished from the other on the above principles by hearing without seeing.

(*a*)	Harmonium	Concertina	Large, small compass.
(*b*)	Bugle	Cornet	Harmonic series, chromatic scale.
(*c*)	Trombone	Flute	Powerful, feeble.
(*d*)	Trumpet	Clarinet	Declamatory, smooth.
(*e*)	Harp	Violin	Sounds die away, sustained.
(*f*)	Oboe	French horn	Penetrating, muffled.
(*g*)	Violoncello	Piano	Melody, harmony.

The endeavour has been made to cite typical examples, but no doubt the discrimination between the members of each of the above pairs would depend partly upon other guiding factors, some perhaps too subtle to be recognised as such.

As to quality of *tone*, we may trace an almost continuous gradation from rough coarse bass quality, through dull, rich, full, or mellow tones, to those which are described as brilliant or even penetrating. Helmholtz has shown that the qualities of tone thus popularly described correspond to compound sounds in which the prime or fundamental sound of lowest frequency is accompanied by a retinue of other (and usually) fainter sounds of higher frequencies. All these sounds (including the lowest) are called *partials*. Musical sounds, as to their qualities of tone, may be scientifically divided into the following classes:

(i.) Those with the *full harmonic* series of partials; *i.e.* the sounds have frequencies as 1, 2, 3, 4, 5, 6, etc.

(ii.) Those with the *odd harmonic* series of partials; *i.e.* the sounds have frequencies as 1, 3, 5, 7, etc.

(iii.) Those with *inharmonic* partials; *i.e.* the sounds have frequencies *inexpressible by small whole numbers.*

(iv.) Those *without any upper partials.*

(v.) Those with harmonic partials, some of which near *fixed* pitches are *specially favoured* whatever the pitch of the prime.

Most musical instruments fall into the first of these classes; a few into the second; church bells, bars, and gongs into the third; tuning-forks into the fourth; while the human voice singing vowels stands alone in the last. (The question of the special tuning of keyboard and other instruments is treated in §§ 5-6.)

§ (25) Compasses of Chief Musical Instruments.—Table VII. (p. 699) gives the approximate compasses of the chief musical instruments classified both scientifically and musically. The notes given show the *true* pitches of the limiting sounds, and not necessarily those written for the instruments, which are often different according to the pitch of the instrument and the traditions of the profession.

§ (26) The Guitar.—This instrument has six strings, the three upper being of catgut, the three lower of silk covered with silver wire. The strings are plucked by the right hand, the thumb being used for the three lower strings, and the first, second, and third fingers for the three upper strings, the little finger resting on the body of the instrument. To obtain the different notes of the scale, the strings are pressed by the fingers of the left hand (or *stopped*) against the *frets* or little pieces of wood which cross the finger-board at the appropriate places. When the vibrating length of the string is thus reduced the frequency is increased and the note produced is accordingly higher. Thus, if the string's vibrating length is reduced to one-half the note is raised an octave, because its frequency is doubled. Again, if the length is reduced to two-thirds the note is raised a fifth, because the frequency is increased in the ratio of two to three. Similar remarks apply to the other notes of the scale. Thus every use of the frets raises the pitch above that of the open string. An account of the theoretical calculation of the frequencies of strings is given in § (52) (i.). Notes called *harmonics* may be obtained by touching the strings lightly with the fingers of the left hand instead of pressing them hard on to the frets. Thus, touching at the middle yields the octave, touching at either point of

trisection (*one-third* up or *two-thirds* up) yields the twelfth, touching at one-fourth up yields the double-octave. Hence (reverting to the typical subdivisions of a musical instrument) the thumb and three fingers of the right hand are the exciters, the six strings the vibrators, the sound box the resonator, while the fingers of the left hand and the frets are the manipulative mechanism for producing the scale. Since the notes are made by plucking they soon die away.

§ (27) THE MANDOLIN.—This instrument has four double strings, those of each pair being set to unison. The e'' strings are of catgut, the a' strings of steel, the d' strings of copper, and the g strings of catgut covered with silver wire. The notation for these strings is that shown at the top of Table VII. The strings are plucked with a plectrum (of tortoise-shell or horn), and *stopped* (that is pressed hard by the fingers of the left hand) upon the finger-board to produce the notes of the scale. H. Berlioz, the composer and writer on instrumentation, states that the quality of tone of the mandolin has a keen delicacy not possible on other instruments. This is probably due in part to the fine point of the plectrum used to initiate the vibrations. As in the case of the guitar the notes of the mandolin are soon damped out.

§ (28) THE HARP.—This is the important representative of stringed instruments played by plucking with the fingers. The double-action harp is tuned in C♭ and has seven pedals. Each pedal acts upon all the strings of a given name throughout the compass of the instrument. Further, each pedal may be used to raise the strings to which it applies by a semitone or by a whole tone at the option of the player. Thus, by the right use of the pedals before commencing a piece, the instrument may be arranged to provide any one of the fifteen major scales in the keys from C♭ to C♯, both inclusive. The melodic minor scales cannot be thus *set* by the pedals, since they require different notes in ascending and descending passages. The harmonic minor scales can be *set* in the twelve keys from A♭ to C♯ inclusive. The octave *harmonics* may be produced on the longer strings of the harp by touching them at the middle with the fleshy part of the palm of the hand and plucking with the thumb and two first fingers of the same hand. In the harp a separate string is provided for each note of the diatonic scale, and the pedals are the only accessories needed to give the accidentals or other sharps or flats.

The harp's quality of tone mingles well with the various brass instruments. The tone is also somewhat under the control of the player, since the strings may be plucked at various places and in a variety of ways.

It is to be noted that the lower notes of the harp, being made by long and heavy strings, are fairly powerful, and not so quickly quenched as those of the guitar and mandolin. Indeed, they often need to be *damped* or *checked by the hands*. Still, since they are plucked, they must die away in time, having no supply of energy to sustain them. Further, the fact that the string is excited by plucking leaves the string free to follow the vibrations natural to it, and this gives a certain characteristic quality to the tone of such instruments. This is due to the fact that the higher partials of a thick string are slightly *inharmonic* and will *so sound* in the case of a plucked or struck string, whereas in a bowed string all the vibrations are forced by the bow into the strictly harmonic frequencies.

§ (29) THE PIANOFORTE.—In this instrument [1] the strings are of cast-steel wire, at most parts of the compass being in duplicate or triplicate, but at the bass end single and over-spun or wrapped with copper or other wire. In the grand pianos the strings are arranged horizontally to admit of greater length and correspondingly increased power. The sounds are excited by the felt-faced hammers *striking* the strings, then rebounding and leaving them free to vibrate. The hammers are set in motion by the *action* (or train of mechanism) intervening between them and the keys which form the familiar keyboard. The action also lifts a felt-covered *damper* from the string when the key is struck, holds it off while the key is held, and replaces it to terminate the sound when the key is released. The depression of the right pedal takes the dampers off all the strings and thus allows a considerable increase of loudness and change of quality of tone through the sympathetic resonances of strings which are not struck. The use of the left or soft pedal either (*a*) restricts the vibrations to a single wire for each note, (*b*) muffles the sound by the interposition of a layer of felt, cloth, or other soft material between the strings and the hammers, or (*c*) obtains a softened effect by shortening the stroke of the hammers. Along the upper part of the frame (in the upright piano) there is the wooden wrest-plank carrying the tuning pins into which the strings are fastened, their lower ends being secured to the hitch pins placed along the lower parts of the frame. The strings rest upon hard-wood bridges glued to the sounding-board. This is often of spruce fir. It is slightly convex towards the strings, and is strengthened by bars of pine glued to its inner concave side.

Having thus outlined the construction and action of the piano, let us turn to the factors upon which depend its retinue of partials and, consequently, the quality of its tone.

		Contralto	G — D	
		Tenor	C — G	
		Bass	F — C	
	Membrane	Kettledrum	F - - - - - F	Percussion Instrument of Definite Pitch.

* When played *pizzicato*, these fall under the heading of plucked strings.

As we have seen, the exciters are the hammers, the vibrators of definite pitch are the strings (one or more for each note), and the sound-board is the resonator. Thus the blow of the hammer, at a spot chosen by the maker, imparts a transverse velocity to a small portion of the string. The state of things produced there runs to and fro along the string. This leads to a particular type of vibration according to the *form and softness* of the hammer face and the *place* at which it strikes the string. A sharp hard edge to the hammer would favour very many partials and develop a tinkling or piercing tone; the rounded soft face of the hammer in actual use gives a justly prized mellow tone. Again, if the string were struck at a seventh of its length from one end, it is impossible for this point to be a place of no motion. Consequently the seventh partial is not encouraged, for it would correspond to the vibration of the string in seven sections with one of its *nodes* (or places of no motion) at a seventh from one end. But this remark as to no motion at the node applies only to the vibration for which it is a node. Hence, though the hammer by striking at a seventh would not encourage the seventh partial, this partial might still creep in. In some pianos the striking place is between the seventh and the ninth of the length of the strings from one end, varying in different parts of the compass. The time of contact of the hammer with the string may be of the order of half the period of the prime or fundamental of that string. Thus for the middle C (of, say, 264 per second) the time of contact might be less than one five-hundredth of a second, perhaps as low as one six-hundredth of a second.

We have seen that the character of the vibrations of the piano string itself depends largely upon the nature of the hammer and the position of its blow. It must be noted, further, that the character of the vibrations depends also on the thickness and material of the strings. Thus, very thick strings of rigid material would be too stiff to form very high partials, since they correspond to the vibration of the strings in many small segments and involve considerable bending. And for the same reasons any moderate partials would be inharmonic and would so sound.

But when the type of the vibrations of the string itself is finally settled, is the instrument committed to a definite effect as to quality of tone? Certainly not. Another very important factor remains to be examined. This is the sound-board and its bridge upon which the string presses.

The importance of the sound-board may be seen thus. If a string isolated from the sound-board vibrated precisely as a pianoforte string does, very little sound would be heard. The reason is that the air would flow and reflow round the string and be scarcely disturbed far away. A sound-board, on the other hand, cannot vibrate without setting in motion a large body of air, thus starting waves of sound that are audible all over a large room. Accordingly we must ask, not merely what vibrations does the string itself execute, but also what vibrations does the string force the sound-board to execute? Of course, the latter vibrations depend upon the former, but may differ from them in essential respects.

If the vibrations of the string itself are precisely all that could be desired, then it is the duty of the bridge and sound-board to reinforce them *without change* of character and convey them to the air. If, on the contrary, the vibrations of the string are defective in any way, then on the bridge and sound-board is imposed the double duty of reinforcing *and improving* these vibrations so that the desired quality of tone is received from the instrument as a whole.

The exact types of complex vibration which are most acceptable as forming the ideal musical tone are to some extent matters of opinion or controversy. Still more difficult is it to assign the precise dimensions of the mechanical details of hammer, string, bridge, and sound-board which would secure their production. Probably the nature of the wood of the sound-board and its seasoning are very important. Possibly also the exact dimensions of a sound-board must be varied according to the particular nature of the specimen of wood used for it. The various points here briefly referred to have been under investigation for some time, but no final solution of such intricate problems can be expected at any early date. In matters of this kind we no doubt owe much to the refined taste and instinct of those concerned in the making of pianos, and to their accumulated experience during two and a half centuries.[1]

§ (30) THE VIOLIN FAMILY.—The instruments of this family now in use in England are four, namely, the violin, the viola, the violoncello, and the double-bass (see *Figs.* 4A, 4B, and 4C). The violin has its strings of catgut tuned to e'', a', d', and g, the latter being covered with silver wire. The notation here used is that at the top of Table VII. § (25). The viola has its strings tuned to a', d', g, and c, all being thus a fifth lower than those of the violin. The violoncello is pitched an octave below the viola, its strings being accordingly tuned to a, d, G, and C. The double-bass may

[1] For research work on piano vibrations see papers by G. H. Berry, *Phil. Mag.*, April and October 1910 and July 1911; also one by C. V. Raman, *Roy. Soc. Proc.*, April 1920, xcvii. 99-110.

have three strings or four, and they may be tuned to fourths or fifths, the earlier alternative in each case being that in more general use in England. Thus the three-stringed bass may be tuned in fourths to G, D, and A_1, or in fifths to A, D, and G_1.

Except for the strings, their tuning, and the corresponding sizes of the instruments, they have much in common. Thus many of the following remarks apply to all of them. The bow with its rosined hairs is the exciter, the strings are the vibrators of definite pitch, the sound-box is the resonator, while the finger-board, *free from frets*, allows the scale to be played by the fingers of the left hand. The vibrating portion of the string reaches from the bridge to what is called the *nut*, the little cross-piece of ebony or wood between the neck and head or peg-box. When the left hand is farthest from the bridge it is said to be in the first position. Then, the first, second, and third fingers when used in turn to *stop* the string (*i.e.* to press the string against the finger-board) give the notes of the diatonic scale required to bridge the interval between one open string and the next. Thus from the fourth or *g*-string of the violin, these fingers give in turn the notes *a*, *b*, and *c′*. The next open string is *d′*, on which the fingers stop the notes *e′*, *f′*, and *g′*. The fourth finger may be used on any of the three lower strings to give a note in unison with the open string above. When the hand is shifted nearer the bridge so that the first finger occupies the place formerly held by the second finger, the hand is said to be in the second position. The third, fourth, fifth, sixth, etc. positions are also used, the odd being easier than the even positions. Each position has its advantages as regards the notes commanded on a given string, either for the sake of (*a*) smoothness of phrasing in certain passages, or (*b*) the special quality of tone of the string on which such notes are now played. For each string, differing in thickness and mass from its fellows, has its own tone and other individual characteristics.

FIG. 4A. Violin.

FIG. 4B. Violoncello.

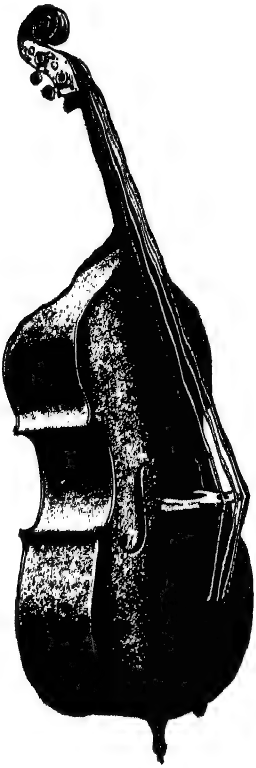

FIG. 4C. Double-Bass.

The fingering of the violin in the first and third positions, in illustration of the above remarks, is shown in *Fig.* 5. In the third position the notes indicated by $\overset{4}{0}$ are played by the fourth finger stretched out a note higher and only *touching* the string lightly at its "centre," thus eliciting the *octave harmonic*. When the term centre is used here it must be interpreted, not necessarily as the point equidistant from bridge and nut, but as that point which divides the string into two segments which vibrate in the same time. This is often not quite the same as the former, because the strings are usually slightly tapering from end to end.

Let us now examine more closely the action of the violin and the rôle played by its various parts. We may thus learn something of the qualities a fine instrument should possess, and also of what its technique demands. The stroke of the bow pulls the bowed part of the string aside at *its own speed*;[1] this part then springs back, usually at a different speed. Further, when the bow properly rosined is applied with due pressure at the right place

[1] Surmised by Helmholtz and recently (1914) established by C. V. Raman. (See *Science Abstracts*, A, 1915, xviii. 87.)

on the string and moved at the appropriate speed at right angles to the length of the string, then the full series of partial tones is elicited, and with a special grading of their intensities as follows:

Relative frequencies of partials	1,	2,	3,	4,	5,	6,	etc.
Intensities in violin tone	1,	1/4,	1/9,	1/16,	1/25,	1/36,	etc.

Or, in words, the intensities of the partials of a well-bowed string are *inversely as the squares of their frequencies.* This highly specialised composition constitutes what may be called violin tone. But these partials do not make any immediate appeal to the ear. The vibrations of the string first affect the bridge (of maple); its feet press upon the pine belly and set that in sympathetic vibration. The belly sets the ribs (of maple) and back (maple or sycamore) in vibration, and thus also the air contained in the sound-box, which passes in and out at the two *f*-holes. The belly is strengthened by the bass bar, which is inside it and lies beneath the *g*-string. Nearly under one foot of the bridge (on the e''-string side), the belly is supported by the sound-post, a little round piece of pine which is held in place by the pressure between back and belly.

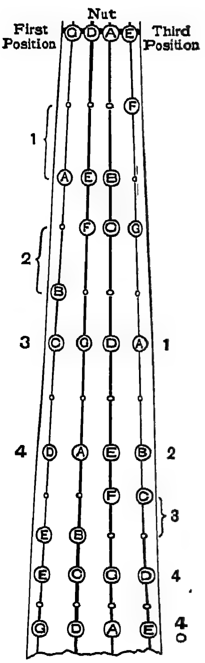

FIG. 5.
Fingering of Violin.

It seems highly probable, therefore, that the main portion of the sound heard is that proceeding from the vibrations of the belly, the back, and the air between them. Further, since these structures are of complicated shape with asymmetrical strengthening pieces, it is not likely that they can follow precisely the vibrations conveyed to them from the string by the bridge. Indeed it has been shown experimentally that the vibrations are modified in character as they pass through the series of moving parts: string, bridge, belly, and air between it and the back. And this is only what may be expected from the practical consideration that the value of the instrument lies in the *sound-box* that *modifies* the vibrations in a certain individual manner, and *not* in the *strings* that *originate* them. The fine old violins have also a special varnish which preserves and perhaps enhances their tone.[1]

Let us now consider what the violin requires from the performer. The fingers of the left hand have to stop the strings so as to produce the notes in the *intonation desired* according to what other instruments are used in concert with the violin. Further, this task must be performed without any help from frets, which are not present on the keyboard. But this leaves the possibility of gliding the finger from one stop to another, thus introducing the grace called *portamento,* which must be used with discretion. The finger holding a stop may also be rocked or rolled, thus producing an effect called the *tremolo.* It may be executed rapidly to intensify dramatic expression, or slowly to impart tenderness to a pathetic melody. Thus, except for the portamento and the tremolo, only *accuracy* (in stop and time) is demanded from the left hand. But from the right hand are required not accuracy only but the production of all the tone and expression of which the violin is capable. The bow should always move perpendicularly to the strings; the place of bowing must be chosen according to the effect desired, near the bridge for loud passages, farther away for softer ones. Again, with each such place must be associated the corresponding pressure and speed. The strings of the harp are plucked, those of the piano struck, and the vibrations of each die away according to the inexorable law of such instrument, over which the player has no control. The vibrations of a bowed string, on the contrary, may be sustained of constant intensity, or may be gradually increased or decreased in intensity at the will of the performer. Indeed, in this respect, everything is possible on the violin, though correspondingly difficult.[2]

§ (31) METAL REEDS WITHOUT PIPES.—The harmonium, the American organ, and the concertina present examples of this class of vibrator, the reeds in question being called *free reeds.* A reed or tongue of this type is a thin oblong metal plate or strip fastened at one end to a block in which there is a hole behind the tongue of the same shape. In some examples of these reeds the tongue, when at rest, closes the hole in the block except for a very fine clearance at its margin. When in motion the tongue alternately opens and (nearly) closes the hole in the block. Now, it is a result of theory that, the more sudden the discontinuity of any periodic motion,

[1] For research work on the violin see *Phil. Mag.*, Aug. 1909, Sept. 1910, June 1912; also *Bulletin*, No. 15, Indian Association for the Cultivation of Science, 1918.

[2] For a research on these points see *Phil. Mag.*, May 1920, xxxix. 535-536.

the greater the relative importance of the high partials which are present in the corresponding sound. Thus, the more sudden the action of the reed, the more obtrusive are the high partials in the sound, and the more cutting or grating is the quality of tone. Further, since in the instruments now under notice there is no pipe whose resonance might modify this quality, it remains of that cutting character which soon palls.

To sharpen the pitch of a reed, a little is scraped off the *tip*. This, while not changing the spring, diminishes the mass at the end where its effect is greatest and so increases the frequency. To flatten the pitch, a little is scraped off the *root* of the reed. This, while not changing the effective mass, weakens the spring and so decreases the frequency.

In the harmonium the bellows *forces* the wind through the reeds, while in the American organ the wind is *drawn* through the reeds into the bellows. The English concertina is tuned to mean-tone and has separate notes for D♯ and E♭, also for G♯ and A♭.

§ (32) REED PIPES IN THE ORGAN.—These differ in two respects from the reeds of the harmonium, *first* in having a pipe to modify the quality of tone produced by the reed, *second* in the manner of their tuning. It is also to be noticed that the reeds are of two kinds, free reeds like those in the harmonium, and *beating* reeds which are too large to pass into the opening with which they are associated. They therefore bend on to the opening like a covering flap until they have nearly closed it. Such a reed is adjusted, or *voiced*, so as to close with a rolling motion, and thus gradually cover the aperture. The harshness of quality consequent upon a sudden discontinuity is thus obviated. The free reed of an organ pipe is tuned by a wire clip which grasps it near its root. The shorter the vibrating part of the reed the higher the pitch. The beating reed has a wire pressing upon it near the root, and by its adjustment the reed is tuned. By varying the design of the reeds and the shape of the pipes with which they are used, various typical tone qualities can be obtained or approached, thus imitating or suggesting the various orchestral instruments.

In these *reed stops* (or sets of pipes of a given type for several octaves) we may note the following parts and functions. The blast of wind is the exciter, the reed of definite pitch is the vibrator, and the pipe with which it is associated is the resonator modifying the quality of tone produced.

§ (33) ORGAN PIPES WITHOUT REEDS.—These constitute the flute, or flue, stops of the organ. They are usually parallel and always have a typical opening called the *mouth*. Above the mouth is the *speaking length* of the pipe, below it is the *rack length*, or portion of smaller tube by which the pipe is put in connection with the wind chest from which it is blown. Metal pipes are usually of circular cross-section, wood pipes are usually rectangular in cross-section. The flute pipes also fall into two main classes according as they are *open* or *stopped* at their top end.

Let us inquire how these pipes come to utter their musical sound. (See *Fig.* 6.) Suppose the pipe is in position, the air in the wind chest at the right pressure, and the key is depressed. Then the blast of air issues from its slit-like opening at the lower part of the mouth of the pipe and passes up in the

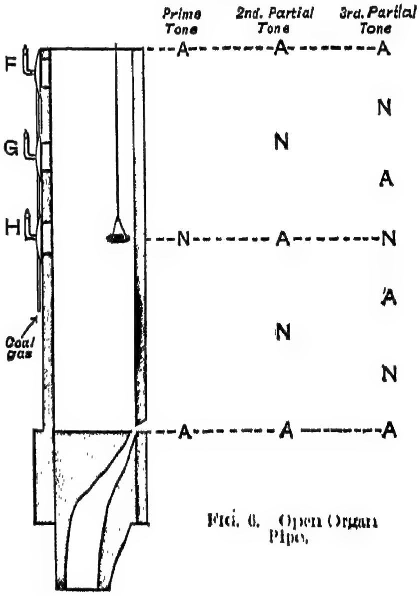

FIG. 6. Open Organ Pipe.

form of a thin sheet or blade and strikes the *lip* or upper edge of the pipe's mouth. It may pass chiefly outside the pipe and so make a rarefaction inside or it may pass chiefly inside and so make there a compression. Whichever state is first produced just inside the mouth advances to the top of the pipe, is there reflected, and returns to the mouth. On reaching the mouth this reflected disturbance reacts upon the unstable blade-shaped stream of air still passing upward at the mouth. Accordingly this stream is easily pushed or drawn aside, and by this very deflection encourages that state which already exists. Thus the wind maintains the sound of the pipe. But its pitch or frequency is fixed by its speaking length, the nature of the reflection at the top, and the speed of sound in the air of the pipe.

(i.) *Open Pipes.*—If the pipe is open then a compression arriving there will be reflected as a rarefaction, for the two opposite states are required to keep the pressure practically constant, as must be the case at an open end. Hence, if a compression starts up from the mouth, it is changed into a rarefaction after its ascent, and after its descent it is again reversed in state by reflection at the mouth, so starts up again as a compression. That is, the original state of things is repeated after *twice* traversing the speaking-length of the pipe. Consider now the case of a stopped pipe. A compression arriving at the top end is reflected as a compression (the double compression being easily supported by the stopped end), descends to the mouth, is there reflected as a rarefaction, and passes up and down the pipe again in that state. Then, by reflection at the mouth, it is changed to its original state of compression. And this occurs after traversing *four times* the speaking-length of the pipe. Thus a stopped pipe has about double the period and half the frequency of an open pipe of the same length. In other words, stopping the pipe lowers its pitch about an octave. All the above remarks apply to the prime or fundamental of the pipe. Let us now inquire what are the pitches of the other partials possible to the pipe. Take first an open pipe as shown in *Fig.* 6. To prepare for the upper partials we may with advantage go into a little closer detail in the prime itself. Thus the mouth and the upper open end are both *antinodes* or places of freest motion. These are accordingly marked A in the first column of *Fig.* 6 under the heading prime tone. But, half a period after a compression leaves the mouth to ascend, a rarefaction leaves it also and starts up the pipe. Now, at this very instant a rarefaction, derived from the previous compression, is starting down from the top. Thus, these two rarefactions will meet at the middle of the pipe, and while (by their opposite direction) annulling all motion they will produce a double rarefaction. This middle point is therefore for the prime a *node*, or place of no motion but greatest change of pressure. It is accordingly marked N on the *figure*. If the pipe were overblown it could sound its second partial tone. The corresponding state is as shown in the column under that heading. Thus, there are again antinodes at the open end and mouth, but now an antinode in the middle also, nodes occurring midway between the antinodes as before. The wave-length of the vibration is accordingly half that for the prime and the frequency, in consequence, is doubled. The next column shows the state of things for the third partial, in which the wave-length is a third that for the prime and the frequency is trebled. In *Fig.* 6 a little tambourine with sand is shown at the middle, by which it may be demonstrated that there is no motion at the nodes and much at the antinodes. The gas jets F, G, H show that there is a fluttering of pressure at the nodes.

Now, when the pipe is supplied with wind of the appropriate pressure it sounds the prime most prominently, but also the other partials too, their intensity falling off as we ascend in the series. A set of pipes intended for use at any given pressure must therefore be so *voiced* (or adjusted at their mouths) as to respond readily to blowing, and start their notes as promptly as possible. If the stream of air were so directed as to fall outside the pipe always, or inside it always; then in each case the pipe would not speak. It must be so directed and of such unstable nature as to be easily pushed out or drawn in by the first feeble pulse that has travelled up and down the pipe. Further, this stream of air must be of such nature as to encourage, not the prime only, but each of the other desired partials also, and each in the degree desired. But the pipe has a great effect upon the final result whatever the stream of air is favouring. Thus, with a narrow open pipe, all the partial tones are well in tune, that is the frequencies possible to the pipe are almost exactly in the ratio 1, 2, 3, 4, 5, 6, etc. Now when the blast is on, all the partial tones actually sounded must be precisely in tune as just mentioned. Hence, on blowing such a pipe these partial tones readily respond and the tone is fairly bright because many partial tones are present. Again, consider an open pipe, but this time a wider one (and perhaps of wood), the possible partials have frequencies nearly as 1, 2, 3, 4, 5, 6, getting more out of tune as we ascend the series. Accordingly it requires more effort to induce these higher partials to speak in tune, which they must do under the influence of the blast if they are to speak at all. The result is that these higher partials speak more feebly in a wide pipe than in a narrow one, and the tone is consequently mellower or less bright.

(ii.) *Stopped Pipes.*—Turning now to a stopped pipe, we must always have a node at the stopped end and an antinode at the mouth. For the prime tone there is no other node or antinode in the pipe, which accordingly has a length about a quarter of the wave-length speaking. For the next partial we should have the state of things represented by ANAN; beginning at the mouth and denoting by A an antinode and by N a node. The length of the pipe is accordingly three-quarters of the wave-length now in use. In other words, the wave-length is now one-third that for the prime and the frequency is trebled. Similarly for the next higher partial we should have the scheme ANANAN. This shows that

the pipe is five-quarters of the wave-length now in use, whose frequency is accordingly five times that of the prime. Thus, for a stopped pipe the frequencies of the partials possible are as 1, 3, 5, 7, etc., *i.e.* as the odd numbers only. With the stopped pipes again (as with the open ones), the narrowness of the pipes favours the upper partials and produces a brighter tone, while widening discourages them and gives a duller tone. But, whether wide or narrow, the stopped pipes have a tone quality distinct from the open ones because of the odd partials only being present instead of all. The tone of stopped pipes may be described as somewhat hollow, the wider stopped pipes have a dull quality of tone, and when very low are said to be soft and powerless.

The tuning of open flue pipes when of metal and cylindrical is accompanied by shifting a sleeve which slides on the upper end. Pushing the sleeve up lengthens the pipe and flattens the pitch, pushing it down shortens the pipe and sharpens the pitch.

Wooden open pipes are tuned by bending a metal piece which shades the top. The pitch is flattened by lowering this flap, because the open end is then more effectively shaded and this is equivalent to lengthening the pipe. For the *virtual* open end, as regards the waves of sound, is always beyond the actual end, and the less open the end is the greater the discrepancy between the two. To sharpen the pitch the flap or shade is raised and the pipe virtually shortened.

§ (34) The Flute and Piccolo.—In these instruments (and fifes) we have a pipe parallel, or nearly so, open at one end and pierced with a special mouth-hole near the other end. They are thus comparable to the flute pipes of the organ as to the manner of maintaining their sound, though the lips and chest of the flautist replace some corresponding mechanism in the organ. The air blast may be regarded as the exciter, while the vibrating system comprises (*a*) the blade-shaped stream of air which passes from the player's lips and strikes the sharp edge of the mouth-hole, and (*b*) the column of air within the cylindrical pipe. The pitch is decided and kept steady by the length of the air column whose vibration causes the stream of air alternately to enter or pass over the mouth-hole. The manipulative mechanism for the production of the scale consists of the holes and keys along the side of the tube which act by regulating the effective length of the tube in use. It is this length which governs the time of passage of a pulse to and fro in the tube. In a very simple form of flute or piccolo there are only six finger holes and six keys, the former being open except when closed by the fingers, the latter closing holes except when opened by the fingers. In such a flute the uncovering of the holes in order beginning at the right-hand or open end would usually give the diatonic scale of D. If, however, the tube is lengthened and other keys provided, the chromatic scale may be continued down to C natural. By some musicians the flute is then said to be in C, although the holes still correspond to the scale of D. In Table VII., p. 699, flute in D

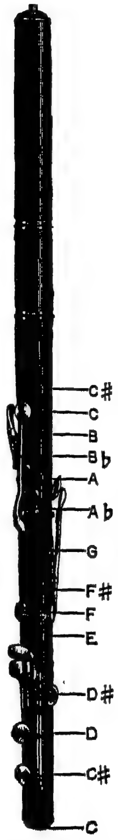

Fig. 7.—Concert Flute, Pratten's Cone.

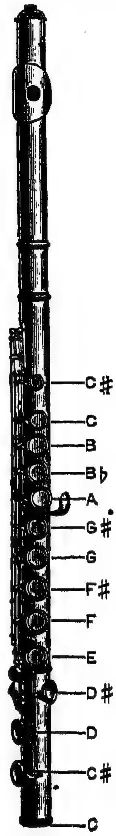

Fig. 8.—Silver Concert Flute, Boehm Cylinder.

is inserted although of this type. In the Boehm flute the holes are all covered, but the positions of these key-holes correspond to all the finger-holes and key-holes in the simpler arrangement. The two flutes are shown in *Figs.* 7 and 8. The musical notes indicated against the open end and the other holes give the pitches sounded in the lowest octave when each place is in turn the first opening counting from the mouth-hole. In other words, the place in question is open but everything else is closed between there and the mouth-hole. The higher octaves are obtained by over-blowing and slightly different fingering

The flute has the full series of partials since its tube is parallel and open at each end, but the partials do not usually extend far. Thus, the quality of the flute's tone is very mellow and pleasing, being somewhat dull in the lower register if sounded softly, but brighter in the middle part of the compass. The partial tones of the flute are in some cases almost limited to the prime and octave. In attempting to obtain low notes *loud*, the octave (or second partial) may be much louder than the prime, and there is difficulty in keeping the prime going at all.

The piccolo is about an octave above the flute, but in other respects similar. The lower part of its register is poor in quality and is not much used, the flute giving better notes in this part of the compass. Also the higher notes of the piccolo, if loud, are somewhat harsh and need toning down by a sufficient accompaniment. But the piccolo, judiciously used, can give an incisive brightness not otherwise obtainable. It can also continue a melody beyond the range of all other orchestral instruments.

The flute and piccolo are the most agile of the wood-wind instruments, being capable of rapid staccato passages which would be difficult and ineffective on reed instruments. This is in great measure due to the possibility of double and triple tonguing on the flute, which is impossible with a reed. To grasp this point we must note that the ordinary method of producing or *tonguing* detached notes on the flute is by articulating the syllable *too*, or something which approximates closely to it. Now this is done by sharply withdrawing the tongue from between the lips and emitting a puff of air. But if this syllable *too* were required for every detached note, however rapid the music, only a confused scuffle would follow. For the tongue would have to perform two motions, backward and forward, for every note uttered. This difficulty is obviated by pronouncing different syllables alternately, say *too* with the backward stroke of the tongue, and *koo* with its forward stroke, a musical *note* being obtained at each stroke. Various syllables are used according to individual choice, clearness and equality of articulation being the aim. It is easily seen that double-tonguing offers the same advantage to the flautist that up-and-down bowing does to the violinist, a note being obtained at each stroke, instead of only one note for both strokes, as in single tonguing on the flute, or using all down-strokes with the violin bow.

§ (35) THE OBOE AND BASSOON.—These are the soprano and bass instruments of the same family. Each is played with a small double-cane reed, and each has a conical tube. It can be shown mathematically that such an instrument (a cone closed by the reed at its vertex) must have the full series of partials. And it is found by experiment to be the case for the oboe. Indeed, some of its high partials are very powerful, and therefore make the tone quality thin but penetrating. The oboe takes so little air that the player is practically holding his breath while sounding a continuous

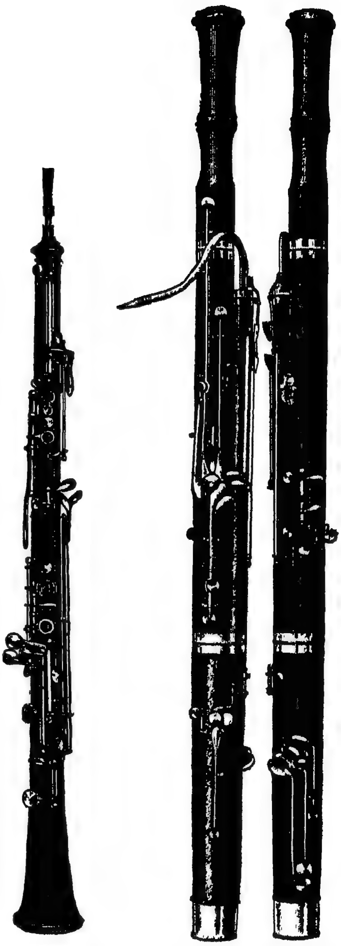

FIG. 9.—The Oboe. FIG. 10.—The Bassoon.

note, and needs rest not to take breath but to expel that which could not be passed through the reed. With these instruments the air blast is the exciter, the reed and its associated tube form the vibrator, and the somewhat complicated system of holes and keys supply the mechanism for the production of the scale. This is accomplished by changing the effective length of the tube from the reed to the first opening.

The conical tube of the oboe is straight,

while the bassoon, about two octaves lower, has a bent tube. The bell of the bassoon is at the upper end, the other or reed end being near the bell, but lower, while the conical tubing passes down from the reed to the concealed bend at the lowest part of the instrument and thence straight up to the bell. Both instruments are shown in *Figs.* 9 and 10.

The English horn or *Cor Anglais* may be regarded as an alto oboe, but the bell is rather different in shape, and the tone is quite characteristic and, in certain cases, extremely effective (see *Fig.* 11).

FIG. 11. Cor Anglais.

All the instruments of this family (like the flutes) yield the octave by overblowing. By this device, therefore, combined with suitable fingering, the higher octaves are obtained.

§ (36) THE CLARINET.—This instrument is very special from the scientific standpoint and justly prized by musicians for its fine tone. It is played with a single beating-reed of cane; the tubing is parallel, except for a small part near the mouthpiece and the end which forms a bell. Thus, since the reed must count as a closed end, the clarinet has the odd-numbered partials most prominent, although the even ones are not entirely absent. It is this, together with the special behaviour of the reed in the mouth of a skilled performer, that gives the tone of the instrument its quality so characteristic of the clarinet. Further, it must be noted that the instrument (because of its *odd* partials) overblows the *twelfth* (instead of the octave, as in the flute above). In other words, since the strong partials have frequencies, as 1, 3, 5, 7, etc., that of triple frequency is the next note to the prime, and so is got by overblowing. And this note is the twelfth of the prime in the musical method of reckoning by counting the notes of the diatonic scale. Accordingly, on the clarinet a sufficient number of holes and keys must be provided to give the chromatic scale over the interval of a twelfth from low E up to B. This requires at least 19 holes and keys, but it has been found preferable to provide 7 holes and 13 keys. These are, as shown in *Fig.* 12, the letters against each hole or key indicating the notes sounded when the place in question is open and all else is closed between there and the reed.

Since the fingering is somewhat complicated in the clarinet it is found preferable to keep it within the limit of keys without more than two flats or sharps in their signatures, at any rate for rapid passages. This necessitates the provision of clarinets in various keys, those in common use in the orchestra being in C, in B♭, and in A. Thus, if a piece of music required performing in the key of E♭ (three flats in the signature), by directing the use of the B♭ clarinet the music would be written in F (one flat only in the signature). For the fingering that produces F on the C clarinet will produce E♭ (a tone lower) on the B♭ clarinet, since the instrument itself is a tone lower by reason of its extra length of tubing. Again, if music in the key of E (four sharps in the signature) were to be played on the clarinet, the music would be written in G (one sharp in the signature) and assigned to a clarinet in A. Then, since this instrument gives A for the note written and fingered as C, it will give E for that written and fingered as G. Of course the C clarinet could be used for the five keys B♭, F, C, G, and D; but the B♭ clarinet would be better for the first of these, about equally good for the second, while the A clarinet would be better for the last. But apart from the case of fingering which has just been alluded to there is the distinctive quality of tone of each instrument to be considered. Thus the C clarinet is in the upper parts somewhat unsympathetic, while the A clarinet is duller than the B♭ instrument, which is considered the richest and fullest in tone.

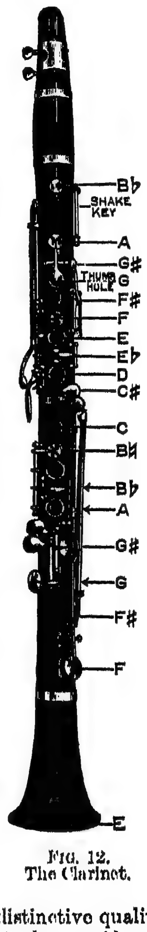

FIG. 12. The Clarinet.

It may be noted that the clarinet is specially capable of the most delicate gradations of *piano* and *pianissimo*. Further, in common with all the other reed instruments, the clarinet is heard at its best in legato phrases. Staccato playing on the reeds is ineffective

in rapid passages, as no double-tonguing is possible (as in the case with the flute).

§ (37) THE FRENCH HORN WITHOUT VALVES.—We now commence the notice of a class of instrument very important musically and of high scientific interest, namely, the *brass* of the orchestra and other bands. All these have hyperbolical pipes and cupped mouthpieces, the human lips forming the very special double-reed. To produce any desired note, that is possible with the length of tube in use, the lips (at the right tension) are applied to the mouthpiece, the tongue is suddenly withdrawn from them and a sound like *too* articulated. This sound is steadied in pitch and much increased in power by the tube. Thus the blast of air is the exciter, the human lips and the tube together forming the vibrator. In the above respects all the brass instruments are alike. They differ, however, very widely in the mechanism for the scale, in compass, in power, and in many other details.

All French horns have very long tubing coiled in a circular form and ending in a large bell, and are played with a long narrow tapering mouthpiece which favours the production of high notes of a soft quality of tone (see *Fig.* 13). In playing, the right hand is placed

FIG. 13.—French Horn without Valves.

inside the bell to give the tone a slightly muffled or veiled quality. The hand can also be changed somewhat in position so as to alter the pitch by various fractions of a tone, quarter-tone, semitone, three-quarters tone, etc. This changed position of the hand involves also a change in the degree of muffling.

In common with all the other brass instruments French horns have the full series of partials. This is due to the fact that a cone closed at the vertex gives this full set, and that all the brass instruments are quasi-conical. The curvature is to correct for the bell and mouthpiece, etc. By a suitable pinch of the lips those different partials may be elicited in turn as the *open notes* of the instrument, those which are lower than the note required being suppressed. In this way the various possible frequencies from 1 to 16 may be sounded. These notes for a horn in C may be represented in ascending order as follows:

[C]	c	g	c'	e'	g'	($b'\flat$)	c''	d''	e''	(f'')	g''	(a'')	($b''\flat$)	b''	c'''.
[1]	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16.

The notation here used is that at the top of Table VII., p. 699, giving the compass of the various instruments. The first note or *pedal* is shown in square brackets and is very seldom used musically. Indeed, it is not strictly in tune, but is somewhat displaced in pitch in order to bring the other notes that are used into more exact tuning. Again, the 7th, 11th, 13th, and 14th notes are in round brackets to indicate that they are not in exact tune with the notes shown by $b\flat$, f, and a, nor indeed with any notes in the tempered scale in use. But, if the instrument is a good one, the notes in question have the frequencies shown by the numbers 7, 11, 13, and 14. It is seen that the series of open notes give some approximation to a diatonic scale in the top octave but not in the lower ones. In the original form of the horn (which is very ancient) no valves were provided, and the fist had to be used to modify the open notes if an approach to the ordinary scale were required in parts of the compass where the open notes left large gaps. For this reason the French horn without valves is often called a *hand*-horn. But when the instrument was used without valves there were still gaps in the lower parts of its compass where the open notes are a musical fourth or fifth apart. To meet this deficiency horns were used in various keys by the addition of coiled tubes, called *crooks*, near the mouthpiece. The crooks were of different lengths, so as to put the horn in A, A♭, G, F, E, E♭, etc. Thus, by having some horns in one key and some in another, a composer could get all the notes he required. Such crooks are still used on the French horns with valves, because, by putting the horn in a suitable key, more open notes are obtained. In order to tune the horn some parallel tubing is provided, of which one piece like a U can be drawn out at pleasure. This is called a tuning slide. When no valves were used the horn would have a characteristic of its own, owing to its scale limitation, apart altogether from its special quality of tone. The same thing is noticeable to-day in bugle calls and in fanfares on trumpets without the use of valves.

§ (38) French Horn with Valves.—Let us now consider the use of valves to complete the chromatic scale on a brass instrument. Such valves act by putting in use additional lengths of tubing and so flatten the pitch (see *Fig.* 14). (This may be contrasted with the method of side openings on the wood-wind instruments which shorten the portion of tube in use and so sharpen the pitch.) For the French horn the longest gap which it is necessary to bridge is that between the second and third open notes *c* and *g*, a musical fifth apart. We thus need six different lengths of tubing to derive, from the upper note *g*, the notes *f*♯, *f*, *e*, *d*♯, *d*, and *c*♯. Then, if this longest gap is bridged, all smaller gaps are bridged also and with something to spare. Further, the valves will be available to extend the scale down from *c*, should that be required. The six lengths of tubing needed are supplied by three valves, of which the middle or second valve adds sufficient length to depress the pitch a semitone, the first valve alone flattens the pitch a tone, while the third valve alone flattens the pitch about a tone and a half. Then the combinations, second and third, give a flattening of about two tones, the first and third two-and-a-half, while all three together flatten the pitch about three tones. It may be noted that the first and second valves are generally used together instead of the third alone. The use of the valves, and the notes produced on a horn (or other valved instrument) in *c*, are shown in Table VIII., together with the order of the partial or open note in use on the total length of tubing.

Any notes above the top C shown would be difficult to obtain and those below the bottom C shown in braces are difficult also.[1]

It is easily seen from the table below that in the higher parts of the compass alternative fingerings are possible. These would be indicated by writing notes in the lines so as to fill up all the blanks, taking care to descend a semitone in each shift to the right. It may be noticed also that two valves (the first and second) would give the chromatic scale over the upper part of the compass. When a longer crook is fitted to the French horn

Fig. 14.—French Horn.

4	C	B♮	B♭	A	G♯	..	..
3	G	F♯	F	E	D♯	D	C♯
2	C	{B♮	B♭	A	G♯	G	F♯}

[1] On the cornet and some other valved instruments no note higher than the C, which is the eighth open note, is usually employed, this limit being indicated by the dotted line. On the cornet, however, the low notes in braces are all readily obtained.

each of the valves needs more tubing also. They are accordingly fitted with slides that are drawn out to suit.

§ (39) Faulty Intonation of Ordinary Valves.—Let us now inquire if the valves can be tuned so as to be strictly correct for use alone and in combination. Suppose that only the equal temperament is aimed at, so that the problem is simplified as far as possible. Even then the theoretical requirements cannot be met by ordinary valves. Perhaps the simplest way to see this is to take some concrete case as follows: Let the first and third valves give the depression of a musical fourth correctly, *i.e.* the length of the tubing is increased in the ratio 3 : 4. (The tempered intonation is practically equal to the just for this interval.) Then, if the second valve used alone depressed the pitch by an equal-tempered semitone, it will need to be $\frac{4}{3}$ of its previous length to depress it a semitone when used along with the other two valves. If therefore the second valve is not altered when in combination with the others it will depress the pitch by $\frac{3}{4}$ of a semitone only; thus leaving the note in question *one-fourth of a semitone sharp.* Hence, with three ordinary valves, some compromise is inevitable. Thus, as exactness throughout the compass is impossible it has to be considered on what notes mistuning will be least objectionable. A glance at Table VIII., § (38), shows that the first and second valves are more used than the third, which is scarcely needed in the upper range. Also the three valves together are needed only for one or two notes near the bottom of the compass. Further, it must be remarked that the resonance of the instruments under consideration is much more *spread* in the lower part of the compass than in the upper. That is to say, it is quite easy to blow the lower notes a little sharper or flatter than their natural pitches, but difficult to do so with the upper notes. Indeed, other things being equal, the difficulty of blowing a note sharper or flatter than its true pitch is proportional to its frequency.[1] All these considerations point to the desirability of keeping the first and second valves, used alone or in combination, as true as possible and allowing errors to accumulate on the combination of all three. But to minimise the sharpness in this last case the third valve slide may be made fairly long. Let us now illustrate this by a numerical example. Suppose some cornet has an approximate length of 50 inches of tubing from mouthpiece to bell when no valves are in use, and, for simplicity, let us ignore any modifications in lengths that may arise from the fact that through the valves the tubing is parallel but is tapering both before and after, then the lengths to the nearest tenth of an inch required for the various notes in equal temperament are as shown in Table IX.

[1] See *Phil. Mag.*, July 1913.

It is to be noted that the *nominal* note C is really the open note natural to the instrument. Next below are given the lengths that might be added by the ordinary valves, the total lengths of tubing so obtained, and the errors in length and in fractions of a semitone. It is seen that the C♯ and F♯ are about a quarter of a semitone sharp, and that the D♯ and G♯ are about one-seventh of a semitone flat. Also if the third valve be used instead of the combination of one and two, we have the E and A about a quarter of a semitone flat.

§ (40) Equal Temperament with Special Valves.—Let us now notice the principle of certain special valves with which it is possible to attain equal temperament. This improvement has been introduced by two firms, the details of construction being different. In each case, however, the main principle is the same, viz. that when the *third* valve is used in combination with either of the others (or both of them) some *extra* length of tubing shall come into use over that in use with the *first and second* valves alone or together. The effects of this arrangement are shown in the lower part of Table IX., by which it is seen that the lengths shown for the first and second valves are greater when the third is in use than when it is not. The results are seen to be errors so slight as to be practically negligible. Hence, musically speaking, the instrument is true to the equally tempered chromatic scale throughout, provided the open notes are so tuned. Messrs. Boosey & Co., of London, obtain this advantage by arranging that certain extra compensating knuckles of tubing shall come into use in connection with the first and second valves when, and when only, the third valve is depressed. They called their device "compensating pistons."

Messrs. Besson & Co., Ltd., of London, have a pair of separate knuckles of tubing for the first valve, and a pair for the second also. One of each pair is called the *short* slide and comes into play when that valve is used *without* the *third* valve. The other of each pair is the *long* slide and comes into play only when the *third* valve is depressed as well as the valve in question. The arrangement of these pairs of slides (long and short below and above) is clearly seen from *Fig.* 15, showing one of Besson's cornets with their "enharmonic" valves. Each of the five valve slides may be drawn for tuning so as to reach the best adjustment. It seemed desirable to show these valves at the outset in connection with the cornet, but it must be remarked that their use is more desirable in the

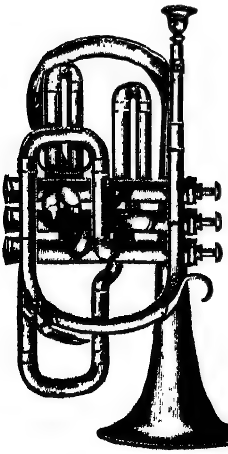

FIG. 15.—Cornet with Special Valves.

euphonion and bombardon. These will be dealt with later. The much greater masses of air in these bass instruments make it much harder for the performer to correct any faulty intonation by blowing so as to force the notes in tune. Whereas, with smaller instruments like the cornet and trumpet, professional players often disdain all complications, since they are so expert at forcing each note into tune.

§ (41) THE BACH TRUMPET.—This trumpet is quite straight and allows the light to pass through it when the valves are not depressed. It is usually made in E♭ and D, the change being made by using the E♭ or the D middle piece between the valves and the bell. (See *Fig.* 16.)

As in the case of the French horn, this trumpet is made with two or three valves according to the musical passages for which it is required. Thus in Handel's *Messiah*, for the trumpet obbligato in "The trumpet shall sound," the solo player generally uses an instrument with two valves only, the third valve not being required. Indeed this part was originally written for a valveless trumpet

of double length and therefore an octave lower. Then the high F and F♯ had to be blown into tune from the eleventh open note, which really lies between them in pitch. This trumpet has a tone of great nobility and brilliance, but yet is susceptible of piano passages and is then comparatively mellow. It reaches easily the highest notes allotted to the orchestral brass. It is tuned by the particular setting of the middle piece between the valve portion and the bell, a certain latitude being available at each end. To put the instrument in the low pitch (or "new Philharmonic") a small *bit* of tubing about an inch and a quarter long is inserted next to the mouthpiece. The valve slides are all drawn the correct distances when this bit is in use or when the trumpet is put in D.

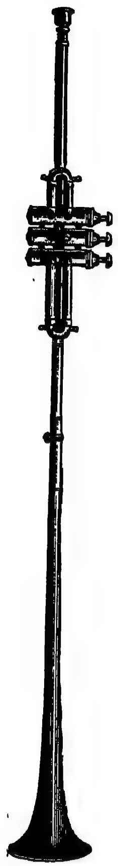

FIG. 16.
Bach Trumpet.

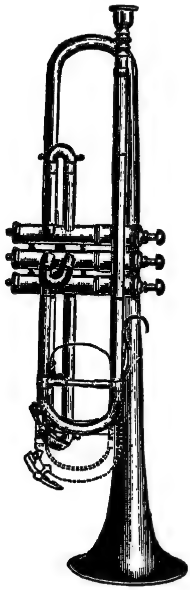

FIG. 17.
Trumpet in B♭ and A.

§ (42) TRUMPETS IN B♭, F, ETC.—The trumpets in ordinary use have the tubing coiled up in the fashion so familiar and as shown in *Fig.* 17. This model changes easily from B♭ to A♮ by drawing the slide as indicated lightly at the right. This kind of trumpet is now made in C also and is much in use in orchestras. *Fig.* 18 shows the symphony trumpet in C with rapid rotating change to B♮ made by C. G. Conn, Ltd., of Elkhart.

Trumpets in F and E♭ of the same model as the above, but without any rapid change, are often used in orchestras for the lower trumpet parts. They can be set to E♭ by the insertion of a crook as shown in *Fig.* 19.

Trumpets in B♭ are also made without valves for fanfares, etc. Their scale is then restricted to the notes of the harmonic series of relative frequencies [1], 2, 3, 4, 5, 6, [7], 8. The first and seventh notes are not generally used. (See *Fig.* 35, § (52) (vi.).) Bugles in B♭ are similar as to the absence of valves and consequent restriction of scale, but are more gently tapering from the bell and so have a mellower, less brilliant tone. (See *Fig.* 34, § (52) (vi.).)

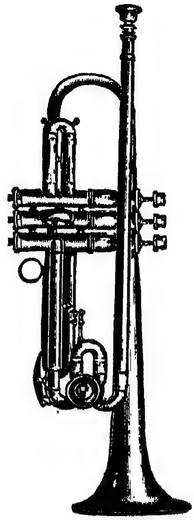

FIG. 18.
Trumpet in C and B♮.

§ (43) TROMBONES.—We now consider a family of brass instruments in which no restriction is placed on the intonation possible. Thus it may be equal temperament or just anything that is wished and the performer has the skill to attain. This is owing to the fact that the mechanism for the scale consists of a U-slide which may be drawn out so as to flatten the pitch continuously by any desired amount to six semitones. When the slide is closed it is said to be in the first position. By extending it to the second position the pitch is flattened a semitone, on reaching the third position the pitch is a whole tone lower, and so on to the full extension of the slide, which is the seventh position and involves a flattening of six semitones. On comparing this arrange-

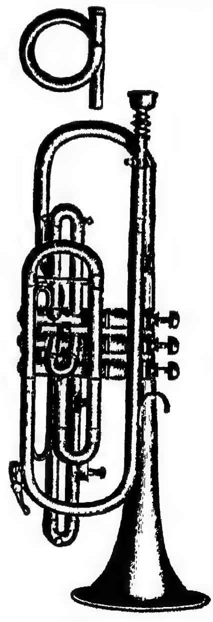

FIG. 19.
Trumpet in F and E♭

ment with the system of three valves it is seen that the first position of the slide corresponds to the open notes on the valved instrument, the second position to the depression of the second valve alone, the third position to the use of the first valve alone, and so on, the seventh position corresponding to the use of all three valves in combination. The full comparison may be shown thus:

Positions of slide	1st.	2nd.	3rd.	4th.	5th.	6th.	7th.	
Flattening involved	0	1	2	3	4	5	6	semi-tones.
Corresponding valves	0	2	1	1 2	2 3	1 3	1 2 3	

Slide trombones are made of various pitches called alto, tenor, and bass trombones; these are in E♭, B♭, and G respectively. A tenor trombone is shown in *Fig.* 20. At the top end is seen the tuning slide, and it may be noticed that its plane is at right angles to that of the long slide used for the scale, which extends downwards from the mouthpiece. This setting of the two bends at right angles is a peculiarity of slide trombones, and distinguishes them from all other instruments, in which the coiling of the tubing is almost parallel to one plane. Although the slide of the trombone allows of perfect intonation, it calls for additional skill on the part of the performer to take all the positions with readiness and right adjustment. Further, it calls for great care on the part of the makers as to the right proportioning of the taper and curvature of the tubing. In any brass instrument there is much difficulty in obtaining a tube of such shape as to give the harmonic series of open notes in tune down to the second. This difficulty is enhanced when the taper is interrupted by a parallel portion to act as a tuning slide or a set of valves. Now in the case of the three ordinary valves there must be a length of parallel tubing provided sufficient to flatten the pitch three tones. The part of this length in use varies from nothing to the full amount. But in the slide trombone an additional length of parallel tubing sufficient to flatten the pitch three tones must be drawn out for the seventh position, and the same length of parallel portion must be present for the slide to close upon into the first position. Hence in the slide trombone the length of parallel tubing provided is *double* that required for three tones, the amount in use varying from the half to all of it. Again, in the slide of the trombone we have a slight change of diameter inevitable on passing from the parallel fixed portions to the movable portions of tubing which slide upon them. To minimise complications and avoid a "break" upon certain notes this difference of diameters must be as small as possible.

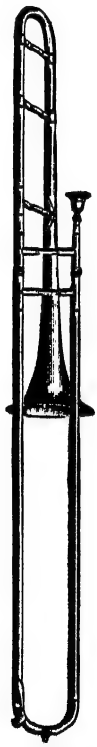

FIG. 20.
Tenor Trombone in B♭.

The trombones are capable of great power and have a rich and brilliant tone. In the hands of sympathetic performers they are also capable of *pianissimo* effects of great beauty and value. The somewhat uncouth mechanism for the scale forbids their use in quick florid passages, especially in the lower parts of the scale where the extreme positions of the slide are needed. They shine rather in slow movements of a certain stately grandeur. It may be noticed in conclusion that the possession of the slide confers the power to produce the grace called *portamento*, or the continuous gliding of the pitch from one note to another. This power in its complete fulness is otherwise possessed only by the instruments of the violin family and by the human voice.

A slide trumpet is occasionally used for oratorios and other purposes. It is very little different from the trombone in essential qualities, so is included here (see *Fig.* 21). By the use of crooks it can be put in various keys.

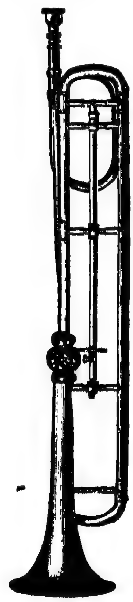

FIG. 21.
Slide Trumpet.

§ (44) VALVED INSTRUMENTS OF BRASS BAND.—We now notice the instruments which form a complete family of similar units and constitute the brass band proper, to which may be added trombones and trumpets. All the various elements of this family have valves, usually three only, but some of the

bass ones occasionally have four or even five valves. Beginning at the upper part of the compass and passing down to the bass, we have in order the following chief instruments: E♭ soprano, B♭ cornet, E♭ tenor horn, B♭

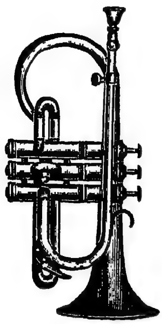

FIG. 22.—E♭ Soprano.

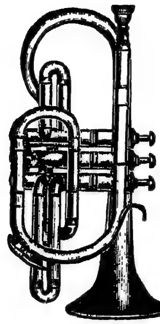

FIG. 23.—B♭ Cornet.

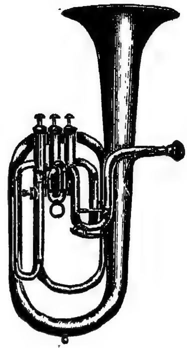

FIG. 24.—E♭ Tenor Horn.

euphonion, E♭ bombardon, BB♭ monster bombardon. These are shown in *Figs.* 22 to 27. Others of secondary importance are B♭ fluegel horn, same pitch as the cornet; B♭ baritone, same pitch as the euphonion but of smaller tubing; B♭ bombardon, same pitch as BB♭

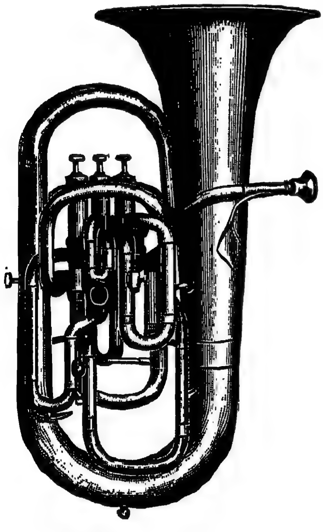

FIG. 25.—B♭ Euphonion.

monster but of smaller tubing. Thus, glancing at the list, we see that the tenor horn is an octave below the soprano, while the bombardon in E♭ is an octave below the tenor horn. Again the euphonion is an octave below the cornet, while the B♭ bombardon is an octave below the euphonion. (The orchestral tuba in C is a note above the B♭ bombardon.)

Of the main instruments, the first four, soprano, cornet, tenor horn, and euphonion, may be compared to the four varieties of human voice, soprano, contralto, tenor, and bass. The bombardons differ from the euphonion more in getting greater power on

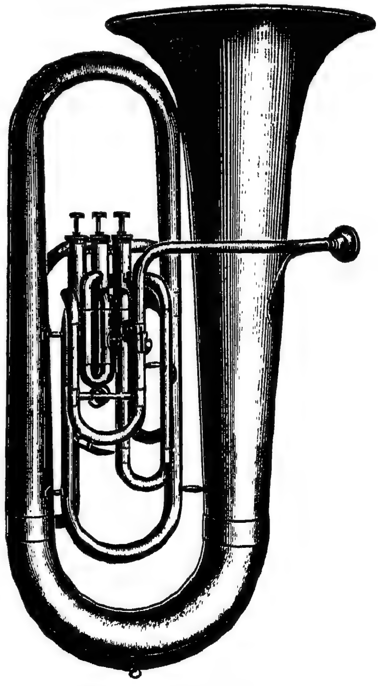

FIG. 26.—E♭ Bombardon.

the low notes than in going so much lower. This is due to the fact that the euphonion is often provided with a fourth valve to enable it to take the full chromatic scale down to its

pedal B♭. This fourth valve lowers the pitch about a musical fourth, so by it, in conjunction with the others, the player can bridge the gap of an octave between the

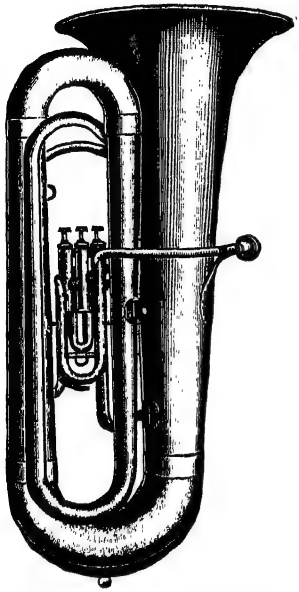

FIG. 27.—BB♭ Monster Bombardon.

second open note and the pedal or first of the same name. This device is occasionally applied, however, to the E♭ bombardon also. In either case the fingering is as follows, the notes being written C to C as is usual for any valve instruments playing from the treble clef:

Notes in pedal octave	C.	B.	B♭.	A.	G♯.	G.	F♯	F.	E.	D♯.	D.	C♯.	C=pedal.
Fingering of four valves	0	2	1	3	2 3	1 3	1 2 3	1 4	3 4	2 3 4	1 3 4	1 2 3 4	0

In these bass instruments the compensated pistons or enharmonic valves are specially important. For the mass of air to be set in vibration is very much greater than in the case of higher and smaller instruments. Consequently it is harder for the player to elicit a full and powerful tone unless the resonance is at its best, because no forcing to a somewhat different pitch is needed. It may also be seen that with uncompensated valves the defect would be emphasised by the addition of a fourth valve to be used with them down to the pedal.

Of the instruments now under review, each has a somewhat different voice and utterance (as well as compass), and each has its appointed place to fill. The cornet is specially prized as a solo instrument, and next to it the euphonion, the two being roughly comparable to a contralto and a bass soloist. By the device of double-tonguing (borrowed originally from the flautist) very rapid iterations on the cornet are quite easy. Also the attack may be varied from one of almost ideal smoothness to the other extreme of declamatory abruptness, the tone very varied to match. Staccato and legato playing are equally easy, shakes and turns (though not quite so fine as on the strings or wood-wind) can be readily executed, and just a slight suggestion of *portamento* is possible. A wide range of power from double *forte* to *pianissimo* is at the disposal of the competent performer, either over a succession of detached notes or in the *crescendo* and *decrescendo* of a sustained note. Further, the grace called *tremolo* is possible on the cornet and may be easily indulged in too freely. This embellishment appears to consist of an alternate waxing and waning of the sound a few times per second, produced by vibrating the instrument in the hand. But the cornet may be and often is vulgarised, as it lends itself so easily to music that is frivolous and ephemeral. Most of the above powers belong as well to the trumpet as to the cornet, but the trumpet, having a more noble and brilliant tone (and often associated with wood-wind and strings), is usually reserved for loftier utterances and is concerned rather with the clash of battle or the pomp of regal appearances than with the more commonplace occasions of life and the sentiments appropriate to them.

Comparing for a moment the piano, organ, bowed strings, and wind instruments, we see that the first lacks sustaining power, the second lacks accent, while the rest have both. In compensation, the first two are harmony instruments in themselves, while the rest are only melodic components of a concerted harmony.

§ (45) HUMAN VOICES.—In many respects, to the human voice must be conceded the highest place among musical instruments. For the variety and depth of expression which can be concentrated into a single note, it stands unrivalled. Though the compass of any one voice may be less than that of most instruments, the four varieties taken together range over and exceed the limits of the treble and bass staves. Among the women's and men's voices and the boy sopranos we have also a delightful variety of tone quality and aptitude for music of distinctly different characters. But the chief characteristic of the human voice is its unique power of so modifying the quality of the sustained sounds

and so specialising their start and cessation as to give utterance to vowels and consonants. That is to say, the human voice alone can render the words as well as the music. For the vowels consist of a very special quality of sustained tone which may be called *vowel quality*. Of the consonants some are produced by specially rapid and irregular vibrations preceding or following an intermediate vowel. Some other so-called consonants can be sustained as long as any recognised vowel and have scientifically the right to be classed as vowels. The letter *s* is a case in point.

This is not the place to enter into any minute anatomical examination of the human organs of song and speech. A very cursory notice of a few salient features must suffice here. Adhering then to our usual subdivision of the essential parts of a musical instrument, we may, for the human voice, state briefly as follows. The *exciter* is the breath from the lungs *via* the windpipe. The *vibrator* of definite pitch is the pair of vocal cords (or ligaments), which form a partial obstruction across the larynx (or voice-box) and leave only the vocal chink or slit between them for the passage of air. The *resonator* is triple, consisting of the cavities of the pharynx (or upper part of the throat), the mouth, and the nose. These are modified by the tonsils, the soft palate, the tongue, and the lips. The *mechanism* for the scale consists of the set of muscles which control the position, tension, and therefore also the vibrations of the vocal cords. The vocal cords in a state of rest are about three-quarters of an inch long in men, and about half an inch long in women. When producing a musical sound the vocal chink (or slit between the vocal cords) is alternately closed and opened at the required frequency, depending on the tension of the vocal cords, their length, mass, and loading. The air-blast is, in consequence, checked and allowed to pass alternately and at the right frequency. Thus the loudness and pitch of a note depend upon the amplitude of vibration and frequency of the vocal cords, and consequently upon the muscles which supply the blast and set the vocal cords in the precise state required. It may be remarked that the resonator, having soft walls, is unable to modify the pitch fixed by the vocal cords. Upon what does the quality of the tone depend? Clearly, (*a*) upon the exact nature of the vibrations executed by the vocal cords and so impressed on the issuing air, and (*b*) upon the resonant cavities which modify these vibrations, encouraging some partials and relatively discouraging others. That special quality which we recognise as constituting a given vowel appears to be due to the special favouring by resonance of any partials near a given *fixed pitch, whatever the pitch of the prime* may be. Thus, the vowel ōō, as in moon, is characterised by the favouring of those partials whose frequencies are near 175 per second. Accordingly, a musical note whose prime was 87·5 per second with a very loud *second* partial (175) would sound like ōō; so also would a musical note whose prime was 175 per second, if the *prime* itself were very loud compared with any of the upper partials. It is easily seen that the cavities affecting the human voice may be set at will to respond to various pitches and thus give utterance to the corresponding vowel. Further, if a given vowel is sung in notes of different pitches, then the setting of palate, tongue, and lips must be preserved unchanged to keep the same vowel (according to the above statement) while the vocal cords are altered to change the pitch of the prime. And this is a matter of experience, as any one may verify.

§ (46) Comparison of the Voice with other Instruments.—We may now naturally compare the human voice with other musical instruments as to the power left to the performer to control the quality of tone produced and in other respects.

In the case of the piano the quality varies somewhat with loudness, but probably the performer has little or no control over it for any specified degree of loudness, though he often imagines he has. Indeed it seems scarcely possible that he should have such control. For the maker has settled the shape and quality of surface and mass of the hammer and the place on the string to be struck by it, also the sound-board and bridges; and upon all these the quality depends. What choice remains to the performer concerning an individual note played without use of pedals? The speed at which the hammer shall strike the string. This appears to be the sole variable at the disposal of the performer, especially in the case of pianos in which the hammer is free from the mechanism of the action before it strikes. But of course for each note struck there may be a different speed of striking in use and consequently a different quality of tone elicited. Thus an air or certain notes in it may be made distinct from those of the accompaniment by a different degree of loudness and consequent difference in quality of tone, and the power to produce this difference is at the instant disposal of the performer.

In the organ it is the maker again who has controlled the quality of tone in the pipes of each stop. The performer has no power over that and can simply mix as he chooses what is provided for him. But even so, what a vast field is placed at his disposal! Where only ten stops are available over a given compass, if all were suitable for the purpose, no less than 1023 different combinations are

possible. (This is easily seen if we note that there are 10 ways of taking a single stop and 10 more for nine stops, 45 ways of taking two stops and 45 for eight stops, 120 ways for three stops and 120 for seven, 210 ways for four stops and 210 for six stops, 252 ways for five stops, and, finally, only 1 way of taking all ten.) Again, for twenty stops the number of combinations is 1,048,575, or 500 per week for about 42 years! The varieties of tone quality at the disposal of the organist are, however, available only for broad effects, and not for single notes as in the case of the pianist.

In the case of the violin much has been done by the maker and the age and ripening of the instrument, but very much is still left to the performer. He may re-set the sound-post to his liking, he may choose his strings to suit the particular instrument, also his bow, and take care that it is well haired and properly rosined. He may often choose upon which string a certain passage shall be taken. He must always choose the place of bowing, the pressure and the speed, and can vary these at will for each string, for every stop upon it, and for every instant while the note lasts. And all these variables affect the quality of the tone.

In the case of the wood-wind there is the right application of the player's lips to the flute, or to the reed of the oboe or clarinet, and the appropriate pressure and air supply. And these variables must be changed in concert for the different notes and for every variety of light and shade on each.

On the brass instruments there is the right application and tension of the lips to the mouth-piece, and the corresponding suitable pressure of air and speed of supply to be arranged and maintained for each note of the scale and each degree of loudness or delicacy with which it is produced.

But, in playing all the foregoing instruments, there is no possibility open to the performer of appreciably varying the character of the resonance arrangements applicable to each note. That has been settled beforehand by the maker of the instrument.

In these respects the human voice has at the command of the singer resources not offered by any musical instrument fashioned by man. For not only can the human voice be controlled at the very seat of its production, where the breath passes between the vocal cords, but the resonant cavities which modify the original vibrations are all under control also. Hence the final resulting quality may be varied from instant to instant so as to render tones expressive of triumph, menace, or entreaty, or passing from artless gaiety to pathetic wailing.

§ (47) Drums.—As is well known, the exciter of a drum is the drumstick, the vibrator is the circular membrane called the drumhead or skin, the resonator is the chamber between the two drumheads, or, in the case of kettle-drums, the space below the single head. In the case of ordinary drums, bass or side, there is such a jumble of sounds produced that it is extremely difficult to assign any definite preponderating pitch to the resulting effect. In the case of kettle-drums it is quite possible for the trained ear to detect the preponderating pitch and to tune the drums to the note required. In *Fig.* 28 is shown an orchestral kettledrum in which the T-shaped tuning handles are clearly seen. It is customary to have three kettledrums in an orchestra, all under the charge of a single drummer. The drumsticks may be entirely of wood, or have felt heads, or have heads of cork covered with chamois leather. Berlioz expressed a preference for drumsticks with their heads covered with sponge.

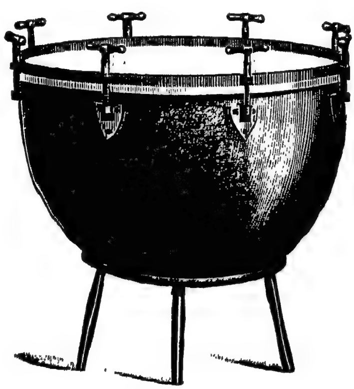

Fig. 28.—Kettledrum.

§ (48) Lateral Vibrations of Bars and Tubes.—If a thin uniform bar of metal, glass, or wood is supported at two places rather more than a fifth of its length from its ends, and then struck or otherwise excited, it will execute its slowest lateral vibrations and sound its corresponding fundamental note. Other higher notes are possible to the bar if supported at two of the places which are nodes for those higher sounds. If the fundamental for such a bar be the note *c*, then the first few of the series are approximately *c*, *f'*♯, *f''*, *d'''*, *a'''*. Expressed more accurately by their relative frequencies these would be 1, 2·756, 5·404, 8·933, and 13·345 respectively. It is seen that the possible partials of this set rise in pitch much quicker than those of strings, open parallel pipes, and open-ended cones closed at their vertices. Indeed, except for the second partial, they rise quicker even than those for a stopped parallel pipe, which

has the series 1, 3, 5, 7, 9, etc. The sounds of these bars afford a good example of inharmonic partials, *i.e.* those whose frequencies are inexpressible by small whole numbers.

Sets of bars supported so as to emit their fundamentals when excited, and arranged to give the chromatic scale over about two octaves, are used occasionally in orchestras under the name of *glockenspiel* (chime). The bars are struck by little mallets or strikers

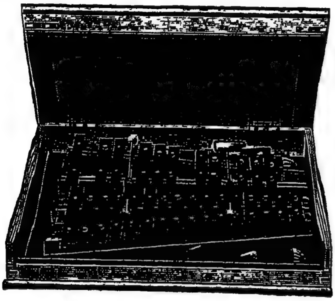

FIG. 29.—Glockenspiel.

(see *Fig.* 29). Bars with both ends free, as here dealt with, are often called *free-free* bars.

Instead of bars laid horizontally and supported at two points, tubes (or bars) may be hung vertically and struck with a mallet or beater (padded or bare) and so imitate bells to some extent. They are usually made in octave sets of 8 tuned to the diatonic scale, or 13 tuned to the chromatic scale. (See *Fig.* 30.) On referring to § (50) it will be seen that the quality of tone of a church bell is different from that of a plain bar or tube, since its partials form a distinctly different series.

§ (49) TUNING FORKS.—As a standard of pitch for ready reference a tuning fork is very convenient as it has no need of supports at special places like a free-free bar. Each prong of the fork is very like what is called a *fixed-free* bar, being practically fixed in the massive part near the shank where the prongs unite, but free at the other end. A single fixed-free bar would be very unsuitable as a standard vibrator since it would be unbalanced and therefore need a very massive base to fix one end. The tuning fork always vibrates with its prongs both out or both in together, and so balances itself and consequently needs very little support. It should be noted that a fork lightly and carefully bowed at or near the ends of the prongs emits practically its prime partial only. Its second partial is very high, having about 6·6 times the frequency of the prime. This is obtained when a fork is struck on a bare table or other hard surface. The prime is much fuller when the fork is mounted on a suitable resonance box.

§ (50) BELLS.—As we have already seen, the musical *string*, whether of catgut or metal, is very simple in its behaviour and yields the full series of harmonic partials. A membrane, though flexible like the string, is two-dimensional, having length and breadth instead of being almost confined to length only like the string. Hence its vibrations are much more complicated than those of a string. We may approach the vibrations of a bell by way of those of a straight bar, which we have seen consist of a set of inharmonic partials. When the straight bar is replaced by a bent one in the form of a fork with special mass and shank at the bend, the vibrations are still more complicated. If we now pass to the case of a bell, whose sides are like a number of prongs all united into one of circular form, we have far more complication still, even if the sides and top were uniformly thin. If the top and the different levels of the side have all varieties of thickness, then the state of things is quite beyond rigorous mathematical treatment. We can only derive

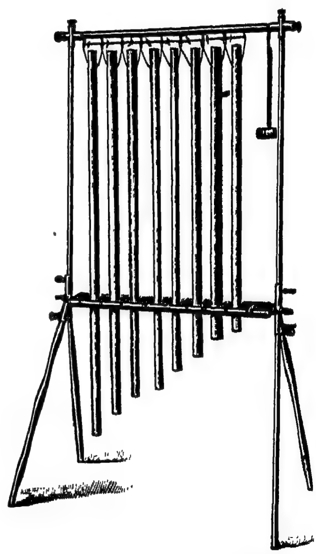

FIG. 30.—Tubular Chimes.

some guidance and light from a combination of theoretical speculation and experimental tests. Thus we might expect the bell to show *nodal meridians*, or lines where an axial plane cuts the surface, and along which there is no radial displacement. Again, we might expect there would be nodal circles where planes perpendicular to the axis cut the surface. Both these surmises are verified by experimental tests. It should be noted that a

node for radial motion may be an antinode for tangential motion. Bell-founders recognise five chief tones or partials in the sound of a church bell. Beginning from the highest these are called the nominal, quint (or fifth), tierce (or third), fundamental, and hum-note. The nominal, fundamental, and hum-note are spaced about an octave apart. The other two approximately fill in the fifth and *minor*-third in the upper octave. At one time none of the five were in any exact relation that could be expressed by small whole numbers, *i.e.* all the partials were inharmonic. But, by turning or boring at certain regions of the bell, it was afterwards found possible to get the three main notes in the true octave relation or nearly so. It has now been asserted that one firm of bell-founders is able to tune *each* of the five tones of a church bell true to a single vibration per second.

§ (51) FOG-HORNS.—For the warning and guidance of mariners fog-horns are erected on capes and other important points, and serve the same purpose during a fog that a lighthouse serves during the night. Small ones may be worked by hand power, but large ones are driven mechanically by an engine or motor of some kind. The passage of air in the throat of the apparatus may be alternately interrupted and freed by a revolving disc or cylinder with holes or slots which pass similar openings in a corresponding fixed plate or cylinder. Such an arrangement is called a siren. The sound thus originated is reinforced and directed to its objective by a large horn. This may be twenty feet long and taper from a few[1] inches diameter at the throat to five or six feet across at the mouth of the bell. If (as is usual) the sound is required to spread over a large distance horizontally and a less distance vertically, then the mouth of the bell is made elliptical with the major axis vertical and the minor axis horizontal. For the less any diameter of the bell is the better does the sound spread in the directions of that diameter. This is an example of the *diffraction* of sound, a phenomenon more frequently met with and studied in connection with light.

§ (52) FREQUENCIES OF SOUND PRODUCERS CALCULATED. We now notice how the frequency of a simple sound producer may be calculated so that arrangements may be made accordingly in any actual case.

(i.) *Strings.*—In the case of strings displaced transversely we may note first that the speed[2] of propagation of such a disturbance is given by $v=\sqrt{(F/m)}$, where F is the stretching force in dynamic units and m is the mass of the string per unit length. Thus, if we want v in cm. per sec., we should take F in dynes and m in gm. per cm. If, on the other hand, F is expressed in poundals and m in pounds per foot, v will be obtained in feet per sec.

Suppose now a harp string be plucked near one end, then the disturbance passes along to the far end, is there reflected with a *reversal* of the displacement, comes back to the end where it first occurred, and is there a second time reflected with a reversal. Hence after passing over twice the length of the string the original state of things is almost repeated. Thus, the time in question must be the period of vibration. Or the reciprocal of that must be the frequency of the string. But this will be the number of double traverses accomplished in one second, and therefore equal to the speed of propagation divided by twice the length of the string. Thus, for the frequency of the fundamental (or prime) of the string, we have the expression

$$N_1=\frac{v}{2L}=\frac{\sqrt{(F/m)}}{2L}, \quad . \quad . \quad (1)$$

where N_1 is the frequency of the prime for a string of length L. The violin family falls under this class. So the pitch is raised by stopping a string on the finger-board and thereby shortening its vibrating length.

For the other possible partials of the string, we imagine it vibrating in two segments with a node at the middle, in three segments with two nodes at the points of trisection, and so forth. Thus the virtual lengths for these become half, third, and so forth of the whole length. Hence the upper partials have frequencies double, treble, etc., that of the prime. Or

$$N_1=\frac{N_2}{2}=\frac{N_3}{3}=\frac{N_4}{4}, \quad . \quad . \quad (2)$$

where N_2 is the frequency of the second partial, etc. On this principle *harmonics* are obtained on the harp, violin, etc.

(ii.) *Open Pipes.*—The case for parallel pipes open at both ends is very similar to that of strings. We are concerned with the speed of propagation in the air[1] or other gas filling the pipe, and with the number of traverses of its length L before the original state of things is approximately repeated. (See § (33) (i.).) Thus, for the open pipe, since at each end a compression is reflected as a rarefaction and *vice versa*, two traverses complete the cycle and constitute the period. Or the frequency of the prime is the speed divided by the

[1] Sometimes surprise is expressed that sufficient range can be obtained with so small a throat. No such difficulty need be felt when it is remembered that the mouthpiece of a cornet narrows to one-fifth of an inch in diameter and that its sounds may be heard with ease half a mile away.

[2] See "Strings, Vibrations of"; also Rayleigh, *Sound*, i. chap. vi.

[1] See "Vibrations of Air in a Tube."

double length of the pipe. Hence we may write

$$N_1=\frac{v}{2L}=\frac{\sqrt{(kP/D)}}{2L}=\frac{v_0\sqrt{(1+(t^\circ/273))}}{2L}, \quad (3)$$

where N_1 is the frequency of the prime, L the length of the pipe, v the speed of sound in the gas, P and D its pressure and density at temperature t° C, k the ratio of its specific heats, and v_0 the speed of sound in the gas at 0° C.

By subdivision of the pipe into segments we see that quicker vibrations can occur, and that the conditions for these segments are (a) antinodes at ends, with (b) freedom to have either nodes or antinodes at other places in the pipe. Hence the pipe may subdivide in 2, 3, 4, etc., segments. (See *Fig.* 5, § (33).) Thus we have for the frequencies N_2, N_3, N_4, etc., of the upper partials

$$N_1=\frac{N_2}{2}=\frac{N_3}{3}=\frac{N_4}{4}, \text{ etc.} \quad . \quad . \quad (4)$$

(iii.) *Corrections for Mouth and Open End.*—We have hitherto supposed that the reflection occurs exactly at the end of the pipe. In reality there is an end correction needed,[1] as though the pipe were a little longer, or as though the vibrations extended a little beyond the end before reflection occurred. For a cylindrical pipe without any flange this correction is three-tenths of the diameter. Further, if the fully open end needs a correction, as though it were not open enough, much more must there be a correction for the mouth, which is far less open. This correction is of the order 1·36 times the diameter. Thus the two together make about five-thirds the diameter. Hence, if we denote by e and m the end and mouth correction respectively, (3) and (4) may be rewritten thus,

$$N_1=\frac{v_0\sqrt{(1+(t^\circ/273))}}{2(L+m+e)} \quad . \quad . \quad (5)$$

$$N_1=\frac{N_2}{2}=\frac{N_3}{3}=\frac{N_4}{4}, \text{ etc.} \quad . \quad . \quad (6)$$

The flute falls under this category. So the pitch is raised by opening a side hole and thereby shortening the vibrating length in use. But it is noteworthy that the end correction e will be much greater for a side hole than for the open end of the flute. And the smaller the hole the greater the correction.

(iv.) *Stopped Pipes.*—As previously shown (see § (33) (ii.)) the disturbance passes four lengths of a stopped pipe before the original state of things is repeated. Hence for the frequency of the prime we may write

$$N_1=\frac{v_0\sqrt{(1+(t^\circ/273))}}{4(L+m)}, \quad . \quad . \quad (7)$$

where v_0 is the speed of sound in the gas at 0° C., t is the temperature of the gas in the pipe, L is its length, and m the correction for the mouth.

Further, as we have seen (§ (33) (ii.)) that the second partial has three times the frequency of the first, the third partial five times the prime frequency and so on, we have

$$N_1=\frac{N_2}{3}=\frac{N_3}{5}=\frac{N_4}{7}, \text{ etc.} \quad . \quad . \quad (8)$$

The clarinet falls approximately under this category, hence its special tone quality and its overblowing the twelfth. It is also seen that the opening of its side holes shortens the vibrating length and so raises the pitch.

(v.) *Conical Pipes.*—Let us now consider the case of a conical pipe closed at the vertex and open at the base. Then it is found that there is an antinode at the open end and that the other antinodes occur equidistantly just as if the whole pipe were parallel and open at both ends. The nodes, on the other hand, are displaced towards the apex from the intervening equidistant positions they would occupy in a parallel pipe. Moreover, those antinodes near the open end are displaced a little, the others more and more till the last is always displaced right up to the vertex. (See *Fig.* 31.) Thus, with due correction for the open end, the possible frequencies for this conical pipe are given by

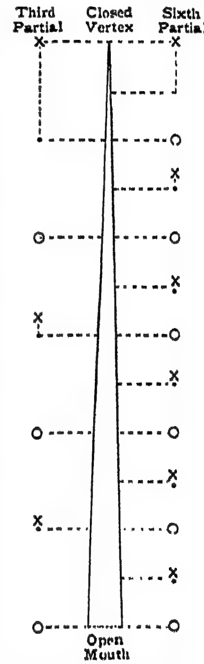

Fig. 31. Conical Pipe.

$$N_1=\frac{v_0\sqrt{(1+(t^\circ/273))}}{2(L+e)}=\frac{N_2}{2}=\frac{N_3}{3}=\frac{N_n}{n}, \text{ etc.,} \quad (9)$$

where N_1, N_2, etc., are frequencies of prime and partial, v_0 is speed of sound in the gas in use at 0° C., L is the actual length of the pipe in use, and e the end correction. In the figure the antinodes are shown by circles, the nodes by crosses, and their undisplaced position by dots. The pipe is shown speaking its third and its sixth partials.

This case includes (approximately) the oboe and bassoon. It should be observed again that the end correction e will be much

[1] See Rayleigh, *Sound*, ii. 201; also *ibid.* chap. xii.

more for a small side hole than for the termination of the pipe at the bell mouth. It is easily seen that the mouthpiece and bell involve a slight departure from the simple form of the ideal cone.

(vi.) *Hyperbolical Pipes with Mouthpieces.*—The case of all the brass instruments with cupped mouthpieces falls under this class, which accordingly merits special attention. It may seem that the simple cone and the larger brass instruments have very little in common, but the wide gap between them may be bridged by a number of quite small steps. Take first the tandem horn shown in *Fig.* 32, and next the drag horn shown in *Fig.* 33.

FIG. 32.
Tandem Horn.

FIG. 33.
Drag Horn.

The first of these departs but slightly from the simple cone, the second rather more. But neither of them disturbs materially the sequence of the partials possible to the pipe. This is on account of the *hyperbolical curvature* of the sides, which is purposely introduced in order to counteract the disturbing effects of the bell and the mouthpiece. The great length of such straight tubes is often very inconvenient. Therefore they are often coiled up into a compact form. Thus, the tandem horn gives place to the bugle (see *Fig.* 34), and the drag horn to the cavalry trumpet (see *Fig.* 35).

When the ideal cone is departed from by introduction of bell and mouthpiece, it is difficult to so model the pipe as to retain *all* the partials in their strict harmonic relation. The practical escape from this difficulty for musical purposes is highly interesting. Such a curvature is adopted as will keep all partials in relative tune *except the pedal*, or prime of the whole series. A mouthpiece is adopted which is usually *too small* to allow of the easy production of the pedal. Then the others are all musically available, and the largest gap to be bridged by valves or slide is a *fifth* (between open notes 3 and 2) instead of an octave (between open notes 2 and 1). The resultant set of partials for some forms of tubing involves a sharpening of the pedal from its pitch as in the cone, but more often we find in use a form of tubing involving a flattening of the pedal.

FIG. 34.
The Duty Bugle.

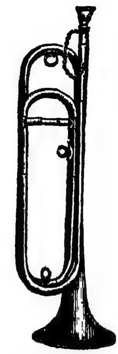

FIG. 35.
The Cavalry Trumpet.

The two cases are contrasted with the simple cone in the following approximate statements of frequencies.

Trumpet and Cornet .	$\frac{9}{8}$, 2, 3, 4, 5, 6, 7, 8, etc.
Simple Cone . . .	1, 2, 3, 4, 5, 6, 7, 8, etc.
Euphonion and Bombardon	$\frac{7}{8}$, 2, 3, 4, 5, 6, 7, 8, etc.

If, therefore, we seek the length for a brass instrument of a given pitch, it is easily seen that there is the choice to be made between calculating for the mistuned pedal or for the other notes musically in tune. Again, if the pitch is to be right at a given temperature of the room, there is the further uncertainty as to the actual temperature (and moisture) of the player's breath in the instrument when in such a room. It is difficult to settle any of these points with precision. In the meantime it is instructive to work out a concrete case for a simple cone and compare the result with an actual instrument, say the B♭ cornet, whose length has probably been fixed by experience. The military pitch of the treble B♭ is 479·3 vibrations per second at 60° F. $= 15\frac{5}{9}$° C. Thus for the length L of the cone with end correction e we have

$$L + e = \frac{1089 + (2 \times 15\frac{5}{9})}{2 \times (479 \cdot 3 \div 4)} = \frac{1120\frac{1}{9}}{239 \cdot 6} = 4 \cdot 675 \text{ ft.} \quad (10)$$

If the diameter of the base is 4·5 in., we have

$$e = 1 \cdot 35 \text{ in.}$$

Hence

$$L = 4 \cdot 675 \times 12 - 1 \cdot 35 = 56 \cdot 1 - 1 \cdot 3 = 54 \cdot 8 \text{ in.}$$

The length of the tubing of a B♭ cornet by Boosey & Co. measures 54·5 in. when in the military pitch. It thus appears that the various departures of this case from the simplicity of the cone are almost compensatory. As to what some of the separate departures are we may note the following.

The player's breath has a temperature well over 80° F., as may be found by breathing on a thermometer. Suppose the breath leaves the cornet at about 64° F. (as a simple test showed), then the mean temperature in the instrument may be taken at say 77° F. or 25° C. Further, the moisture due to the breath might be accountable for an extra 5 ft. per second in the speed of sound. Then the speed of sound in the cornet might be $1089+(2\times 25)+5=1144$ ft./sec. Again, taking the pedal as expressed by $\frac{5}{8}$ instead of unity, its frequency would be $\frac{5}{8}$ of $(479\div 4)=100$ per sec. nearly. Then, finding the length as though it were not changed by the hyperbolic shape, we should have

$$L+e=\frac{1144}{2\times 100}=5{\cdot}72 \text{ ft.}=68{\cdot}64 \text{ in.} \qquad (11)$$

So that for $e=1{\cdot}35$ in. as before, $L=67{\cdot}3$ in. nearly. Hence, the higher temperature and the moisture both increasing the speed and the flatter pedal note decreasing the frequency, all concur in increasing the length of tubing required. The factors which reduce the length are therefore to be sought in (*a*) the hyperbolic shape of the tubing from the bell to the valves, (*b*) the parallel part through the valves and tuning slide, (*c*) the slight taper from the valves to the mouthpiece, (*d*) the shape of the cupped mouthpiece itself, and (*e*) the different *diminutions of the speed of sound* in each part, because the air is not open but in a small pipe. And these factors must act so as to reduce the length from 67·3 to 54·5 in.

It must not be assumed that pipes of a different proportion, like those of the euphonion say, would show the same departure as above from what might be expected as to the length from considerations of actual temperature, or that all the disturbances in this case would mutually cancel. Probably in all these forms of tubing the lengths have been settled as a matter of trial and error, tradition, etc.

(vii.) *Temperature and Pitch of Wind Instruments.*—It is evident from the foregoing that the pitch of wind instruments depends somewhat upon the temperature of the room in which they are played. But this dependence must be slight for a small instrument easily warmed by the player's breath (like the flute) and more pronounced for a large instrument, like the bombardon or the organ, where the player's breath has little or no effect. The details given in Table X. are taken from lectures delivered by D. J. Blaikley at the Royal Military School of Music.

Reeds, on the other hand, flatten with a rise of pitch. Hence, if the temperature of the air used in an organ on some occasion is much warmer or cooler than usual the reed and flue-pipes will be oppositely affected and cannot be used in combination.

Table X

Temperature and Pitch

Instrument.	Rise of Pitch due to Rise of 10° F. in Room.	
	Percentage Increase of Frequency.	Actual Increase of Number of Vibrations per Second in B♭ (479 per sec.).
Flute and Oboe .	0·31	1·50
Clarinet . . .	0·43	2·06
Cornet and trumpet . .	0·51	2·45
French horn . / Trombone .	0·60	2·88
Euphonion . .	0·66	3·16
Bombardon . .	0·73	3·50
Mean of full wind band . . .	0·54	2·60
Organ flue-pipes.	1·05	5·04

(viii.) *Free-Free Bars.*—The calculation of the frequency of lateral vibrations of uniform bars is very complicated, only the result can be quoted here. If N_1 be the frequency of the fundamental of a steel bar of length L cm. and thickness *a* cm., then it can be shown [1] that

$$N_1=538{,}400\times a\div L^2 \text{ per sec.} \quad . \quad (12)$$

Thus for a steel bar 29 in. long and $\frac{1}{2}$ in. thick we find

$$N_1=538{,}400\times \frac{2{\cdot}54}{2}\div(29\times 2{\cdot}54)^2=126 \text{ per sec.},$$

which is the value experimentally found for the prime tone of the bar in question.

(ix.) *Fixed-Free Bars.*—We meet with an approximation to this case chiefly in the prongs of tuning-forks. If of steel, we have for the frequency N_1 of the prime executed by a uniform bar of thickness *a* cm. and length L cm., the expression

$$N_1=84{,}590\times a\div L^2 \text{ per sec.} \quad . \quad (13)$$

Hence for a prong of steel 11 in. long and $\frac{1}{4}$ in. thick, we find

$$N_1=84{,}590\times \tfrac{1}{4}\div(11^2\times 2{\cdot}54)=68{\cdot}8 \text{ per sec.},$$

which is in agreement with experiment.

(x.) *Temperature-Change of Pitch in Forks.*—Since the frequency of a tuning-fork depends on its dimensions and the density and elasticity of the steel, it is scarcely likely that the value of its frequency will escape unchanged when all these factors are changed by an alteration of temperature. The variation with temperature is too small to be important in ordinary musical practice. But, as a matter of strictness, it needs notice for the sake of accuracy in copying forks or comparing one with

[1] See Rayleigh, *Sound*, i. 273.

another. If N_t is the frequency at $t°$ C. and N_0 that at 0° C. we have the relations

$$N_t = N_0(1 - 0{\cdot}000112\,t°). \quad . \quad . \quad (14)$$

The change per 1° F. would be only 5/9 of the above decimal fraction or 0·000062. This is equivalent to about one vibration in sixteen thousand per degree Fahrenheit. Thus the Kneller Hall B♭ fork, giving at 60° F. the military pitch of 479·3 per second, has at other temperatures the values shown below.

Temperature of fork	40° F.	50° F.	60° F.	70° F.	80° F.
Frequency of fork	479·9	479·6	479·3	479·0	478·7 per sec.

§ (53) Experimental Determination of Frequencies.—We shall notice first a few comparative methods that yield the difference or ratio of the frequencies and then pass on to methods that obtain absolute values of the frequency.

(i.) *Difference by Beats.*—When two musical sounds of nearly equal frequencies are about equally intense and remain so we may notice the phenomenon of *beats*, which is the alternate waxing and waning of the sound. Thus, if we start with two tuning-forks of the same pitch, bow each and place them together with the mouths of their resonance boxes side by side, we shall find a smooth flow of the sound as though there was only one fork sounding. Next, let a little soft wax be stuck on the end of the prong of one fork and some lead shot embedded in the wax. Then, on bowing the forks, an alternate loudening and softening of the sound will be noticeable. If the number of throbs or *beats per second* be counted, this will give the *difference of frequencies* of the two forks in their state at the time: for the loudest phase of the beats corresponds to the instant when the forks are impressing the ear with vibrations just in step with one another. The softest phase of the beats corresponds to the instant when the vibrations at the ear from the two forks are just out of step. To hear beats to advantage from strings and forks they should be plucked or struck and *let go.* If one continues bowing the vibrations are liable to be changed by the act of bowing and the beats will not be trustworthy, if indeed audible.

(ii.) *Detection of Mine Gases by Beats.*—The method of beats has a useful application in the detection of deleterious gases in coal mines. A portable equipment has been devised to be carried in the pit, by which two similar pipes are blown so as to emit simultaneously their notes, one pipe taking pure air from a reservoir, the other pipe being blown from the air, etc., present in the mine. Long before the air is bad enough to be dangerous its vitiation is in this way detectable by the beats between the two pipes.

(iii.) *Ratio by the Ear.*—Very often only a rough gauge of the interval between two musical sounds is required, and for this purpose the *musical ear* (where possessed) may suffice even when the sounds occur successively. The result of the test can be announced almost instantly if the interval is one in musical use. But if it is not of that simple musical character, it may take longer to decide quite what it is. The accuracy of results obtained in this manner should be quite right as to the number of semitones in a musical interval. Such decisions could be scarcely trusted, however, to discriminate between the large and small tones of just intonation, their ratio frequencies being 9/8 and 10/9 respectively. When the sounds occur simultaneously the sensitiveness of the ear is distinctly greater, and fairly good tuning is possible in this way, especially as the occurrence of beats often assists in the final judgment.

(iv.) *Forks compared by Smoke Traces.*—A convenient way of comparing frequencies of forks is that of letting each write a wavy trace on smoked glass or paper. This method has the advantage of being independent of hearing altogether. Each fork has a small style of aluminium foil fixed on it, and the forks must be so arranged that the two traces can be obtained side by side for comparisons. This may be accomplished in a variety of ways. One plan is to have both forks fixed by their shanks and some wood packing in a vice so that the four prongs are all side by side horizontally, the styles being on the underside of the prongs. Then, the forks are set in vibration, preferably by bowing, and the smoked glass moved by hand parallel to the prongs and in contact with their styles. Another plan is to have the forks mounted on a frame along which the smoked glass can slide. When the traces are obtained their wave-lengths are compared with whatever nicety is desirable for the purpose in view. Thus the ratio of the frequencies is found, since $N_1\lambda_1 = N_2\lambda_2$, where the N's are the frequencies and the λ's the corresponding wave-length of traces. Both these frequencies are slightly different from those of the forks without the styles. If the latter are sought the method of correction at end of § (53) (viii.) may be adopted.

(v.) *Lissajous' Figures.*—This is an optical method for testing the accuracy of tuning of some simple interval (unison, octave, etc.) between two forks. The arrangement is shown in *Fig.* 36.

The light from an arc lantern passes through the focussing lens L, and is reflected at a little mirror P on the fork A, then at a mirror Q on the fork B, and finally reaches the screen at O,

if both forks are at rest. The vibration of fork A will displace the spot of light parallel to XOX′, those of fork B will displace it parallel to YOY′. Hence, if both forks are vibrating together in *unison*, a special figure is described, which may be an oblique straight line or an ellipse or circle according to the phase difference of the vibrations; but nothing else is possible if the unison is exact. If, however, the unison is not exact the figure slowly melts from one of the above figures to another, and after a time, t seconds say, returns to its original form. Let the frequencies be N and N′, the latter being the less. Then in the time t one vibration has gained a complete period on the other. So

$$Nt - 1 = N't,$$

or

$$\frac{N - N'}{N} = \frac{1}{Nt},$$

whence

$$\frac{N'}{N} = 1 - \frac{1}{Nt}. \qquad (1)$$

As an example, suppose one fork is known to have the frequency 100 per second = N say, and the figures are found to go through their cycle in 2 minutes = 120 seconds. Then

$$\frac{N'}{N} = 1 - \frac{1}{12{,}000},$$

or

$$\frac{N'}{N} = \frac{11{,}999}{12{,}000}. \qquad (2)$$

So that N′ is accurate to one in twelve thousand, or N′ = 99·9917 per second. This illustrates the accuracy possible; the interval is less than one five-hundredth of a semitone.

(vi.) *Resonance Tube.*—If a tall, narrow jar or tube be taken, and the level of water in it quickly and quietly adjusted, the air column above the water may be set to respond well to a vibrating fork held over the top of the tube. Suppose the shortest length of air column that responds is L_1, then this is like a closed organ-pipe, whose length we have seen is traversed four times in the period of the vibration. Thus this distance multiplied by the frequency N of the fork gives the speed of sound in the air at the temperature ($t°$ C.) in the room at the time. Hence we may write

$$N4(L_1 + e) = v = (33{,}200 + 61t) \text{ cm./sec.}, \qquad (3)$$

where e is the end-correction for the tube and equals 0·3 of its diameter, whence N the only unknown can be found. Let the next larger air column that responds be L_2. Then one-third the length of this must correspond to the previous L_1. Thus we have

$$N4(L_2 + e) = 3v = 3(33{,}200 + 61t) \text{ cm./sec.}, \qquad (4)$$

whence, by subtracting (3) from (4), we find

$$N = \frac{v}{2(L_2 - L_1)} = \frac{33{,}200 + 61t}{2(L_2 - L_1)}. \qquad (5)$$

This is preferable to using (3) alone, if the jar or tube is long enough to permit of finding this second place of resonance.

(vii.) *Monochord Method.*—To find the frequency of a fork it is sometimes convenient to set the string or wire of a monochord so that a certain length L of it (adjusted by a movable bridge) is in unison with the fork. This adjustment should be done first by ear, and second by beats. Finally, it may be made more exact by setting the vibrating fork with its stem on the string where it crosses the bridge. It should start the string in vibration. This last is a very delicate test of the exact unison, the vibration of the string being repeatedly started and detected by the finger. Then, the tension of the string being due to a weight of M grams and the mass of the string m grams per cm., the frequency of the fork and string being each N, we have

$$N = \frac{\sqrt{Mg/m}}{2L}, \qquad (6)$$

where g is 981 cm./sec².

(viii.) *Fall Plate.*—A very useful method for the frequency N of a fork is that known as the fall plate method and illustrated in *Fig.* 37. A smoked-glass plate is allowed to fall so that a style G carried by the fork F traces the wavy mark P, Q, R on it. As seen, the plate hangs by a thread, which is burnt between the pins HH when all is ready. At

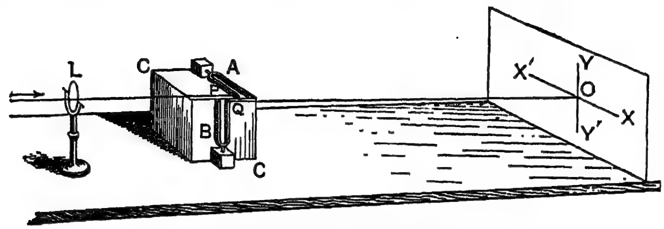

FIG. 36.—Lissajous' Figures.

the very beginning of the trace the waves are too crowded to be distinguished; but a little farther on, say at P, let them become clear. Then count an exact number of waves n, and measure the length $PQ = l_1$ totalled by them. Then, from the end Q of that set, count the same number n of waves and let them occupy the total length, $QR = l_2$ say.

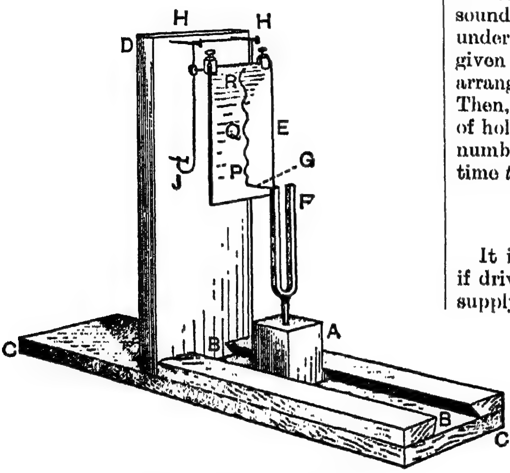

FIG. 37.—Fork and Fall Plate.

Then if u denotes the speed of fall of the plate when the style touched P, we have for the fall PQ

$$l_1 = ut + \tfrac{1}{2}gt^2, \quad . \quad . \quad . \quad (7)$$

where t is the time of n waves $= n/N$. Again, for the fall QR, the speed at Q is $u + gt$; thus we have

$$l_2 = (u + gt)t + \tfrac{1}{2}gt^2 \quad . \quad . \quad (8)$$

Hence (8) - (7) gives

$$l_2 - l_1 = gt^2 = \left(\frac{gn^2}{N^2}\right),$$

or

$$N = n\sqrt{\left(\frac{g}{l_2 - l_1}\right)}. \quad . \quad . \quad (9)$$

It should be noticed that the presence of the style on the fork will load it and flatten its pitch somewhat. This flattening could be evaluated if another fork were available exactly like that used, so that without its style they were in exact unison. Then the difference due to the style could be found by observing beats between the two forks. If it were two per second, then we should have to add two to the value found by (9) to obtain the frequency of the fork when the style was removed.

(ix.) *Siren.* If the frequency of an organ pipe is to be evaluated, some of the methods already described are not available. Indeed some other sound produced by an air blast seems preferable as a standard of comparison. For this purpose a siren may be used in which a disc with a circle of holes in it spins so that the holes are alternately opened and closed by passing a similar set of holes in a fixed plate, an air blast giving the sound. When the siren is set rotating at such a speed that its sound is in unison with that of the pipe under test, the number of revolutions in a given time must be observed by the counting arrangement on the siren and a stop-watch. Then, if the frequency sought is N, the number of holes in the circle on the disc is m, and the number of revolutions of the disc is n, in time t seconds, we have

$$N = \frac{mn}{t}. \quad . \quad . \quad . \quad (10)$$

It is not possible to keep the siren steady if driven by air alone unless some mechanical supply is available and a screw-clip or similar adjustment is used on the india-rubber pipe conducting the air to the siren. Another method is to supply the siren from a wind-chest in which the air is kept at a constant pressure by means of a loaded safety-valve. If it is not possible to keep the siren in unison, we may keep it a little too slow all the time, t, and count the total number, b, of beats thereby produced. Then, obviously, (10) changes to

$$N = \frac{mn + b}{t}. \quad . \quad . \quad . \quad (11)$$

(x.) *Tonometer.*—This arrangement consists of a set of tuning-forks extending throughout an octave or through a number of octaves. The successive forks differ in frequency by a few vibrations per second only, say, about four, all these differences being observed by beats and carefully noted, till the series building up an *exact octave* is dealt with. Then, if the bottom fork of this octave has a frequency N, the top fork has a frequency 2N. Further, let the number of beats per second between successive forks be a, b, c, d, etc., and let the sum of all these through the octave be found. Then obviously this sum is the value of N. Then the frequency of one fork being known, that of any other in the series is known by adding the beat-numbers. We can then compare any other sound with the forks of neighbouring frequencies, note the beats, and thus ascertain the frequency of the sound in question. Thus, suppose we have forks of frequencies 132, 136·1, 140·2, 143·8, and 147·9 per sec. Then, if our sound to be tested gives about 5 beats per second with the first fork, 1 beat per

second with the next one, and 3·1 beats per second with the third, and about 7 per second with the fourth, we see that the frequency sought is 137·1 per second. Such a set of forks, ranging over a number of octaves, may be taken into a belfry and so the exact pitches of the partial tones of any or all the church bells there be ascertained.

IV. Sound Detectors

§ (54) Air Resonators.—The air in a globular or conical gas or lamp shade may sometimes be observed to ring or resonate in response to some sound made by chance near it. In such cases it is often found that a musical sound a semitone higher or lower awakes very little response. Thus, the response of such an arrangement would act as a detector of the presence of a sound of particular pitch mixed up with other sounds of different pitches. To apply this principle we may use a jar, bottle, or flask and tune it to a particular pitch (as given by a tuning-fork) by pouring water into the flask to sharpen it, or partly shading its mouth by a cardboard to flatten it. In this way the first bottle picked up may be readily tuned to respond well to any ordinary fork. Then, in the case of a tuning-fork an octave lower but very vigorously bowed, this improvised resonator may be used to detect the presence of the octave of this lower fork's prime. For with large amplitudes of a big tuning-fork the air near its prongs executes a complicated motion in which the octave may be detected, although the prongs do not give that octave by simple subdivision of vibrating segments as a string does. Such a resonator may also be used to detect the octave or higher partials in the human singing voice. The use of a special form of resonator for a determination of pitch is given in § 53 (vi.).

§ (55) Sensitive Flames.—Various flames have been found to be sensitive to sounds of high or medium pitch and have been studied from several points of view. Apparently this phenomenon was discovered first by J. Leconte [1] and then independently by W. F. Barrett in 1865.[2]

(i.) *Tyndall's Vowel Flame.*—This is a high-pressure gas flame sensitive to very high-pitched sounds, and so can detect and exhibit peculiarities in certain sounds owing to the presence in them of different high partials. The gas issues from the single small hole of a Sugg's steatite pinhole burner, and the flame is about two feet high. The gas may be derived from a weighted gas bag or a steel cylinder of compressed gas with regulator. The flame must be adjusted to the sensitive state, as tall as possible without flaring. This flame responds, by falling down to a half or a quarter of its normal height, when excited by suitable sounds, such as a tap on a distant anvil, the shaking of a bunch of keys, the jingling of coins, the creaking of boots, the crumpling or tearing of paper, or the ticking of a watch. A loud *oo* leaves it unaffected, it quivers to *o*, is strongly affected by *ee*, and still more so by *ah!*

(ii.) *Rayleigh's Sensitive Flame.*—The late Lord Rayleigh devised an enclosed jet sensitive to sounds of ordinary pitches, say those through the compass of a piano. It has the advantage of working off the ordinary gas supply. A jet of coal-gas rises from a steatite pinhole burner placed in a chamber (which may be cubical of about two inches side). The gas then passes up through a vertical tube $\frac{3}{8}$-inch diameter and $6\frac{1}{4}$ inches high, mounted on the chamber. On reaching the top of the tube it burns in the open air. The front of the chamber is covered with tissue paper to receive and yield to the sound and affect the jet inside. To adjust the flame to sensitiveness, begin with the full pressure of the ordinary gas supply and slowly turn the tap down till the flame suddenly assumes a fluttering lop-sided appearance, being at one side drawn down the inside of the tube a little. Lower the pressure yet more till the flame, though still lop-sided, is steady. It is then right for use and will be found sensitive to the crumpling of paper, clapping of hands, and the piano. Its recovery after stimulus is rather slow.

(iii.) *Bunsen-burner Sensitive Flame.*—For this purpose the Bunsen burner must be carefully chosen. The following type has been found suitable: upright tube of brass 5 inches high and $\frac{3}{8}$-inch bore, only *one* side hole for air, which is *perfectly* closed by a *half*-turn of the sleeve. To obtain the sensitive state exclude the air completely and reduce the pressure of the ordinary gas supply until the flame is lop-sided but quiet. The maximum pressure consistent with these conditions seems to give the best results. The flame is about 4 inches high, that side of its base next the supply tube being detached from the lip of the upright tube and extending down into it about a third of an inch. The burner is *not*, however, *lit back*. When responding the flame falls to about $1\frac{1}{2}$ inches high and quickly recovers. It is insensitive to crumpling of paper and to the jingling of keys, but responds promptly to clapping of the hands, shuffling the feet on boards, coughing, speaking, whistling, or singing. It is possible to whistle a slow staccato passage, each note being acknowledged by a lowering of the flame and each rest by a recovery to the normal height. This flame is very useful for

[1] *Phil. Mag.*, 1858, xv. 335-339.
[2] *Ibid.*, 1867, xxxiii. 216-222 and 287-290.

detecting the nodes and antinodes where a sound is reflected from a wall. The wave-length can thus be found and the frequency of the sound calculated.

§ (56) THE RAYLEIGH DISC.—It is found that any flat obstacle in a stream of fluid tends to set itself across that stream. This was utilised by the late Lord Rayleigh in the form of a disc suspended by a fibre with its zero position at angles of 45° to the directions of flow of air in the vibrations to be detected. The quantitative treatment of such a disc was given by König in 1891. The turning couple or torque is thus shown to be expressed by

$$G = \tfrac{4}{3}\rho a^3 W^2 \sin 2\theta,$$

where G is the couple, ρ the density of the air (or other gas) moving at speed W, a is the radius of the disc, and θ is the angle between its normal and the direction of the wind W when undisturbed by the disc. A simple experiment with the disc is as follows: Just inside the mouth of the resonance box of a tuning-fork suspend by a cocoon fibre a disc of mica, thin card, or very thin mirror about an inch in diameter. Arrange that the zero position of the disc shall be at 45° with the plane of the mouth of the box. Then on bowing the fork, or singing its note in front, the disc will promptly set itself across the mouth. By light reflected from the mirror the effect may be made evident to an audience, or by use of a scale in addition the action may be used as an absolute measure of the intensity of the sound in question. In this quantitative manner the Rayleigh disc has been used in various researches in architectural acoustics and other investigations.

§ (57) HUMAN HEARING.—This is a vast subject taken in all its possible aspects; only a few of the physical ones can be noticed here. But their importance is very great, because almost all sounds are brought to the arbitrament of the human ear, hence the necessity of gaining what insight we can into the organ itself and its manner of working.

(i.) *The Ear.* A general view of the human ear, somewhat departing from exact scale for the sake of clearness, is given in *Fig.* 38.

In this we easily recognise the external ear, the ear passage ending at the drum-*skin* (often improperly spoken of as the drum). Beyond this lies the cavity which is properly called the drum. From the drum the Eustachian tube proceeds to the pharynx. This tube opens when swallowing occurs and so sets the pressures equal on each side of the drum-skin. This equality is essential to hearing, and if by plunging or diving under water, or ascending in an airplane, the equality is lost, it may be restored by purposely swallowing. The cavity of the drum is bridged across from the drum-skin to the labyrinth by a train of three little bones called respectively the hammer, the

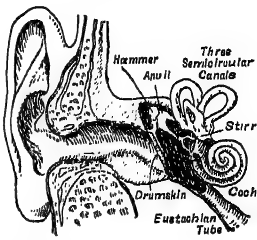

FIG. 38.—General View of Human Ear.

anvil, and the stirrup. The labyrinth comprises the vestibule, the three semicircular canals, and the cochlea. The vestibule is the middle part of the labyrinth, and contains the oval window which receives the foot of the stirrup. Forward and downward from the vestibule we have the important structure resembling a snail-shell and called the *cochlea.* It contains a spiral canal, which is seen in the cross-section of a single turn or whorl given in *Fig.* 39.

The cochlear canal (*canalis cochlearis*) is seen to be almost triangular in cross-section, and is divided from the *scala vestibuli* by the membrane of Reissner, and, by the basilar membrane, from the *scala tympani*, which ends in the round window when it reaches the

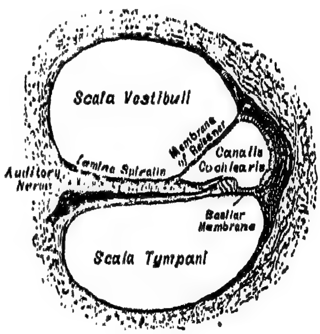

FIG. 39.—Cross-section of a Whorl of the Cochlea.

drum. These two *scalae* (or staircases) are separated by the *lamina spiralis*, through which the fibrils of the auditory nerve are distributed to the sensitive structures of the basilar membrane.

(ii.) *The Act of Hearing.*—When minute but rapid alternations of air pressure of suitable frequency and range occur at the external ear, they pass along to the drum-skin and set it in vibratory motion. This motion passes through the chain of tiny bones (hammer,

anvil, and stirrup) to the oval window, whose displacements, according to Helmholtz, never exceed a tenth of a millimetre. But the area of the drum-skin is fifteen to twenty times that of the oval window. Thus, the train of bones receives the motion of the comparatively large drum-skin moved by the *air* and changes it into the more forcible motion of the very small oval window, which has to move the *liquid* in the labyrinth. Hence the motions are handed on to this liquid, and the waves passing along the *scala vestibuli* are felt in the *canalis cochlearis* and then affect the sensitive apparatus on the basilar membrane. At the tip of the cochlea the partition ceases between the *scala vestibuli* and the *scala tympani*, so the waves proceeding along the first can return by the second. This ends at the drum with a round window which seems to play the part of a safety-valve. Much controversy has raged as to which are the structures that form the sensitive part of hearing and how they act. Some hold that these structures are some tuned vibrators which are set in sympathetic vibration by impulses of their own natural frequency. On this view, a vibration of 100 per second, say, would set in full vibration any vibrators which had the same or a near frequency (sharper or flatter), these vibrators would stimulate the nerve fibrils, and so the message would reach the brain that certain vibrators were in motion. This would constitute hearing a sound of frequency 100 per second. Any other audible frequencies would be dealt with in like manner, each setting in action those responders of frequencies near to that of the external stimulating sound. And all these could be heard simultaneously as separate sounds if not too close in frequency, or some of them too faint to be recognised amid the din of the others. Some reject this so-called resonance theory of hearing, but have little to put in its place which is intelligible or acceptable to a physicist. It is perhaps too early to feel certainty with respect to any hypothesis of audition. But it may be pointed out that one objection to the resonance theory has been recently removed. It was at ne time imagined that thousands of differently tuned responders would be needed in the ear to satisfy the requirements of that theory. It has now been shown that about *twelve to the octave* in the musical range of hearing, and, say, a *hundred* in all, may be taken as sufficient to account for all the delicacy of perception of pitch possessed by us.[1]

(iii.) *Limits of Audition.*—Separate impulses may have a frequency too slow to be heard as a continuous sound, and vibrations may be too rapid to be heard at all. Thus for each person there are limits of pitch outside which no sound is heard as such. These limits are very different for different persons, and vary with time for the same person. Some cannot hear much continuous tone for less than thirty per second, though others may hear down to fifteen per second. Some gigantic organ pipes are effective by a series of throbs shaking the floor or panes of loose glass rather than by any continuous influence they may have on the ear. The highest pitch audible is also somewhat uncertain. Thus, some can hear sounds up to or beyond 40,000 per second, while others fail at an octave lower. We might then place the extreme limits at 15 to 40,000 per second, those useful for musical purposes at about 40 to 5000 per second. Thus, while the eye only sees one octave, the ear hears about eleven octaves, of which about seven are musically available. It should be noticed that not only are the qualities unpleasant at the extreme pitches, but that the sounds are useless musically for another reason, namely, that the discrimination of pitch is obscured and lost beyond certain points both up and down. And this is just what would be the case if we heard by means of a set of vibratory responders. For obviously such a set must have its limits up and down. Further, any note *within* the range of this set would be located in pitch quite distinctly. But, beyond the range of this set, if upwards, the note would be recognised as high because only the high-pitched responders would be affected. But the pitch could not be precisely discriminated, because there would be no other responders still higher in pitch than the note heard. And to locate a pitch, on this view, it would need some responders too high to be disturbed by the sound, some responders too low to be disturbed by it, and some between that were powerfully affected. Thus a sound so high as to be beyond the range of the vibrators present would be known to be high but not clearly discriminated in pitch. Similarly, a sound lower in pitch than any of the responders present in the ear would be acknowledged to be low, but its exact pitch would elude discrimination. And this is just what we actually experience at each end of our auditory range.

It is also a matter of some interest to ascertain the total number of vibrations needed to enable an observer to decide the pitch of a sound heard. Kohlrausch investigated this by attaching to a pendulum an arc of a circle with a limited number of teeth on it. On letting go the pendulum the teeth struck a card, and on hearing the sound a monochord was set to agree as closely as possible with the pitch as it was judged to be. As the number of teeth was reduced so was the fineness of judgment as to the pitch heard. Thus, the error of judgment rose from 0·14

[1] *Phil. Mag.*, 1910, xxxviii. 164-173.

of a semitone with 16 teeth to 0·5 of a semitone with 2 teeth. Hence, even with two vibrations the judgment of pitch was only in error by a quarter of a tone.

(iv.) *Minimum Amplitude Audible.*—So far back as 1870, Toepler and Boltzmann made an estimate on this subject by experiments on an organ pipe. Their result was that with an amplitude (or displacement each side of the mean position) of 200×10^{-8} cm. a sound of frequency about 180 per second was just audible. The late Lord Rayleigh carried out experiments on two plans, one with a whistle, the other with a tuning-fork. The first, with a frequency of 2730 per second, gave an amplitude of 8×10^{-8} cm. as being just audible. The second, with a frequency of 256 per second, gave a minimum audible amplitude of $12{\cdot}7 \times 10^{-8}$ cm. Dr. P. E. Shaw in 1904 applied his electrical micrometer to test the minimum audible amplitude of the diaphragm of a telephone receiver. For an expected sound he found the minimum audible motion of the diaphragm to be 7×10^{-8} cm., and inferred that the motion of the air produced by it at the ear was only one-fifth the above. Thus the minimum audible amplitude would be $1{\cdot}4 \times 10^{-8}$ cm., or about 1 : 180,000,000 of an inch!

(v.) *Perception of Sound Direction.*—In 1907 the late Lord Rayleigh published a series of experiments undertaken to ascertain the powers of the ears in estimating the directions from which sounds came, and how these powers may be explained. By theory and experiments it was concluded that for sounds higher in pitch than about *c''* (512 per second) the discrimination of right and left is made chiefly upon the difference of intensities at the two ears, but that at low pitches, at any rate below *c* (128 per second), the recognition of phase-differences at the two ears must be appealed to. But it is to be noticed that we have very little judgment about front and back in attempting to locate the source of a sound heard. Thus, on board ship, if wishing to locate the source of a fog-signal, a combination of several observers facing different ways offers advantages. In comparing their judgments attention should be paid only to which of his sides, right or left, each listener supposed the sound source to lie.

V. Sound Reproducers and Recorders

§ (58) The Telephone. In 1876 Graham Bell patented his speaking telephone.[1] At this time his instrument acted both as a transmitter (giving to the line signals corresponding to the sounds spoken into it) and as a receiver (which reconverted those signals into sounds at the receiving end). In essential principle, Bell's telephone, as a receiver, is in use to-day; though alterations have been made in details. But, as a transmitter, the Bell telephone is superseded by some form of carbon transmitter. The Bell telephone is shown in section in *Fig.* 40, and an Edison carbon transmitter is shown in *Fig.* 41.

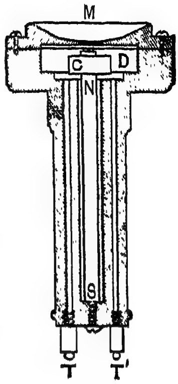

Fig. 40.
Bell's Telephone.

When using for telephony a carbon transmitter, a battery is needed to generate the current, and it is the function of the transmitter, by the variation of its own resistance, to vary the current thus produced. How this is done may be seen from the figure. The sound waves pass through the mouthpiece M and set the diaphragm D in vibration. This motion acts upon the button B and the adjoining platinum plate, which thus makes a variable contact with C, a disc of carbon (sometimes now replaced by separate carbon balls). The electrical circuit in the instrument is from the terminal T through the spring S to the platinum plate, thence through the carbon and the case of the instrument to the second terminal T'. The variations of the electrical resistance (due to the movement of the diaphragm upon which sound waves fall) are thus impressed upon the current through the line to the other station, and there act upon the telephone receiver (see *Fig.* 40). The current enters and leaves by the terminals T and T', and so passes through a coil C near the end of a magnet NS. The variations of the current attract in varying degrees the diaphragm of the receiver. It thus vibrates in correspondence with that of the transmitter, and so emits sounds which agree in essentials with those falling upon the transmitter's diaphragm.

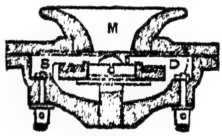

Fig. 41.
Edison Carbon Transmitter.

Portable telephone sets (called audiphones) have been arranged to relieve partially deaf persons, the carbon transmitter being on the dress and the receiver or receivers applied to one or both ears. To some patients they have proved beneficial. But at present the details of a scientific test of defective hearing seem to be not so far advanced as the corresponding ones applicable to a test of eyesight.

[1] See also "Telephony," § (17), Vol. II.; "Microphones," Vol. II.; "Microphone, The Hot Wire," Vol. II.

§ (59) Duddell's Speaking Arc.—This arrangement may be said to utilise the arc light as a special form of telephone receiver. The arc is at the same time (i.) part of the direct-current circuit which supplies its main current and (ii.) part of an oscillating circuit containing a condenser and a coil. On this oscillating circuit are impressed the alternating currents obtained by induction from the fluctuating currents of a telephone transmitter. The arc then changes its state in such wise as

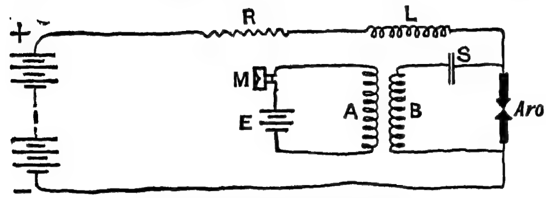

Fig. 42.—Duddell's Speaking Arc.

to emit very feeble sounds, but it can yet render speech and song and the performance on musical instruments so as to be just audible to an audience of several hundreds. The arrangement is shown diagrammatically in *Fig.* 42. It is seen that in the direct-current circuit of main supply is included an inductance L to prevent any appreciable part of the alternating current obtruding there. Also in the oscillating circuit a condenser S is included to prevent the direct current from flowing there. Only in the arc itself are both the steady and the alternating currents allowed to flow. The alternating currents are inductively produced in the coil B by the variations of current in the coil A through the waves of speech, song, etc., falling upon M the microphone (or telephone transmitter).

§ (60) Miller's Phonodeik.—Various arrangements have been adopted by different experimenters to analyse the motions of the strings and other parts of musical instruments, separately or simultaneously. Probably the first was the vibration microscope of Helmholtz. Others have involved the photographs of an illuminated portion of the vibrating string together with a uniform perpendicular motion of the sensitive film or plate. They also include the use of rocking mirrors reflecting a spot of light and so recording photographically the motions of the bridge, belly, and air of a violin, etc. These methods have been used by F. Krigar-Menzel and A. Raps, by E. H. Barton and by C. V. Raman.

In 1912 D. C. Miller published an account of his apparatus, for the demonstration and photography of sound curves, called the *phonodeik*. This is shown diagrammatically in *Fig.* 43. It collects from the air what we may call the total resulting sound from all parts of the instrument under test. This passes down the horn *h* to a diaphragm of glass about three-thousandths of an inch thick, held lightly between soft rubber rings. To the middle of the diaphragm a few silk fibres (or a platinum wire 0·0005 inch in diameter) are attached, and after passing once round a tiny pulley finish at a spring tension piece. This pulley is on a spindle carrying a mirror *m*, 1 millimetre square, the whole mass being under one five-hundredth of a gram. Light from a lamp *l* passes to the mirror focussed by a lens on to a film *f* moving in a special camera. The uniform motion of the film is perpendicular to the motion on it of the spot of light due to the vibrations to be recorded. Thus a displacement-time graph is obtained. The apparatus can be arranged also with a rotating mirror and screen instead of the camera, thus projecting the curves in the sight of an audience listening to the sounds which produce them.

Many interesting results have been obtained with the phonodeik, a few of which are reproduced here. *Figs.* 44 to 48 show records of the violin, flute, oboe, piano, and bass voice respectively. Finally, *Fig.* 49 is from a gramophone and shows Tetrazzini singing alone

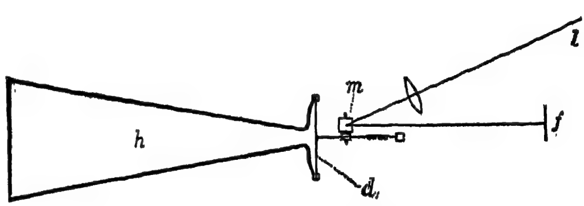

Fig. 43.—Miller's Phonodeik.

a high B♭ in *Lucia di Lammermoor*, the fluctuations in amplitude being due to a slight *tremolo*. The whole record for this one note lasts about three seconds; only about a tenth of it, just at the finish, is here shown.

§ (61) Rankine's Photophone for Transmission of Speech by Light.—In 1919 A. O. Rankine published an account of his arrangements, which may be described briefly as follows. Light from a point source is collected by a lens and an image formed on a small concave mirror which is attached to the diaphragm of a gramophone recorder. The light diverges and passes through a second similar lens, which projects it to the distant station. Two similar grids are mounted, one

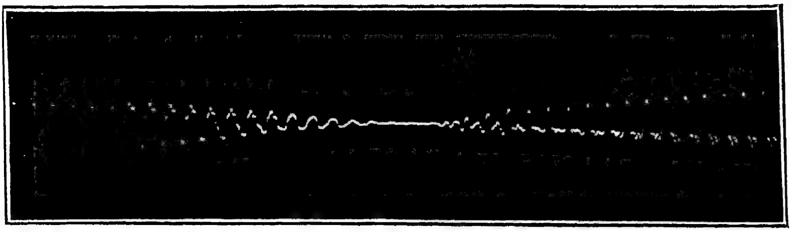

FIG. 44. - Photograph of the Tone of a Violin at the time of Reversing of the Bowing.

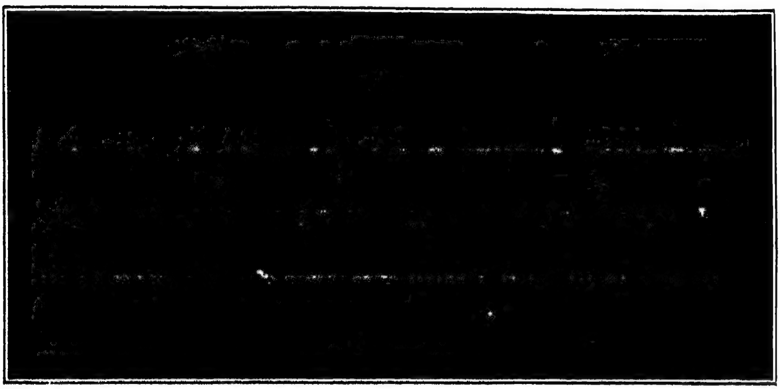

FIG. 45. —Three Photographs of the Tone of a Flute, played *p*, *mf*, and *f*.

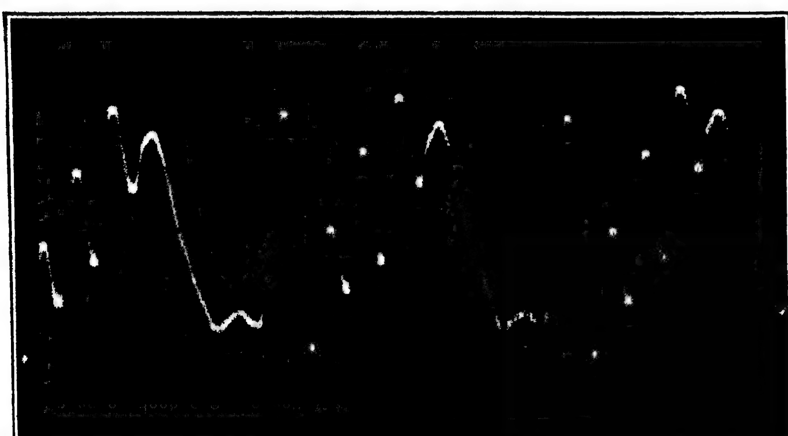

FIG. 46. Photograph of the Tone of an Oboe.

in front of each lens. An image of the first grid is superposed on the second by reflection in the concave mirror when silence reigns. But when the mirror oscillates under the vibrations of speech, the dark spaces of the image move over the openings of the second grid, thus producing fluctuations of the intensity of the beam. The light is received by a collecting lens and focussed on a selenium cell in circuit with a battery and telephone receiver.

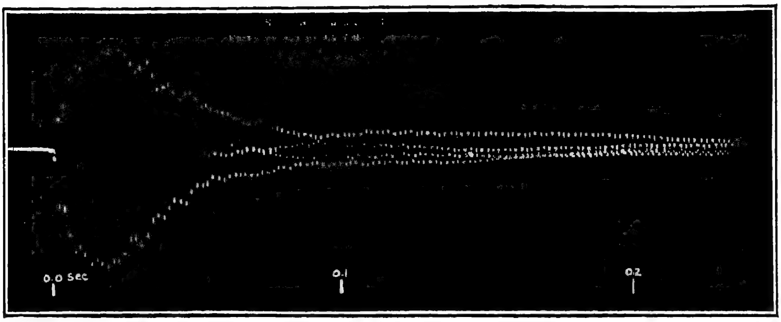

FIG. 47.—Photograph of the Tone of a Piano.

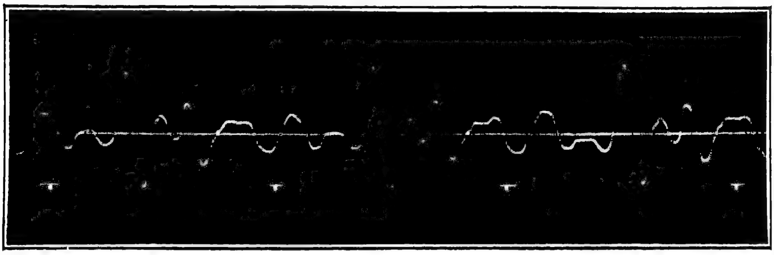

FIG. 48.—Photograph of a Bass Voice.

FIG. 49.—Sound Waves from the Soprano Voice (Tetrazzini) singing high B♭.

If the light from the above *photophone* transmitter is concentrated on a narrow slit, an image of which is produced by another lens on a cinematograph film, then the variations in intensity of the light (caused by the sounds on the photophone) are recorded as variations in the density of the film after development. For reproduction of the sounds light from an illuminated slit is focussed on the film, behind which a selenium cell is placed connected to a telephone circuit in which may be heard the sounds.[1]

SOUND RANGING

§ (1) GENERAL.—"Sound Ranging" consists in the location of a source of sound by means of measurements made on the sound wave which spreads from the source. *Fig.* 1 illustrates the manner in which this may be done. A sound originates from the point S in the figure, and is received at three stations A, B, and C. At each station the time is registered at which the sound wave arrives, and so the time intervals between its reaching A and B, B and C, can be measured. A geometrical construction such as that shown in the figure then gives the position of the source with reference to the surveyed stations A, B, and C. If the sound arrives at B t_1 seconds after reaching A, and at C t_2 seconds after arriving at A, circles are drawn with B and C as centres and with radii equal to Vt_1, Vt_2, where V is the velocity of sound in air. The centre of a circle which passes through A and touches the other two circles will coincide with the point S. This point S may alternatively be regarded as the intersection of two hyperbolas. If the time interval for the stations A, B is t_1 seconds, all possible positions for S lie on a hyperbola, with A and B as foci, and which is determined by the relation $SB - SA = Vt_1$. A similar hyperbola can be drawn for B and C, and the two curves intersect in S.

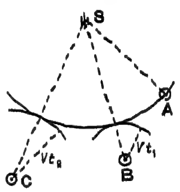

FIG. 1.

It will be clear that the method is not applicable to a source of continuous sound; it can only be used when the sound has a sharply defined commencement.

Towards the end of 1914, when the fighting in France and elsewhere developed into "trench warfare," it became clear that Sound

Ranging might provide a valuable means of locating hostile artillery. The batteries on both sides took up fixed positions, in which the guns were protected from shell fire by emplacements, and were carefully camouflaged to screen them from aerial observation. Their location became increasingly difficult. At the same time the stability of the front line made it possible to develop more complex methods of determining their positions. For instance, one method which soon proved of great value consisted in the installation of observation posts at suitable points behind the front line, from which bearings were obtained of the flashes and smoke puffs when hostile guns fired. These positions were accurately surveyed, and the locations determined by the co-operation of several posts. Experiments were also commenced in the French and German armies, and later in the British army, to test the practicability of Sound Ranging, and their successful result led to the establishment of Sound Ranging as a valuable means of location.

§ (2) Sound Ranging in Practice. (i.) *Difficulties of Location.*—Although the principle of Sound Ranging is simple, in practice many difficulties had to be surmounted. The batteries to be located were situated from 5000 to 15,000 metres from the points where it was possible to put the recording stations. In order that the locations may be of value they must be accurate to within 100 or 200 metres. A consideration of the displacement of the plotted position which is caused by errors in timing the sound shows that these timing errors should not exceed one-hundredth of a second. For this reason it is impossible to use human agency to record the sound wave, except under the most favourable conditions. A man recording the commencement of a gun report, by pressing a key or starting a watch, will make errors of at least one-tenth of a second. Some success was attained by systems of sound ranging in which stop watches, or registering mechanisms actuated by the pressing of keys, were employed; and in the German army these methods were continued until a later date than in the British and French armies. Finally, however, they were replaced by an automatic registration of the sound by means of microphones or similar devices connected by cable to a central station.

The velocity of the sound wave is affected by the wind and is dependent on the temperature, so that allowances must be made for these factors. Both wind velocity and temperature vary with the height from the ground, and measurements of them made at ground level will not serve as a basis for calculation. This question will be dealt with more fully below, for the calculation of the true wind and temperature corrections is a complex and difficult problem.

(ii.) *Effect of Wind.*—Until experiments were made, it was not generally realised to what an extent the audibility of a sound coming from a point several miles away depends on the direction of the wind. The wind velocity almost invariably increases with the height from the ground. A sound wave proceeding in a direction opposed to that of the wind is in consequence refracted upwards, its velocity along the ground being greater than that at some distance above it. Its energy is dissipated upwards, and it will not affect a microphone or observer on the ground level. It was found impossible to make locations when the wind was blowing from our side of the line towards the enemy; the reports of the guns never reached the microphones, or were drowned by other noises on our side of the line. On the other hand, when the wind was blowing from the batteries towards the recording stations, the reports were heard clearly and had a sharply marked commencement.

The wind, besides displacing the apparent centre from which the sound wave is spreading, also causes irregularities due to local variation in velocity. The sound wave is slightly distorted and cannot be represented on the plotting board by the arc of a circle. No perfection in the accuracy with which timing is made will obviate this, and the errors thereby caused can only be reduced to reasonable dimensions by having the recording stations a long distance apart. The system of recording stations, generally five or six in number, constitutes what is termed the sound-ranging "base," and it is necessary to have a base from 5000 to 8000 metres in length in order to record with accuracy guns at normal ranges.

§ (3) Sound-ranging Stations. (i.) *The Base.*—*Fig.* 2 shows diagrammatically the general arrangement of the microphones and central station which was employed on the British front. The receiving stations were six in number. They were arranged regularly along a base three or four miles in extent, at positions which were surveyed with extreme accuracy. The relative positions of the microphones must be known to a metre, and their absolute positions with relation to the trigonometrical framework to about twenty metres, if the locations are to be accurate. The base was situated about 3000 metres from the front line. Each microphone was connected by cable to a central station behind the base, and at this station a recording apparatus registered the variations in electrical current caused by the impinging of the sound on the microphones. It consisted of an Einthoven galvanometer, in which six

fine wires were mounted between the poles of the electromagnet, each wire being connected to one of the microphones. The shadows of these six wires were thrown, by a suitable arrangement of lamp and lenses, across a narrow slit in the side of a camera. A strip of cinematograph film passed continuously behind the slit while a record was being taken, and, if the Einthoven wires were stationary, the film when developed showed six continuous straight lines where the shadows of the wires had protected it from exposure to the light. If a wire quivered in response to a signal from a receiving station, the line on the film had a corresponding "break." The illumination was cut off one hundred times a second by a toothed wheel rotating in front of the lamp, the angular velocity of the wheel being regulated by a tuning-fork. In this way a series of timing lines was ruled across the film. By counting the number of lines between two breaks, the time interval between the arrival of the sound at the two stations could be read. *Fig.* 3 shows a typical record, that of the report of a howitzer which has reached all six microphones in turn. The film has run from right to left, so that the left-hand edge of each break marks the arrival of the sound. The time interval can be estimated on the film to ·002 of a second.

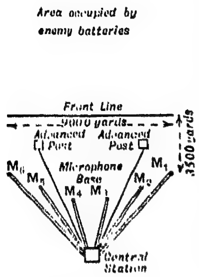

FIG. 2.

(ii.) *Observation Posts.*—In front of the sound-ranging base two forward observation posts were stationed. These were so placed that enemy guns were heard at one post or the other at least three seconds before the sound arrived at the nearest microphone. The observer in each post pressed a key when he heard a gun fire, and the key operated electrically a switch at the central station which set in motion the recording apparatus. The observer kept the key depressed until he judged that the sound of the gun and of the shell-burst had reached all the microphones. He then stopped the recording apparatus and telephoned to the central station such information about the sound as would aid the computing staff to make the location. The film was developed and fixed, the time intervals read, and the position of the gun plotted on a chart of the surrounding district. An automatic means of developing and fixing the film was finally adopted by means of which these two processes could be completed in fifteen seconds.

(iii.) *The Microphone.*—The microphone was of a special type.[1] The report of a gun differs from other sounds in that a great part of the energy is represented by waves of very low frequency. In the case of a 15-in. gun, for instance, the main oscillations of pressure occur at the rate of four or five per second. The microphone was made responsive to waves of low frequency, and was practically unaffected by the rapid oscillations of pressure caused by other noises than reports or shell-bursts. A gun-report almost imperceptible to the ear was recorded by it, whereas rifle fire, the noise of traffic, and other disturbances, produced no effect. This tuning was done by placing it in a small aperture opening into a

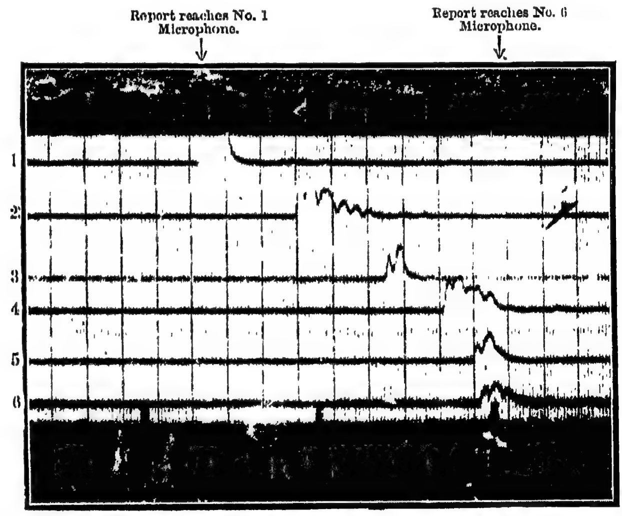

FIG. 3.—The figure is an enlarged print of the record of a 15-cm. howitzer, the report of which has reached No. 1 microphone first and No. 6 microphone last. The film has been moving from right to left while the record was being taken. The time intervals are marked by vertical lines, one hundred to the second, every tenth line being heavier so as to facilitate counting. The horizontal lines represent the shadows of the Einthoven strings, which lie across the slit behind which the film is exposed, and the movements of which are shown on the record.

[1] See "Microphone, The Hot Wire," Vol. II.

canister of large volume, on the principle of the Helmholtz resonator, constituting a highly damped system whose natural period was about one-twelfth of a second. It was further necessary to devise a type of microphone which recorded the amplitude and wave-length of the sound, and therefore gave characteristic records. Many other sounds interfere with those from the gun being located, and this made it necessary to be able to recognise on the film the breaks which belonged to the same series.

§ (4) The "Onde de Choc."—One of the most formidable difficulties in measuring the time of the arrival of the report was found to be the "Onde de choc," or "Shell-wave," which precedes the true report when the observer is within a certain area in front of a gun which is firing. The shell from a gun travels initially with a velocity greater than that of sound, and in so doing it creates in the air a conical bow-wave such as is evident in the well-known photographs of a rifle-bullet in flight. This bow-wave is heard as a sharp crack, the intensity of which, as judged by the ear, is generally very much greater than that of the report which succeeds it. The shell-wave affects the ordinary type of contact microphone to a far greater extent than does the gun-report, and generally masks the latter in consequence. The special type of microphone employed, invented by Lieut. Tucker and named after him, distinguishes between the two sounds, and the adoption of this microphone contributed very greatly to the success of Sound Ranging in the British army.

§ (5) Location of Shell-bursts.—When a record of a battery in action was obtained, it was possible to locate the bursts of the shells as well as the guns which were firing. The distance between gun and burst told the range at which the battery was firing, and a simple calculation from the time interval on the film between report and burst gave the time of flight of the shell. By comparing the range and time of flight with those for various types of guns as given in the range-tables, a guide to the calibre of the piece could be obtained. The shell-wave was also of assistance in the determination of the type of gun. No shell-wave is created by the low-velocity shell from a howitzer, so that howitzers and guns could at once be distinguished. The heavier the piece, and the greater the initial velocity of the shell, the longer is the time interval between the shell-wave and the gun-report as heard by an observer in the line of fire. This interval can be calculated from the range-tables for each gun, and when the interval read off from the film is corrected for the elevation and line of fire, it is a guide in the determination of type. It was also found that the wave-length of the sound increased with the calibre, and could be used as an indication of it. Finally, since the position of the bursts had been recorded, it was possible in many cases to tell the calibre from the fragments of shell and the fuses in the shell-craters.

This information was of great value. The number and character of the batteries on any particular section of front was an indication of the offensive or defensive intentions of the enemy in that area. Further, in cases where large numbers of batteries were placed in a limited area, locations, owing to errors, might overlap to a considerable extent. If the calibre were determined in each case, this mass of locations could be resolved into groups which were assignable each to one battery, and the probable position of that battery fixed with greater certainty.

§ (6) Wind and Temperature Corrections.—It has been stated that wind and temperature corrections play an important part in accuracy of location. If rays are drawn from the source of the sound, these rays being everywhere normal to the wave, like those used to illustrate the propagation of light, then the sound will travel from source to microphone along that path for which the time taken is the shortest possible. When the wind is blowing from the gun towards the microphone, the highest point on the path may be one or two thousand feet above the surface of the ground, since at these heights the greater wind velocity more than compensates for the longer distance over which the sound has to travel. The temperature may be very different at these heights from that near the ground. The problem of calculating the corrections is so complicated that it was found necessary to determine them empirically. At certain points, at some distance behind the front, microphones were arranged on the arc of a circle of about 7000 metres radius. Every hour a charge was exploded at the centre of the circle and the average velocity of the sound travelling to each microphone was determined directly. From these data values for the "effective wind and temperature" could be calculated which, when applied as corrections to the results obtained by sections at the front, brought their locations on to the true gun positions. The effective wind and temperature found in this way were nearly the same for all the stations on the front, except when some rapid change in the weather conditions was taking place. By comparison of these results with the meteorological data measured in the ordinary way, empirical relationships between them were formulated which could be used when the special installa-

tions to measure wind and temperature were not in action.

§ (7) METHOD OF USE.—Sound Ranging could only be employed when the front remained stationary for several days at the least. In installing a section, a base must be planned and carefully surveyed, positions made for the microphones, central station, and advanced posts; some forty or fifty miles of cable laid in an exposed situation, the apparatus set up, and the chart constructed on which the results are plotted. The time necessary to carry this out was reduced by training and experience to two or three days, and could no doubt be still further reduced by improved methods. If a method of wireless transmission of the signals could be devised, it would obviate the labour and delays caused by the constant cutting of the cable by traffic and shell-fire. Though the use of Sound Ranging has hitherto been restricted to conditions of stationary warfare, it may develop into a means of location available under all conditions.

SPECTROPHOTOMETRY

I. INTRODUCTION

ALL sources of illumination, such as the sun, the electric arc and spark, the incandescent electric lamp, the gas and kerosene flames, the fire-fly, and countless others, emit what is known as radiant energy. When this impinges upon any obstacle and is in part absorbed, there is, in general, a rise of temperature of the absorbing substance. Other manifestations of the reception of radiant energy are also well known. Some kinds, for instance, when reaching the retina of the eye give rise to the sensation of colour, some cause blackening of a photographic plate (when it is exposed and developed), some give rise to an electric current under certain conditions, and so on. The time-rate of transfer of radiant energy is called the radiant power, and this may, of course, be expressed in the same units as other power. It has become of great importance in many branches of science and industry to be able to analyse qualitatively and quantitatively the radiant power which any source emits, or that which a given material may transmit or reflect.

When this radiant power is examined by means of a prism and the resulting spectrum, it is found that only a part is visible to the eye; that beyond the red end of the spectrum is a large invisible region, called the *infra-red*, which may be detected by means of the rise in temperature of various kinds of sensitive radiometers; and that in the other direction beyond the violet is a second invisible region, called the *ultra-violet*, which may, if sufficiently intense, be detected by these same radiometers, but much more easily by the photographic plate or photoelectric cell.

The usual types of radiometer, which depend for their action primarily upon the heating effect of the incident radiant power, are non-selective as regards wave-length or frequency, and can be used to measure this power in absolute quantities. The eye is different from the radiometer, however, in being sensitive to only a part of the radiant power from any source, that part by definition being the visible region of the spectrum. It is also different in that it cannot give the absolute

value of this radiant power. When, however, two beams of light of the same quality and brightness are brought into the proper juxtaposition, the eye can detect very small variations of brightness in either beam provided the other remains constant. Therefore, if the proper means are available for varying the brightness of either beam, the two may very accurately be brought to the same brightness. This fact is the fundamental basis of photometry.

Spectrophotometry, strictly speaking, is the *visual* measurement of *relative* radiant power as a function of wave-length or frequency. The term, however, is usually not limited to visual methods; it is often made to include also certain radiometric, photoelectric, and photographic methods of measurement used not only in the visible region but in the ultra-violet or infra-red. The term is so used herein. The kinds of work are many and varied, but may be classed, in general, under three heads:

(i.) The measurement of the *relative spectral distribution of radiant power* of sources of light. If the absolute or relative spectral distribution is known for any one source, used as a standard, the others may easily be computed.

(ii.) The measurement of the *spectral transmissive properties* of transparent materials, such as eye-protective or signal glasses, dyes, oils, and all kinds of organic and inorganic solutions—in fact, solid, liquid, and gaseous matter of great variety.

(iii.) The measurement of the *diffuse spectral reflection* of opaque objects, such as paints, cloth, paper, and so on. Magnesium carbonate or oxide is usually taken as a standard white for comparison purposes.

Spectrophotometry is generally admitted to be the *fundamental basis* of colour specification. "A spectrophotometric table, derived from at least twenty-five points (for a continuous spectrum), gives the only unique description of a colour, and it appears probable to the writer that the requirements of precision technical colour measurement are most likely to be met by the development of simple and rapid means of plotting and recording accurate spectrum plots of reflection or transmission characteristics." [1] The large and growing demand made by industrial and commercial as well as scientific interests for the standardisation and specification of colours may be partly realised by referring to a paper on "The Work of the (U.S.) National Bureau of Standards on the Establishment of Colour Standards and Methods of Colour Specification." [2] The relation between spectrophotometry and colourimetry will be brought out more fully in Part II.

[1] Ives, *Jour. Franklin Inst.*, 1915, clxxx. 700.
[2] Priest, *Trans. I.E.S.*, 1918, xiii. 38.

It has not been attempted to give a history of the science of spectrophotometry nor a complete bibliography. Such will be found, up to the year 1905, in Kayser's *Handbuch der Spectroscopie*, vol. iii. A fairly detailed description of visual instruments in use up to 1909 is also given in Krüss' *Kolorimetrie und Quantitative Spektralanalyse.* The references given herein, however, cover the field in a general way; and a study of the papers cited, together with the references which they in turn suggest, will lead one directly into a comprehensive study of the whole subject.

Most of the different types of visual instrument are mentioned herein. Since certain fundamental principles underlie the use of all of them, one of these instruments has been selected for a detailed description of method of use. The instrument and method so selected have been proved accurate and reliable by direct and extensive comparison of results with those obtained by other methods, not visual. The photoelectric and photographic methods so tested are likewise, by this intercomparison, proved accurate and reliable. They are both null methods and eliminate many possible errors, uncertainties, and difficulties. Because of their importance in confirming and extending results obtained visually, these are also described in detail. A fourth method available in this intercomparison of methods has been the thermoelectric method. This is briefly described, but the large and important subject of spectroradiometry in the infra-red is otherwise untouched. This fourfold comparison of methods has made it possible to found a statement of the accuracy at present obtainable by spectrophotometric methods upon a basis of fact rather than of opinion; but there is no reason to believe that the accuracy obtainable may not be still further increased by further work along this line.

II. Relation of Spectrophotometry to Colourimetry

§ (1) The Need for a Recognised Nomenclature and System of Standards.—For an intelligent discussion and understanding of any science there should be available an exact and well-known nomenclature and system of standards. Otherwise one is under the necessity of giving detailed definitions of all terms used if he wishes to be sure that the reader will understand by the terms what he himself has in mind. This has been largely the case in papers on spectrophotometry, especially those which have reference to the measurement of the transmissive properties of materials, which part of the science has probably had a wider field of application than the others.

The sciences of spectrophotometry and colourimetry are inseparably connected; and a majority of the terms and expressions used in one are also necessary in the other. An effort to eliminate the present confusion in the nomenclature of the science of colourimetry has been initiated by the Optical Society of America and a preliminary report made.[1] The following paragraph from the introduction to this Report is very pertinent in this connection:

In the field of chromatics and colourimetry, experiment and knowledge have outrun established and recognised language. There are many names for the same thing and many different things designated by the same name. Progress requires the co-operation of individuals and the co-ordination and discussion of results; and co-operation and discussion are primarily conditioned upon unambiguous language. While numerous pleas for standardisation and some detached recommendations for particular definitions and terms have been made in the past, no attempt at all commensurate with the magnitude and importance of the subject has been made to formulate and present a consistent organised system of nomenclature as extensive as is found necessary in practice. Probably the most urgent need of colourimetry is the establishment of a recognised nomenclature and system of standards. To one not thoroughly familiar with the subject, the insistence upon this, and particularly the elaborate and extensive system with fine distinctions of meaning to be set forth in this report, may appear pedantic and academic. Not so to him whose daily work is in this field, for in his preparation of reports and ordinary conversation with his colleagues and assistants, he is continually inconvenienced and annoyed by the circumlocution and misunderstanding occasioned by lack of suitable terms and symbols to express his ideas and findings cogently and without ambiguity. He finds that the orderly and efficient conduct of his work compels him to assume the tedious and unpleasant task of formulating a nomenclature. This necessity is the cause of the present report.

Certain parts of this Nomenclature Report are of special value for the science of spectrophotometry, and are therefore presented here. All the quotations in Part II. of the present article are taken from that Report.

§ (2) General Terminology.—"Colour is the *sensation* due to stimulation of the optic nerve."

"Colour may be evoked by various stimuli acting on the optic nerve, for example, mechanical and electrical stimuli; but the only one of these with which we shall be much concerned is *light* (see definition below), which may be called the proper or ordinary stimulus of colour.

"In adhering to the strictly subjective definition of colour we are not estopped from the use of such convenient expressions as 'the colour of light,' or the 'colour of a material,' for we proceed consistently to define:

"The colour of light as the sensation which that light evokes; and

"The colour of a material as the sensation evoked by the light transmitted or reflected by that material under specified conditions of illumination."

"Chromatics is the science of colour."

"Colourimetry is the science and practice of determining and specifying colours by reference to the stimuli and conditions which evoke them."

"Light is *radiant power* multiplied by the visibility of the radiant power in question."

"Radiation is the *process* by which energy is propagated through space. . . ."

"Radiometry is the measurement of radiant energy or radiant power." Spectrophotometry is thus seen to be one branch of radiometry.

"The Spectrum is a graphic arrangement or setting in order of radiant energy with respect to wave-length or frequency."

The *wave-length units* which are convenient for use in spectrophotometry are the *micron*, μ (one-millionth of the metre), and the *millimicron*, $m\mu$ (one-thousandth of the micron). The latter unit is used throughout this article.

"Brilliance is that attribute of colour without which colour cannot exist, the attribute in respect of which all colours may be classified as equivalent to one or another of a series of *grays* of which *black* and *white* are the terminal members."

"Hue is that attribute of colour in respect of which it differs from *gray*, the attribute in respect of which colours may be classified as *red*, *orange*, *yellow*, *green*, *blue*, *violet*, and *purple*, or their intermediates."

"Saturation is the distinctness or vividness of *hue*."

"Quality is the property of colour due to its *hue* and *saturation*."

§ (3) Methods of Specifying Colour.—"A colour may be specified by reference to stimuli in the following ways:

"(i.) By specification of the identical radiant power actually evoking the colour, both in regard to

(*a*) Its total amount,

(*b*) Its spectral distribution.

"The crude specification of spectral distribution referring roughly to spectral *regions* rather than points is sometimes used for special purposes,[2] but its limitations must be kept in mind.

"The *partial* specification of spectral distribution may be used as a colour specification in particular

[1] Optical Society of America, Committee on Nomenclature and Standards, Sub-committee on Colourimetry, L. G. Priest, Chairman, *Report*, 1919 (Preliminary Draft), U.S. Bureau of Standards Library, Washington, D.C.

[2] Ives, *Tint Photometer*, Hess-Ives Co., Philadelphia; Block, "Die Kennzeichnung der Farbe des Lichtes," *Electrot. Zs.*, 1913, xlvi. 1306.

cases,[1] but as in the case above, its limitations must be carefully observed in order to avoid erroneous conclusions."

"(ii.) By specification of a stimulus empirically found to evoke the same colour in juxtaposition.

"There are, in practice, several important special cases of this. They are:

"(*a*) The stimulus composed of heterogeneous light of the spectral distribution which alone evokes the colour gray plus homogeneous light—the wave-length of the latter, the total light, and the ratio of heterogeneous to homogeneous light all being adjusted by trial and error until the sensation evoked is exactly like the colour to be specified.[2] This method we call homo-hetero-analysis.

"(*b*) The stimulus composed of lights of three (or more) different frequencies (or frequency ranges), the relative and absolute values of which are adjusted by trial and error until the sensation evoked is exactly like the colour to be specified.[3]

"(*c*) The spectral distribution of energy of the stimulus modified by rotatory dispersion, and its total radiant power adjusted in any way by trial and error to evoke a sensation exactly like the colour to be specified.[4]

"(*d*) The spectral distribution of energy of the stimulus and its total radiant power modified by the selective transmission of glasses or solutions[5] chosen by trial and error to evoke a colour exactly like the colour to be specified.

"(*e*) The stimulus being radiant power from a complete radiator ('black body'), the temperature of which is varied until the quality of the colour evoked is exactly like that of the colour to be specified, the spectral distribution of energy being a known function of temperature."

§ (4) The Fundamental Physical Basis of Colourimetry.—"The method indicated under (i.) of § (3) is, of course, the primary basis of colourimetry." In this connection, note the statement by Ives[6] already referred to.

"Radiometry, *in its most general sense*, is the key to all fundamental work in colourimetry. Some empirical testing and comparing may be done without *direct* reference to it; and its bearing on the subject may not be obvious to the casual observer of routine testing; but the essence of all fundamental standardisation is radiometry. Note the following:

"(*a*) The fundamental reference standards of colourimetry are light sources of specified *energy distribution*.

"(*b*) The most important specification of the colour of a transparent plate is its *spectral transmission*.

"(*c*) The most important specification of the colour of an opaque object is its *spectral reflection*.

"If two transparent objects have identical spectral transmissions, or two opaque objects identical spectral reflections, they will evoke colours exactly alike *in light of any spectral energy distribution*. Moreover, this is the only form of colour specification for materials which will *ensure* this result."

§ (5) Technological Applications of Spectrophotometry.—The following examples will illustrate to what uses the science of spectrophotometry has been or may be put as regards its technological applications:

Many vegetable oils, such as cotton-seed oil, for example, have for many years been graded from the standpoint of their colour, approximate and empirical methods being used. The present status of this work, and the growing demand that the standardisation be put upon a spectrophotometric basis, may be noted by referring to recent numbers of the *Cotton Oil Press*.[7]

Accurate spectrophotometric data are of value in the analysis of dyes,[8] or would be if such were available to any great extent. The concentration of all kinds of solutions might also be determined from known transmissive data.

The great importance of securing adequate protection from injurious radiant energy is now well recognised, and a large number of glasses are on the market advertised to protect the eyes from the ultra-violet and infra-red and from excessive brightness in the visible region. Since both the amount and the wave-length of the transmitted energy determine the value of these glasses for protective purposes, it is obvious that their transmission curves should be accurately known. The results of such a study on a large number of glasses in the ultra-violet, visible, and infra-red have been published.[9] The last of these papers gives also the spectral transmission of

coloured railway signal glasses and of glasses used in ultra-violet signalling.

Selective ray filters, both of glass and of dyed gelatine films, are now widely used to increase visibility (*i.e.* the ability to see clearly).[1] This is true not only visually, but has become of great importance in aeroplane photography. The increase in visibility is brought about by absorption of the shorter wave-lengths, and the spectral transmission of the glasses and dyes used is necessary to make any intelligent study of the subject. Other filters, especially the dichromatic red-blue kind, are of value in the detection of chromatic camouflage.

III. Visual Instruments

§ (6) General Characteristics.—The *visual spectrophotometer*, as the name would imply, is really composed of two separate instruments, the spectrometer and the photometer; and various problems in the construction and use of these instruments are, therefore, present in their combination. Those which have special reference to spectrophotometry as a single and separate science will be discussed at the proper places.

(i.) *The Photometric Field.*—In practically all visual spectrophotometers two beams of light (beams 1 and 2) of approximately the same wave-length are finally brought to form the two parts of what is called a photometric or comparison field, which may be viewed by the eye, and the brightness of one or both parts of which may be varied at will in a known manner, the two parts being finally brought to a match—that is, to an equality of brightness.

Some of the common types of photometric field are shown in *Fig.* 1. The light in parts

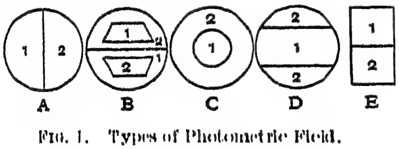

Fig. 1. Types of Photometric Field.

1 and 2 comes from beams 1 and 2, respectively. Type B is slightly different from the others and is known as a contrast field. Its construction is such that the trapezoidal parts are slightly darker than the surrounding field, equality of contrast being the criterion for a match. Type E is that usually obtained when a simple spectrometer with eyepiece is used, the light in parts 1 and 2 coming from different parts of the same slit. No one of these types has any special advantage over the others, unless it is type B, which is probably less fatiguing to the eye, and in the faint red and blue regions more sensitive than the others.

(ii.) *Conditions for High Sensibility.*—One of the most important conditions for obtaining maximum sensibility is that the dividing line or lines between parts 1 and 2 of the photometric field should be as fine as possible and should disappear when the match has been made. Another essential condition is that the field be of the proper angular size. A field subtending an angle of 3 to 5 degrees is considered very suitable. These two conditions are, of course, understood and, so far as possible, complied with by the makers of commercial instruments.

A third condition for obtaining maximum sensibility is that the field be of the proper brightness. In spectrophotometry one is seldom troubled by having too much light. For the sake of the measurements in the low-visibility parts of the spectrum—the red, blue, and violet—one should, in general, strive to have as much light as possible available. If the field becomes too bright throughout the green and yellow, it may easily be reduced by narrowing the slits of the instrument or by means of rotating sectors. It is also very important for accurate work that each separate part of the field be of uniform brightness.

In addition, the eye should be protected from all stray light; the room should be dimly lighted, if at all; and if the observer has to record his own observations, the illumination of the record sheet should be as low as can be used. A single glance at a bright sheet of paper or other light may incapacitate an observer's eye for several minutes if he is working at low brightness.

With any instrument or method, too, there will be certain conditions under which measurements may be made with maximum precision; and every instrument should be studied and used with this in mind. For example, at what value on the scale (*i.e.* at what slit-width, at what distance, at what angle of the nicol, etc.), at what concentration and thickness of solution, etc., will the percentage error in the final result be the least if an error of one division is made in the setting? Such a study is too often neglected.

(iii.) *The Sources of Illumination.*—When the relative spectral distribution of radiant power of a light is to be obtained, the following essential conditions should be met:

(*a*) A source of illumination must be available whose relative spectral radiant power is accurately known, so that it may be used as a standard.

(*b*) Light from this standard and from the unknown source must be subject to the same conditions; that is, they must travel along identical paths and be compared in turn with the same illumination, supplied by a third source.

(*c*) All the sources of illumination must be kept of constant value while measurements are being made.

If the spectral transmissive or reflective

[1] *Phys. Rev.* (2), 1919, xiv. 261.

properties of materials are to be studied, the apparatus should be so constructed, if possible, that the following conditions are true :

(*a*) The two beams of light should originate from the same source, so that fluctuation will not introduce errors.

(*b*) It should be possible to obtain diffuse spectral reflection as quickly and as accurately as spectral transmissive properties.

(*c*) In work on transmissive properties no error should be introduced or correction needed because of the change in length of the optical path caused by the beam traversing the specimen.

(*d*) In reflection work the illumination of the surface should be as nearly as possible equally diffuse from all directions, and the sample should be studied from a direction normal to its surface.

(*e*) The illumination should be intense enough to permit of very narrow slits being used; for the narrower the slit the purer the spectrum and the more accurate will be the measurements. An intense source of light will also make possible further and more accurate readings in the red and violet.

(*f*) In addition to heterogeneous illumination, sources of homogeneous illumination should be available at as many different wavelengths as possible, that all slit-width errors may be completely eliminated and the heterogeneous readings checked.

(iv.) *Methods of varying the Brightness of the Photometric Field.*—Different well-known methods are available for varying the amount of light which comes to form the parts of the photometric field. In spectrophotometry the actual amount of light which enters the slits of the instrument is not required; it is rather the relative amounts under specified conditions.

One may vary the brightness by varying the distance of a small source of light from the slit, the amount of light entering the slit for any two positions of the source being inversely proportional to the squares of the distances between the source and slit (or screen before the slit) in the two cases. This relation is very accurate, provided the diameter of the source is very small compared to the distances being used, *e.g.* 1/25.

A second accurate method is to use a pair of polarising nicol prisms in the path of the light. The light transmitted is then zero when the nicols are crossed and a maximum at a position 90 degrees from that, and the amount transmitted at intermediate positions is proportional to the square of the sine of the angle measured from the position of extinction. The faces of the nicols should be perpendicular to the direction of propagation of the light, the light entering the first nicol should be unpolarised, and the first nicol only should be rotated. Other combinations of polarising prisms may be also used, such, for example, as three nicol prisms (the middle one being rotated), or a Wollaston prism and nicol.

Varying the widths of the slits is a method often used with certain types of instruments, the brightness being taken proportional to the slit-width. This method is, however, "bad at heart," and should not be used where other methods are possible. In order to secure a suitable range of variation the slit-width has to be varied from a large part of a millimetre, which includes too much of the spectrum, making it very impure, down to a few hundredths of a millimetre where errors due to diffraction from the edges of the slit may become serious. It is probable, however, that this diffraction error is approximately eliminated by subtracting 0·02 mm. from all readings.[1] The error resulting from the use of too wide a slit may become enormous if, for example, one is measuring the transmission of substances like didymium glass or the solutions of certain rare earths which have very strong and narrow absorption bands. Methods for making the slit-width correction have been derived.[2] If it is necessary to use the slit-width method of varying the brightness, a thorough calibration should be made with a rotating sector or other means under the same conditions of wave-length and brightness as are to be used in the investigation.

A fourth method of varying the brightness is by the use of rotating sectors at speeds where flicker is no longer noticeable. The transmission of the sector as judged by the eye is accurately proportional to the aperture being used. Where this cannot be changed while the sector is rotating, the method is of greatest use as an auxiliary to increase the range of other methods. Sectors whose aperture may be changed while in operation have, however, been designed,[3] and in this form the method is as accurate and convenient as any other.

Other methods are sometimes used, such, for example, as interposing an absorbing wedge of varying thickness in the path of the light · but these are, as a rule, not as suitable as the others mentioned.

(v.) *Calibration of the Dispersing Prism.*—In spectrophotometric work the wave-length (or frequency) calibration need not be made as exactly as is required for most spectroscopic work. Because the amount of the spectrum being examined at any wave-length is usually one or more millimicrons, it

[1] Nichols and Merritt, *Phys. Rev.*, 1910, xxxi. 502.

[2] *Ibid.* xxx. 328; Hyde, *Astrop. Jour.*, 1912, xxxv. 237.

[3] Hyde, *Astrop. Jour.*, 1912, xxxv. 257; Abney, *Researches in Color Vision*, p. 68; Brodhun, *Zeitschr. f. Instrk.*, 1907, xxvii. 8. The instrument described in the last reference has a rotating beam of light and a stationary but variable sector.

is as a rule sufficient if the calibration can be guaranteed to a few tenths of a millimicron. The use of symmetrically opening slits is, of course, highly desirable, so that changing the width of a slit will change the effective wave-length as little as possible.

The usual method of calibration is to locate the position of a number of well-known spectral lines on the arbitrary scale of the instrument. (If the scale is already graduated in wave-lengths it should be checked very carefully before using.) These lines should be well distributed from the extreme red to the extreme violet, no extensive part of the spectrum being omitted. As a rule, the more lines one observes, the more accurate will be the calibration. The sources often used for this purpose include the mercury, helium, and hydrogen vacuum lamps, and the electric arc of metals like cadmium, copper, zinc, etc., whose spectra contain not too many lines.

The known values of wave-length, or frequency, and the corresponding readings on the arbitrary scale of the spectrophotometer should be plotted to a proper scale and a smooth curve carefully drawn through these points. It is then a simple matter to obtain the value of the arbitrary-scale reading for any desired wave-length or frequency. The frequency curve will be found to have much less curvature, and is therefore safer to use if but few known values are available. Empirical equations have been found which represent the wave-length curve quite accurately and which may be obtained when three or four lines well distributed over the range to be used have been accurately located. The constants of the equation having been obtained from these values, it may then be used to compute the value of the arbitrary-scale reading for any desired wave-length. The use of equations, however, is apt to be quite laborious, and the graphical method first mentioned is ordinarily sufficient.

§ (7) Individual Types. (i.) *The Lummer-Brodhun Spectrophotometer.*—The Lummer-Brodhun spectrophotometer [1] is a well-known instrument, a brief description of which will illustrate some of the points already mentioned. (A much more complete illustration of the various principles underlying the use of any spectrophotometer will be found in Part IV.) An outline diagram (plan) of the instrument is shown in *Fig.* 2. The light in beams 1 and 2 enters slits S_1 and S_2 respectively of collimators T_1 and T_2, and is made parallel by lenses L_1 and L_2. These two beams of parallel light then enter the Lummer-Brodhun cube at right angles to each other.

This cube is composed of two pieces of glass. Part 2 is a right-angled total-reflection prism, and if used alone would reflect all of beam 2 towards P and all of beam 1 away from it. A small part of the surface of part 1 is, however, cemented on to part 2 with Canada

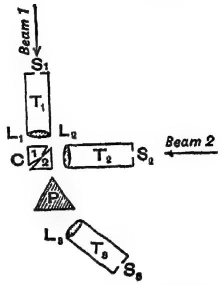

Fig. 2.—The Lummer-Brodhun Spectrophotometer.

T_1, T_2 = collimating telescopes; T_3 = observing telescope; S_1, S_2, S_3 = vertical slits; L_1, L_2, L_3 = lenses; P = dispersing prism; C = Lummer-Brodhun cube—giving field of type C, *Fig.* 1.

balsam, the rest of that surface of part 1 being ground away so as not to be in contact with part 2. Under these conditions the central part of beam 1 and the outer part of beam 2 will form the photometric field of type C, *Fig.* 1. (Type B is another common form of photometric field found with Lummer-Brodhun spectrophotometers.) This is viewed by the eye placed at slit S_3, no eyepiece being used. Uniformity of the field is obtained by using pieces of ground glass before slits S_1 and S_2 or by having the light come from illuminated pieces of magnesium carbonate.

This instrument is especially well adapted to compare the relative spectral distribution of radiant power of two light sources. When this is being done, it is best to compare each one of them in turn with a third source, this third source being placed, for example, before S_1, giving rise to beam 1, and the other two being in turn placed before S_2, giving rise to beam 2. Any one of the methods already indicated, or a combination of them, may be used to vary the amount of light entering slits S_1 and S_2 and thus bring the two parts of the photometric field to equality.

In transmission work two sources may be used—or better, only one, the light being reflected by mirrors or pieces of magnesium carbonate into the two slits. This will depend somewhat upon the method used for varying the brightness to obtain the match when the sample being examined is placed in or out of one of the beams of light. For the measurement of diffuse or specular spectral reflection special auxiliary illumination apparatus is necessary. This may be easily devised.

(ii.) *The König-Martens Spectrophotometer.*—A second well-known instrument operating on a very different principle is the König-Martens

[1] *Zeitschr. f. Instrk.*, 1892, xii. 132. See "Photometry and Illumination," § (18).

spectrophotometer.[1] In this case variation of brightness of the photometric field is brought about within the instrument by polarising the light and intercepting it with a nicol prism. An outline diagram (plan) is given in *Fig.* 3.

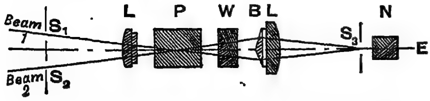

FIG. 3.—The König-Martens Spectrophotometer.

L = lenses; W = Wollaston prism; B = bi-prism, giving field of type A, Fig. 1; P = dispersing prism (the deviation is away from the plane of the paper); N = nicol prism; S_1, S_2, S_3 = horizontal slits (S_1 and S_2 are parts of the same slit); E = position of the eye.

The light from beams 1 and 2 traverses the instrument approximately as shown. By means of the Wollaston prism each beam is split up into two parts vibrating at right angles to each other. One part of each beam is lost within the instrument; the remaining parts, polarised mutually perpendicular, are brought by means of the bi-prism and lens to form the two halves of a photometric field, which is viewed by the eye through the nicol prism. Errors do not result from the partial polarisation by the dispersing prism P, because the light is polarised by W after leaving P. The field is of type A, *Fig.* 1, the dividing line being produced by the apex of the bi-prism. Uniformity of field may be secured in the same way as with the Lummer-Brodhun spectrophotometer.

Since the two beams of light reaching the nicol are polarised in directions at right angles to each other, a rotation of the nicol prism will obviously increase the brightness of one half of the field while decreasing that of the other, one becoming a maximum when the other becomes extinct, and *vice versa.* The angular scale is made to read zero for one of the positions of extinction.

If one of the original beams, *e.g.* beam 1, is kept constant while the other, beam 2, is varied, and a match has been obtained in two different cases, the brightness of beam 2 in the first case to that in the second case will be given by the ratio of the squares of the tangents (or cotangents) of the angles of match. If beams 1 and 2 may be interchanged, the ratio of brightness is the product of the tangent of the angle of match in one case by the cotangent in the other. Methods of using this instrument are explained in detail in Part IV.

(iii.) *Other Instruments.* — These two examples are illustrative of the great variety in method which has been employed to bring two beams of light of the same wave-length into the proper juxtaposition in a photometric field, and to enable either or both beams to be varied in brightness at will in a continuous and known manner. They are illustrative of the two general classes into which visual spectrophotometers are often divided—viz. polarisation instruments and others (mostly of the variable-slit type). They are also illustrative of another general division which might be made—viz. those which are designed primarily for the comparison of the spectral distribution of radiant power in two sources, and those in which the measurement of the spectral transmissive properties of materials is the main purpose in mind. With the proper auxiliary apparatus, however, most instruments may be used for both these purposes as well as for the measurement of diffuse reflection.

There are many other well-known instruments in addition to the two already described. One of the earliest types was the double-slit spectrometer of Vierordt,[2] in which a single collimator carried a divided slit, either half of which could be varied in width independently of the other, values being computed from these known slit-widths. The type of field is that represented by E of *Fig.* 1. The accuracy possible with this instrument was increased by later investigators. Krüss [3] used slits which opened symmetrically on either side instead of having one side fixed and the other variable. Further improvements in this method by various investigators consisted in devising means for making the dividing line of the photometric field as fine as possible and at the same time separating the two beams of light a short distance to make it easier to insert a specimen in one beam without interfering with the other beam. One of the modern varieties of the double-slit instrument, but with two collimators and a Lummer-Brodhun cube, is called the Differential Spectrophotometer,[4] in which the two slits work by a single screw in such a way that the sum of the two slit-widths remains constant.

The Brace [5] spectrophotometer is very similar in action to the Lummer-Brodhun, it having two collimators widely separated. In this instrument, however, the photometric field is formed in the prism itself; it is of type D, *Fig.* 1.

While much valuable work has been done with variable-slit instruments, the general accuracy and reliability of all of them are increased if some other means of varying the brightness of the photometric field is used; and this has often been done.[6]

Spectrophotometers which make use of polarising apparatus to vary the brightness of the field do not require the use of variable slits, but retain the same ease and speed of making settings. They should, however, likewise be subjected to thorough test as to the possible presence of errors resulting from the polarising action of the dispersing prism or other parts of the apparatus. The objection often made to polarisation instruments, viz. the loss of light within the instrument, has become of little weight because of the high efficiency, especially in the blue and violet, of the gas-filled incandescent lamps now available. In addition to the König-Martens instrument, elsewhere described in detail as to construction and use, the following methods have been used.

In Glazebrook's[1] instrument two widely separated beams are each polarised by a nicol prism, but mutually perpendicular. These are brought into juxtaposition and viewed by the eye through a third nicol. By rotating this nicol a photometric match is obtained, values being computed by the $\tan^2$ relation as with the König-Martens instrument.

In another type of instrument,[2] similar in many respects to the König-Martens spectrophotometer, a single collimator is used. Light from two separated parts of the slit are polarised mutually perpendicular by means of a Rochon prism. The two beams, after passing through a nicol prism, finally form two contiguous spectra, any width of which may be examined by the eye. Equality of brightness is obtained, again, by rotating the nicol and values computed from the $\tan^2$ relation.

A polarisation instrument of different type is that by Crova,[3] in which the light in only one beam is polarised. In that beam two nicol prisms are placed and equality of brightness obtained by rotating one of the nicols, the $\sin^2$ relation being used for the computation. In this instrument the two beams of light come from different parts of the same slit, but that in one half is deflected in by means of a total reflection prism, its original direction being at right angles to the other. Three nicols instead of two have sometimes been used.[4] In this case the middle one is rotated; and the $\sin^4$ relation must be used in computations.

In Hüfner's spectrophotometer[5] one beam only is polarised, one nicol being placed in one beam before the collimator slit, the other in the observing telescope. Hüfner's rhombic-prism scheme is used to bring two slightly separated beams into the proper juxtaposition through different parts of the same slit.

The action of a polarisation instrument by Wild[6] depends upon the vanishing of the interference bands formed by the proper superposition of the two beams of light from any one source.

Various devices are available by which any spectrometer may be converted into a spectrophotometer; in fact, some of the instruments already mentioned are practically that. Total reflection or rhombic prisms are used for this purpose, bringing two beams of light into separate but contiguous parts of the collimator slit. Auxiliary means must be provided for varying the brightness of one or both beams. Such methods have been used by Nichols,[7] Houston,[8] Ives,[9] Nutting,[10] and others.

One of the most recent forms of spectrophotometer is the Keuffel and Esser Color Analyser, a direct-reading instrument. A constant-deviation spectrometer is used. A bi-prism placed over the telescope lens gives a field of type A, *Fig.* 1, with horizontal dividing line. The two beams come from different parts of the same slit. The brightness of one beam relative to the other is varied by means of a variable rotating sector, and the scale reads transmissive or reflective percentages directly.

A somewhat different method from any of the above is that by Abney,[11] where the illumination of two shadows, side by side and touching one another and cast on a screen by placing a rod in the path of the two sets of rays, is equalised by placing a variable-aperture rotating sector in the path of one of the beams.

Mention might also be made of spectrophotometers operating on the flicker principle.[12] This subject, however, is one for heterochromatic photometry rather than spectrophotometry, and is, therefore, untouched here.

§ (8) Photometers and Homogeneous Light.—Considerable work of value in the line of checking and studying other methods, or in actual experimental work, if a spectrophotometer is not available, may be done by means of a photometer, source of homogeneous light, and selective ray filters. The Martens photometer[13] has been used at the U.S. Bureau of Standards for this kind of work; other types would also be suitable. The mercury, hydrogen, and helium lamps are of value because of having several widely separated lines of sufficient brightness to be used. If

all three sources are available, the following wave-lengths may be obtained:

Hg—404·7 + 407·8, 435·8, 546·1, 576·9 + 579·1 mμ;
H —434·1, 486·2, 656·3 mμ;
He—587·6, 667·8 + 706·5 (706·5 weak in comparison to 667·8), 706·5 mμ.

The helium lines in the blue are too close together to be efficiently separated.

Glasses for filtering out these lines are described in *Bur. Stand. Tech. Pap.* No. 148; and gelatine filters for the same purpose are advertised by the Eastman Kodak Co., Rochester, N.Y.

A Variation-of-Thickness Photometer has recently been designed for measuring the transmissivity of liquids. The following are the essential features:[1]

"Two beams of light proceed horizontally, one above the other, from a uniformly illuminated vertical surface.

"A rotating sector disc of known transmission can be interposed in the upper beam.

"By means of two totally reflecting partially immersed rhombs, the lower beam is diverted through a variable thickness of oil determined by the distance between the rhombs, one of which is carried by a slide on a track parallel to the beams of light. The oil is contained in a horizontal trough with open top into which the rhombs dip.

"The two beams are brought into juxtaposition in the photometric field by means of an arrangement of biprisms.

"The thickness of oil in the lower beam is varied until its transmittance[2] equals the transmission of the sector disc as judged by equality of brightness in the photometric field.

"A suitable scale provides for *direct* reading of transmissivity[3] or the logarithm of transmissivity.

"Light of definite wave-length may be obtained either by:

"(1) Use of light filters with a *selective source*, such as a mercury lamp, or

"(2) Dispersion with a prism, which converts the instrument literally into a spectrophotometer."

IV. Description and Comparison of Methods

For several years the subject of spectrophotometry has been given considerable attention in the chromatics section of the U.S. National Bureau of Standards. This has been necessitated by the many requests continually being received there for tests of the spectral transmissive and reflective properties of all kinds of material, and by the large and increasing demands for the standardisation and specification of colours. Spectrophotometry, as already noted, is the fundamental basis of all work of this kind.

It was early realised that sufficient attention had never been paid to the detection and elimination of errors by the comparison and counterchecking of radically different methods. It is no trouble at all to obtain, for example, "smooth" spectral transmission curves by any one method, the observational error being perhaps very small, and repetition of the measurements being easy to obtain. It is only when the same specimen is measured by a different method over the same range that one realises there may be enormous errors present though previously undetected. Moreover, any one method is limited in range and becomes somewhat unreliable as the outer regions are approached. The limits of the visible spectrum are often taken as 400 and 750 mμ, but little accurate visual work has ever been done at wave-lengths less than 450 and greater than 700 mμ. And yet cases arise where measurements within these regions are of great importance.[4]

For these reasons several independent methods of spectrophotometry have been developed, in addition to the construction of much auxiliary apparatus for use with instruments already available; and by means of the counterchecking thus made possible the work has been brought to a high degree of efficiency and reliability. It has therefore been thought that the ends of this article can be served in no better way than by describing in considerable detail the apparatus and methods now being used there. Most of this material has been obtained from published papers, and reference will be made to these at appropriate places.

§ (9) The Visual Method with the König-Martens Spectrophotometer and Auxiliary Apparatus.—As already noted, a spectrophotometer for general purposes should be of such a kind and used in such a way that any one of three different kinds of experimental work may be accurately and conveniently performed with it; that is, it should be available for the determination of (i.) the relative spectral distribution of radiant power of the various sources of illumination in commercial use at the present time, (ii.) the spectral transmissive properties of all kinds of substances, up to a considerable thickness if necessary, and (iii.) the diffuse spectral reflection of a great variety of materials. The König-Martens spectrophotometer, when used in the proper way and with suitable auxiliary apparatus, meets these conditions admirably, as will be illustrated.

The usual working range of the instrument has been from about 450 to 700 mμ, with slit-widths of 0·10 mμ in collimator and telescope. But by widening the slits reliable

[1] Priest, *The Cotton Oil Press*, July 1920, p. 96.

[2] *Transmittance*: the ratio of the radiant power incident on the second surface of a substance to that transmitted by the first surface.

[3] *Transmissivity*, t: Let T = transmittance, b = thickness; then $t = \sqrt[b]{T}$.

[4] *E.g.* in chromatic camouflage, *Jour. Opt. Soc. America*, 1920, iv. 390.

work has been done as far as 420 and 750 mμ with the heterogeneous source. The brilliant mercury line at 435·8 mμ has been of great assistance in obtaining reliable readings in this region. The use of the bright homogeneous lines of the mercury and helium lamps has proved of considerable value for checking purposes.

Methods of computation, which would ordinarily be very laborious with this instrument, have been simplified by the design of slide-rules, by which the various computations involving tangents and cotangents, or their squares, may be performed as conveniently and accurately as in ordinary numerical work with the ordinary slide-rule.

(i.) *Comparison of Light Sources.*—The use of this spectrophotometer for the comparison of light sources is described in a paper on the "Colour and Spectral Composition of Certain High-Intensity Searchlight Arcs."[1] By the method therein given in detail it is possible to obtain the relative spectral distribution of radiant power of even a varying source like the electric arc. The following diagram and description of the method are taken from that paper.

An illumination box was constructed and fastened to the spectrophotometer immediately in front of the slits (*Fig.* 4). This consisted

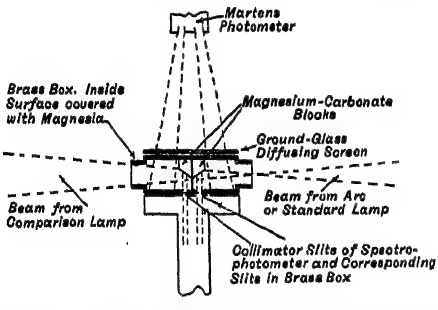

FIG. 4.—Details of Illumination Box, used with the König-Martens Spectrophotometer for the comparison of light sources.

of a brass box divided into two compartments by a brass partition. "The interior of each compartment was coated white with magnesium oxide, put on by burning magnesium ribbon, and blocks of magnesium carbonate were placed as shown. Thus the whole interior was white and the reflection from all surfaces was entirely diffuse. The magnesium-carbonate blocks were illuminated as shown, and light from these two illuminated surfaces entered the double slit of the spectrophotometer through small openings in the illumination box. The whole interior of the box is, of course, illuminated by diffuse reflection from the magnesium-carbonate blocks, and two beams of light from the sides of the box next to the spectrophotometer pass through openings in the opposite side and are compared by means of the Martens photometer." A red glass filter was placed over the eyepiece of this photometer to eliminate the colour difference between the arc and the comparison lamp, and a ground-glass diffusing screen used, as shown, to make the photometric field still more uniform and of the proper brightness. Lenses were used to obtain sufficient illumination of the magnesium-carbonate blocks, care being taken that this illumination was uniform, and that chromatic effects were avoided. Rotating sectors of known aperture were used on one side or the other, as needed, so that the comparison field of the spectrophotometer might be brought to equality within a suitable region on the scale.

[1] *Bur. Stand. Tech. Pap.* No. 168, 1920.

The substitution method of measurement should always be used in this kind of work; that is, a comparison lamp should be kept on one side and light from it compared first with light from a standard lamp whose relative spectral radiant power has been determined radiometrically, and then with that from the lamp, arc, or other source of illumination whose relative spectral radiant power is to be determined. If the unknown source of illumination is one that may be easily maintained constant, *e.g.* an incandescent light, but two observers are needed—one to watch and control (by means of a potentiometer) the voltage around the lamps, thus maintaining constant illumination on either side, the other to make observations at different regions in the spectrum. If the unknown source is an arc (in this case the Sperry searchlight arc), more observers will be required.

"Five people were necessary in making the observations on the arc, one to watch and control the arc, recording the readings of the voltmeter; a second to regulate the current through the arc, recording the readings of the ammeter; a third to observe the illumination through the Martens photometer; a fourth to take readings on the spectrophotometer; and a fifth to record these readings and keep the proper voltages on the lamps by means of the potentiometer. The procedure for taking a series of observations under these conditions was as follows:

"The arc was allowed to run a few minutes in order that conditions might become as steady as possible. While this was being done, the comparison lamp was kept at its proper voltage and the variations of the illumination from the arc followed on the Martens photometer. Finally, the photometer was set for equality of brightness between the two sources at what seemed to be the best mean value of the illumination from the arc. This setting was then unchanged during the run. Now, for any given wave-length, the variations in the illumination from the arc were followed on the spectrophotometer, the attempt being made to keep the two halves of the

photometric field always equal in brightness. Whenever conditions were right, as shown by the Martens photometer, a sharp signal was given and the reading of the spectrophotometer taken at that instant. It was not attempted to do this, of course, if the illumination varied too rapidly through the proper value. Usually the variations were quite slow, the illumination often staying constant at the correct value for a considerable part of a minute. It was noticed during the course of the investigation that the value of the current through the arc would have served nearly as well as the auxiliary photometer for enabling measurements to be made always at the same illumination; for the current was practically always at a given value, about 75 amperes, when the signal was given by the observer at the Martens photometer.

"At each wave-length from four to ten readings were taken on the spectrophotometer, the number depending on the agreement obtained among the readings. Measurements were made between wave-lengths 430 or 440 and 710 mμ usually at every 20 mμ.

"After this series of measurements was completed, the total reflection prism was set up to locate the position of the arc and kept there until the standard lamp had been put in position. It was then removed, and another series of measurements made at the same wave-lengths as previously on the arc. Only two observers were now necessary, one to make the measurements on the spectrophotometer, the other to record the data and keep the voltages constant with the potentiometer.

"In this manner all the data were obtained, either a complete run or check points being taken on the standard lamp between any two of the runs on the arc.

"The spectral distribution of radiant power of the arc was computed as follows: All the values of the angles of the nicol prism read on the spectrophotometer for the standard lamp were plotted at the proper wave-lengths and a smooth average curve drawn through these points. All values for the standard lamp used in the computations were taken from this curve. Thus the same values of the standard lamp were used for all computations. For each wave-length the square of the cotangent of the average angle, read on the spectrophotometer when the arc was in position, was divided by the square of the cotangent of the angle as read from the curve when the standard lamp was in position. When this is done for all the wave-lengths, the radiant power of the arc relative to that of the standard lamp is obtained. By multiplying these values by the known relative values of radiant power of the standard lamp at the different wave-lengths, the relative spectral distribution of radiant power in the arc was obtained."

(ii.) *Spectral Transmissive and Reflective Measurements.*—No complete account of the illumination apparatus which has been developed for use with the König-Martens spectrophotometer has yet been published, but brief reference to it has been made in two papers.[1] The essential features are as follows:

A metallic box was constructed large enough to contain ten 500-watt, incandescent, Mazda-C lamps and three large M-shaped mercury lamps well distributed throughout the interior. A system of air and water cooling prevents undue heating of any part of the apparatus. The interior of the box was painted white and finally coated with magnesium oxide, giving diffuse illumination from all parts.

The box was set up in front of the spectrophotometer at sufficient distance to allow samples of considerable thickness to be interposed. In the side of the box next to the slits two small openings were cut just large enough to include the angles subtended by the slits and lens of the spectrophotometer. On the opposite side of the box, two pieces of magnesium carbonate are placed, in such a position as to cover the same angles. These two surfaces of magnesium carbonate are illuminated from all directions within the box by means of the lamps and the white walls, the incandescent lamps or the mercury lamps being used at will.

A telescope arrangement within the box prevents any of the light entering the slits of the spectrophotometer except that coming from the surfaces of magnesium carbonate. Thus the comparison field of the instrument is filled with light, half from one magnesium-carbonate surface, half from the other; and any variations in the amount of light from the lamps will be exactly neutralised. The lamps may thus be run on an ordinary, fluctuating circuit, even the flickering of the mercury lamps causing no trouble. Throughout the part of the spectrum of high visibility only a part of the lamps need be used, and these can be run below the maximum efficiency to prolong their life. It is only in the red, blue, and violet that it is necessary to make use of all available light.

When the spectral transmission of any material is to be obtained, the sample is placed in its carrier between the box and the slits and made to intercept the light first in one beam and then in the other. This interchange may be quickly effected by the observer without leaving his seat. For any one position in the spectrum he first takes from one to five readings with the sample in one beam; he then transfers the sample to the other side and takes twice as many readings; finally he returns it to the first beam and repeats his readings there to detect any possible change of conditions. The transmission is then computed by the product of the tangent of one set of readings with the cotangent of the other.

When the spectral diffuse reflection of any

[1] *Bur. Stand. Tech. Pap.* No. 148, 1920; No. 167, 1920.

material is to be measured, a sample is cut to the right size and substituted for one of the magnesium-carbonate surfaces. Interchange of sample and the other magnesium-carbonate surface is easily made by the observer, and a set of readings taken analogous to those already described for transmission work. The result will be the reflection relative to that of magnesium carbonate. This latter is nearly 100 per cent.

The carriers for holding the specimens in both transmission and reflection work were very carefully made so that in transferring the specimen from one beam to the other it might always be returned to exactly the same position. This is very important, for it often happens, especially in reflection measurements, that the samples are not absolutely uniform throughout. The carrier for transmission measurements has, of course, to be adjustable in order that specimens of varying thickness and diameter may be accommodated.

In connection with the study of the spectral transmissive properties of dyes and other solutions, special apparatus has been constructed. The cells to hold the solution and solvent were made after the pattern of those put out by Hilger for use with the sector photometer. While it is unnecessary to describe this cell in detail, it has four valuable characteristics which should be possessed by all cells used in this kind of work: (1) evaporation is prevented; (2) nothing but glass (or quartz) comes in contact with the solution; (3) no wax or cement of any sort is used; (4) in order to refill, it has to be completely taken apart, and may therefore be easily and thoroughly cleaned for each new solution.

Inasmuch as some solutions change their transmissive properties rapidly with change in temperature, holders for these cells have been constructed, in which water at constant temperature is circulated, the constant temperature and circulation being maintained by a pump-and-thermostat arrangement. The solutions may thus be kept constant within a fraction of a degree at any desired temperature over a considerable range. A detailed description of this auxiliary apparatus for use with solutions has been published.[1] Similar apparatus has also been constructed for use with the other methods whose description follows.

§ (10) THE PHOTOELECTRIC NULL METHOD. (i.) *Advantages of the Method.*—The well-known difficulty of obtaining accurate spectrophotometric measurements in the blue and violet by any other method led to the development of the photoelectric null method herein described.[2] The potassium-hydride, gas-filled, photoelectric cells now on the market make it possible to obtain as reliable determinations throughout the blue and violet, and even beyond those regions, as are obtained at other wave-lengths by other methods.

The photoelectric cell has been used in various ways by different investigators.[3] Either the galvanometer or electrometer may be used with it; and in practically all measurements of spectral transmissive or reflective properties some form of deflection method has been used, much valuable work having been performed. For example, the absolute specular spectral reflections of a large number of metals have been determined in the ultra-violet between wave-lengths 380 and 180 $m\mu$.[4]

In various ways, however, a null method seems to be more suitable than a deflection method. It has been concluded by the majority of investigators that it is not safe to assume a direct proportionality between photoelectric current and exciting radiant power; and therefore any cell used in a deflection method, unless it be a method of equal deflections, must be tested and calibrated if there is deviation from this straight-line relationship. The so-called dark current must also be eliminated or a correction made, unless the radiant powers used are so great that it may be neglected, which is seldom the case in spectral work.

When the electrometer is used, still further difficulties are met by one using a deflection method. A strict proportionality between deflections of the disc, as read by means of the mirror and scale, and the potential acquired by the quadrants, must be proved by test or a calibration made. Timing devices are also necessary with their accompanying inconvenience and possible errors. But the electrometer is so much more sensitive than the galvanometer that it is desirable to use it if possible.

In the following description of the null method are shown the ways in which the questions of the current-irradiation[5] relationship and the dark current may be avoided and their errors eliminated while retaining the extreme sensitivity of the unshunted electrometer.

(ii.) *Spectral Transmissive Measurements.*—The principles on which the null method is based are very simple and may be understood in connection with the accompanying diagram (*Fig.* 5).

"When the earth connection is made at U, both pairs of quadrants are at zero potential. Under this condition the charged electrometer needle will be at rest. Let the voltage applied to P_1 be V_1 and that applied to P_2 be V_2, and let the total resistances (mainly that of

[5] The terms irradiate and irradiation, as emphasised by Ives (*Astrop. Jour.*, 1917, xlv. 39), should be used analogously to the terms illuminate and illumination when radiant energy rather than light is discussed.

the photoelectric cells) between U and G′ be R_1 by way of P_1 and R_2 by way of P_2. Then through P_1 a current will flow of magnitude $I_1=V_1/R_1$ and through P_2 of magnitude

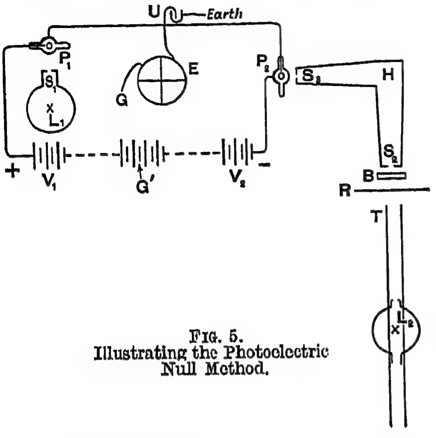

FIG. 5.
Illustrating the Photoelectric Null Method.

E = Dolezalek quadrant electrometer, disc charged to +150 volts; motion shown by spot of light and scale, as usual; P_1P_2 = Kunz photoelectric cells; GG′ = earth connection, zero potential; U = make-and-break mercury connection; V_1V_2 = voltages applied to P_1 and P_2, respectively; H = position of Hilger constant-deviation glass-prism spectrometer with slits S_2 and S_3 ($S_2=S_3$ always); B = location of specimen whose transmission is to be measured (means provided for moving in and out of beam); R = rotating sector to increase range of measurements; T = track on which distance of 600-watt lamp L_2 from slit S_2 may be varied; S_1 = slit by which irradiation of P_1 by miniature lamp L_1 may be varied, the amount being accurately proportional to the width of S_1.

$I_2=V_2/R_2$. No radiant energy to which the photoelectric cells are sensitive is considered as falling on them, I_1 and I_2 being what are ordinarily called the dark currents.

"If the earth connection at U is broken, the electrometer disc will be deflected (shown by the drift of the spot of light) unless I_1 is exactly equal to I_2. If they are not equal, they may be made so by changing the relative values of V_1 and V_2. This is done by varying the point of ground connection at G′.

"Now let P_1 and P_2 be irradiated by L_1 and L_2. This will bring about a great increase in the photoelectric currents I_1 and I_2, and the irradiations may be so adjusted (by varying the currents through the lamps, the width of S_1, or the distance of L_2) as to make I_1 again exactly equal to I_2, as shown by the zero motion of the electrometer disc when the ground connection at U is broken. Now let the irradiation of P_2 from L_2 be reduced by interposing the specimen B. Then I_2 will be less than I_1, and, with U broken, the spot of light will be deflected. Two methods may be employed to make I_1 and I_2 again equal, a means of obtaining a measure of the transmission of B being thus possible: (1) The amount of radiant energy falling on P_1 may be decreased by narrowing S_1 until I_1 becomes equal to I_2, the ratio of the slit-widths in the two cases being a measure of the transmission; or (2) the amount of radiant energy falling on P_2 may be increased by moving L_2 nearer the slit S_2 until I_2 again becomes equal to I_1, the inverse ratio of the squares of the distances in the two cases giving the transmission.

"The value of the transmission obtained by the two methods will be the same only in case the dark currents are exactly equal and in case the two photoelectric cells obey exactly the same irradiation-current law. In case either of these conditions is not fulfilled, the value of the transmission obtained by the first method will be in error, but by the second method the accuracy of the value of the transmission will be unimpaired though either or both of these conditions are not fulfilled. Therefore, the transmission is measured by merely varying the distance of L_2 from the slit S_2, this distance being the only variable in the operation; for the width of the slit S_1, the amount and quality of the radiant energy falling on P_1 and P_2, the photoelectric currents I_1 and I_2, and the currents through L_1 and L_2 are unchanged, whether the specimen is in or out."

"The distance of L_2 from S_2 can never be made less than 46 cm. because of the other apparatus on the bench, such as the sector, carrier, etc. This, combined with the fact that the filament of L_2 is in a plane only 1 cm. square, enables the inverse-square law to be assumed; that is, the amount of radiant energy entering the slit S_2 varies inversely as the square of the distance of L_2 from S_2. The rotating sector serves as a means of making sure that the apparatus keeps in perfect working condition from day to day. The length of the photometer bench enables L_2 to be moved back to 255 cm. from the slit. Therefore, the range of transmission possible with the 10 per cent sector is from 1·00 to approximately 0·004."

Between 410 and 550 mμ inclusive, the method is very reliable as shown by agreements with other methods. These will be discussed later. If a quartz-prism spectrometer were used, measurements could be extended into the ultra-violet. In the long wave-length direction the cell itself soon becomes very insensitive. The usual working range of the apparatus has been from 390 to 600 mμ inclusive, but values have been obtained as far as 380 and 650 mμ.

(iii.) *The Measurement of Diffuse Spectral Reflection and other Applications.*—The apparatus was designed primarily for the measurement of spectral transmissive properties, but has also been used to obtain the diffuse spectral reflection of substances relative to that of magnesium carbonate. For this purpose the lamp L_2 is moved forward, and by means of lens and mirror the rays are brought to a focus upon the substance to be studied, the angle of

incidence being approximately 45 degrees. The diffuse reflection leaving this substance (or the magnesium carbonate) at right angles then enters the slit S_2, and the resulting photoelectric current in P_2 is balanced by that in P_1 excited by L_1, as was done in the case of spectral transmission. The method of obtaining the balance now, however, has to be by the means of varying the width of S_1.

The method has not been as thoroughly tested as that for the transmission measurements. Comparison with other methods, however, has shown that for approximately diffusing surfaces the method is very reliable except at wave-lengths where the sensitivity is low or the reflection being studied is very small in value. Where values have to be obtained by varying the width of S_1, however, the accuracy is about half that resulting when the distance of L_2 from S_2 can be varied as explained under spectral transmission. But as already noted this accuracy is dependent upon the two cells obeying the same current-irradiation law.

Measurements of relative specular reflection have also been made by the method of varying the width of S_1.[1]

"The apparatus is well adapted for the comparison of spectral distribution of radiant power of two sources over the same range of wave-lengths as used in transmission and reflection measurements. If the two sources are such that they obey the inverse-square law, the method of varying their distances from S_2 could be used, S_1 being kept constant. If the inverse-square law were not obeyed by either source, the other method could be used, their distances from S_2 being kept constant and S_1 varied to obtain a balance."

(iv.) *The Elimination of Errors.*—In setting up the apparatus the usual precautions were taken to eliminate so far as possible all mechanical vibration, moist air, stray radiant energy, and electrical disturbances. This was accomplished by the proper use of a metallic enclosure for the electrometer and photoelectric cells, and by resting this upon a cement pier in a basement room.

The use of the null method eliminates the errors liable to be found with electrometer-deflection methods. "Such errors may be those due to the deflections of the electrometer disc as given by the spot of light on the scale not being strictly proportional to the charge or potential acquired by the quadrants, those due to leakage of charges because of imperfect insulation or moist air, or those connected with the use of timing devices."

The method of varying the distance of L_2 from S_2, as illustrated under spectral transmission measurements, eliminates two other possible errors: (1) "Errors due to the photoelectric current not being strictly proportional to the radiant power incident on the cell. No calibrations of the cells are necessary, and it makes no difference what the relation is between radiant power and photoelectric current;" (2) "Errors due to what is ordinarily known as the dark current. It makes no difference whether or not it is eliminated. Nor do the dark currents through the two cells have to be the same, though approximately this condition is desirable for convenience' sake."

Errors which might result from undetected changes of the dark currents through P_1 or P_2 or of the currents through L_1 or L_2 are largely eliminated by taking the first and third readings with the sample in the beam, the second with it removed, etc.

Errors arising because of the inverse-square law not being exactly obeyed by L_2 "would be expected to be very small because of the filament occupying an area of only 1 cm.^{2}, and because it is not possible to move the filament closer to the slit than 46 cm. It has been tested by means of the rotating sector. Other investigators[2] have found that Talbot's law holds for the photoelectric cell; and a great number of observations at different times and at many wave-lengths on the apparatus herein described prove that the inverse-square law is obeyed, assuming Talbot's law to hold, or that Talbot's law is obeyed, assuming the inverse-square law to hold. Actually, the error due to any failure of L_2 to obey the inverse-square law is too small to be detected over the range of distances used. It might be noted here that when the transmission of thick specimens is measured, correction is made to the distance as read on the scale, this reading being larger than the true optical distance of L_2 from S_2."

Errors of observation are small because the final result is not a question of judgment, as in visual and photographic methods.

Errors to which all methods of spectrophotometry are liable, such as those resulting from stray radiant energy and inaccurate wave-length calibration, were carefully guarded against. Slits of 0·20 mm. (S_2 and S_3) have been usually used. This includes approximately from 1 $m\mu$ in the violet up to 4 $m\mu$ in the red. Errors due to these finite slit-widths are considered negligible except for very narrow bands.

§ (11) The Thermoelectric Method.—All that has been done in this connection is to adapt one of the well-known radiometric methods[3] to the measurement of spectral transmissive properties in the red and infra-red as far as 1350 $m\mu$. This limit was necessitated in this case because the thread of the spectrometer was cut no farther. The same spectrometer, glass prism, was used as already described in the previous section. A Coblentz linear thermopile and sensitive galvanometer were used. The apparatus has been arranged so that the thermopile and galvanometer may be substituted, in a moment's time, for the photoelectric cell P_2 (*Fig.* 5) and electrometer. L_1 is not used. Radiant energy from L_2 is focussed upon the slit S_2 and measurements made by moving the specimen in and out of the beam. The following points are of interest:

[1] Karrer and Tyndall, *Bur. Stand. Sci. Pap.* No. 389, 1920, p. 388. In this work the Brace spectrophotometer was used to measure the spectral transmission of the atmosphere.

[2] Ives, *Astrop. Jour.*, 1916, xliii. 24; Kunz, *Astrop. Jour.*, 1917, xlv. 69.

[3] See, for example, Coblentz, *Carnegie Inst. of Wash.*, Pub. No. 35, 1905.

(i.) The absorption of 1 cm. of water becomes so great at 1350 mμ that readings could not be made with any precision much beyond that point. The ordinary glass spectrometer is therefore sufficient for work upon aqueous solutions.

(ii.) Over this range and for a considerable way beyond, where large glass spectrometers and high-power incandescent lamps may be used, such an arrangement seems better than the usual infra-red spectrometer, because it is possible to work with very narrow slits. In this particular case slits of 0·20 mμ width were sufficiently large, that being equivalent to about 4 mμ in the red and about 18 mμ at 1000 mμ, less than 1/5 of the widths often used. This is important in the study of narrow absorption bands.

(iii.) Instead of a single lens it would be better to use two lenses, the light between them being in a parallel beam and the specimen inserted in this parallel beam. No errors because of the thickness of the specimen would then arise.

(iv.) The quartz-mercury lamp is excellent for calibration purposes in this range, it having strong lines at 1014 and 1129 mμ and weaker lines above 1300 mμ.

(v.) The method is of great aid to visual work between 650 and 800 mμ.

§ (12) The Photographic Method with the Hilger Sector Photometer and Auxiliary Apparatus.—A great advance in the ease and accuracy of photographic spectrophotometry has been made possible by the sector photometer, manufactured by Adam Hilger, Ltd. While this might be used in any spectral region where photography is applicable, its primary importance is in the ultra-violet. The measurement of the spectral transmissive properties of all kinds of organic and inorganic chemicals is of great importance to the chemist and the physicist, theoretically and practically, and an immense amount of work has been done along this line. The great outstanding fault, however, of most of this work in the ultra-violet is that it is merely qualitative. As noted by Hilger, "it must not be forgotten that not only the intensity but the actual position of the maximum of an absorption band is undetermined until quantitative measurements have been made, since any variations throughout the spectrum of intensity of the light source, or sensitiveness of the photographic plate, or of dispersion, may cause the apparent maximum of absorption to be in a position different from that of the actual maximum." While quantitative work is possible by the older photographic methods,[1] it is apt to be tedious and liable to serious errors which are entirely eliminated by the sector-photometer method.

[1] Résumé, Ewest, *Photog. Jour.*, 1914, liv. 90.

Auxiliary apparatus is necessary consisting of a quartz spectrograph and a source of ultra-violet radiant energy. The following descrip-

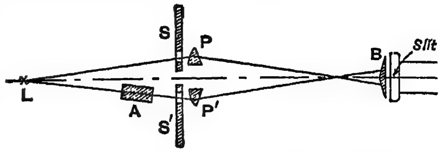

Fig. 6.—Hilger Sector Photometer Method.

tion of the method is taken from a paper published by Messrs. Hilger.

"Immediately in front of the slit and attached to it is a bi-prism, B, which receives the light from the source in the following manner. The light emanates from the source, L, and may reach the slit by two alternative paths. An upper beam passes through a rotating sector, S, the aperture of which can be varied. The beam then passes through the wedge prism, P, and, falling on the bi-prism, is deviated by the lower half of that prism to pass axially along the collimator of the spectrograph. The second beam traverses first the absorbing liquid under examination contained in a suitable cell, A, then through a rotating sector, S′, of fixed aperture, and a wedge prism, P′, similar to P but so arranged as to divert the light upwards instead of downwards. The beam is then diverted by the upper half of the bi-prism, B, and passes axially along the collimator of the spectrograph like the first. We thus have the spectrograph fed by two beams, the one capable of being varied in intensity at will by varying the aperture of the rotating sector, the other subject to the absorption of a known thickness of the liquid under examination. A series of photographs is taken with the sector S set to different apertures. If we consider one of these photographs we shall see that it consists of a pair of spectrum photographs in close juxtaposition, one of which is of reduced density throughout its whole length, the other—that, namely, which has passed through the material under test—being more dense than the first in certain parts and less so in others, there being certain wave-lengths where the density of the two is equal.

"It is found that the wave-length at which the densities of the two spectra are equal is, within wide limits, independent of the exposure, of the intensity of illumination, and of the speed of rotation of the sectors.

"Furthermore, the photographs are taken simultaneously, and there are, therefore, no errors arising from fluctuations in the light source.

"Let the fractions of whole revolutions

during which the variable and fixed aperture sectors allow light to pass be respectively t and t', and let the intensities of light of wave-length λ reaching the slit by the upper and lower beams in *Fig.* 6 be respectively I and I′.

"Then if at wave-length λ the density is exactly the same in both spectra, we have

$$\frac{I}{I'}=f(t', t).\text{"}$$

The makers of the instrument assume the Schwarzchild[1] relation, $I/I'=(t'/t)^n$ for uninterrupted exposures, to hold in this case, n being different from unity, and supply a calibration from which I'/I may be obtained from the known values of t/t'. It has been found,[2] however, that "the photographic plate, the use of which in photometric measurements is usually considered questionable, integrates intermittent exposures in such a way that the comparison of two intensities can be made directly in terms of sector openings, provided that the time from the beginning to the end of the exposures is the same, and that the two exposures produce equal blackening of the plate"; *i.e.* the constant n for the sector photometer is unity within the limits of photometric accuracy. This relation has been further verified by comparison with other methods,[3] and extensively by comparison with the König-Martens visual method and the photoelectric null method at the Bureau of Standards. These data have been published in the *Bureau of Standards Paper*, No. 440, on the spectral transmissive properties of the seven food dyes.

The sector photometer at the Bureau of Standards has both sectors variable, so that, for example, the cells containing solution and solvent may be interchanged for check readings. The quartz spectrograph is a Fuess instrument (slit-width = 0·10 mm.) with a dispersion of nearly 14 cm. between 500 and 250 mm. The source of radiant energy is a high-voltage (Tesla coil) spark under water, which gives a continuous spectrum from the visible as far as the quartz system will transmit. The vertical spark is more satisfactory than the horizontal, for it keeps the two spectra in contact throughout their whole length. Two pieces of magnesium carbonate diffusely illuminated as in the König-Martens auxiliary apparatus, but by the spark, would be still better and would enable measurements of diffuse spectral reflection to be made as well, provided sufficient intensity could be obtained.

Errors in locating the wave-length or frequency of equal density have been made very small by means of a special comparator, described in Appendix to *Bur. Stand. Tech. Pap.* No. 148, which permits of readings being made without marking the negative. Therefore any number of readings may be made and an average taken. The principal source of error at present is thought to be due to occasional non-uniformity of the spark. Displacement of the electrodes, and therefore of the spark as a whole, from the proper position may be quite accurately controlled. Interchange of solution and solvent will test this, as well as exposure with both cells containing solvent.

[3] *Trans. Opt. Soc.*, 1917, xviii. 36; *Phys. Rev.* (2), 1917, x. 707; *Bur. Stand. Tech. Pap.* No. 119, 1919, and No. 148, 1920.

§ (13) General Comparison and Relative Accuracy of the Different Methods.—The agreements and lack of agreements found when the spectral transmissions of a large number of glasses were first obtained by different methods are well illustrated in *Bur. Stand. Tech. Pap.* No. 119. In this investigation four methods were used: the König-Martens and the Lummer-Brodhun spectrophotometers in the visible, and also the Martens photometer with selective ray filters and monochromatic light, and the Hilger sector photometer method in the blue, violet, and ultra-violet. Each apparatus was considered to be in reliable working condition, but the comparison of results showed occasional very serious discrepancies, especially in the blue and in the red beyond 650 mμ. Much of this was due to insufficient precautions against stray light.

Since that time the four methods already described in detail—viz. the visual, the photoelectric, the thermoelectric, and the photographic—have been developed or improved; and values of spectral transmissive characteristics may now be obtained from about 230 to 1350 mμ with no "weak" regions and no serious discrepancies. In the paper on the food dyes noted above the observed values of transmittancies[4] by all four methods are plotted for all the concentrations, thicknesses, and temperatures studied. As a result of this investigation the following statements may be made:

(i.) Errors of method are believed to have been eliminated in the visual method with the König-Martens spectrophotometer when homogeneous light is used.

(ii.) There is very close agreement between the visual and photoelectric methods. This is true not only between 500 and 550 mμ, where both methods are very reliable, but throughout nearly the whole range of either.

(iii.) In comparing the photographic determinations with the visual or photoelectric between 390 and 500 mμ, it has been found that the agreement is usually better the shorter the wave-length, the less the transmittancy, and the "steeper" the transmittancy curve. From the nature of the photographic method it is difficult to determine exactly the value of maximum or minimum

[4] *Transmittancy*: the ratio of the transmission of a cell containing a substance in solution to that of the same or an equivalent cell filled with the solvent only.

transmittancy. But the agreement in the blue and violet indicates that in the ultra-violet, where the dispersion is greater, the method is very reliable, especially for the determination of the frequency and magnitude of *absorption* bands, the main purpose of most investigations in this region.

(iv.) Agreements between the visual and thermoelectric methods between 600 and 700 mμ indicate that no serious errors are present.

(v.) On the König-Martens spectrophotometer with homogeneous light, values of k, the specific transmissive index,[1] may, as a rule, be obtained accurate to within ± 2 per cent, provided that suitable concentrations and thicknesses are used.[2]

(vi.) Values of k at any wave-length between about 400 and 680 mμ visually or photoelectrically (*i.e.* both methods being used) with a heterogeneous source may be obtained with slightly less accuracy than this.

(vii.) Definite maximum values of k, *i.e.* the absorption bands, if not too narrow, may be obtained in the visible accurate to within ± 3 per cent; but in the ultra-violet, because of certain characteristics of the method, the uncertainty may often be greater than this.

(viii.) In the visible and ultra-violet the wave-lengths of definite maximum values of k are accurate within ± 1 mμ; in the infra-red the uncertainty becomes greater, but is considered less than ± 5 mμ even at 1350 mμ.

The visual method is the only one so far developed by which measurements of diffuse spectral reflection may be made under approximately ideal conditions, and there is no reason to doubt that values of reflection are obtained with as high accuracy as is possible in transmissive work. As already noted, the photoelectric method gave values of reflection considered of perhaps half the accuracy of transmissive measurements, for approximately diffusing surfaces. Examples of the close agreement between the visual and photoelectric methods for such surfaces are given in *Bur. Stand. Tech. Pap.* No. 167. Approximate measurements on some of the same samples by the photographic sector photometer method with a quartz-mercury lamp as source indicate the reliability of the method if proper irradiation is used.

K. S. G.

SPECTRO-POLARIMETER: an instrument for measuring the rotation for different wave-lengths of the plane of polarisation of light by various substances. See "Polarimetry," § (14).

[1] *Specific transmissive index*, k: Let T = transmittancy, c = concentration, b = thickness; then $k = -\log_{10} \sqrt[cb]{T}$.

[2] The photometric precision of this instrument, as tested by means of accurately calibrated rotating sectors, is better than 1 per cent.

SPECTROSCOPES AND REFRACTOMETERS

I. Theory

§ (1).—When light falls on a prismatic piece of a transparent substance it is deviated by an amount depending on the angle of the prism, and on the property of the substance known as its refractive index, which varies with the wave-length of the light. Light of different wave-lengths is therefore deviated to different extents; and if the incident beam contains constituents of more than one wave-length, each constituent beam emerges from the prism in a different direction.

The deviation of a beam of light by a prism depends, therefore, on two inter-related physical quantities, the refractive index of the prism and the wave-length of the light; and it may be measured with a view to determine unknown wave-lengths, if the properties of the prism are known (or eliminated), or to determine the refractive properties of the prism for known wave-lengths. The instrumental requirements for precise determinations vary somewhat, depending on which of these purposes is in view; and the spectroscopist, who is primarily interested in wave-length measurements, would rarely have much use for the instrument best suited to the requirements of the refractometrist, who is primarily interested in the refractive indices of the prism.

Since the determination of refractive indices may be said to be the basic measurement in applied optics, inasmuch as the design of any optical instrument depends for its realisation on a precise knowledge of the refractive properties of the materials used in its construction, we shall devote some consideration to the methods and instruments best adapted to this measurement; and in the first place we shall investigate generally the conditions which govern the refraction of light by a "prism" with a view to determining the comparative accuracy of different methods and the actual accuracy likely to be obtained with a given instrumental equipment.

§ (2) Passage of Light through a Prism.—All the methods suitable for precise refractometry involve the determination of the angular deviation, with respect to some fixed direction, of a beam of light which has been refracted by a system of plane surfaces, usually two in number. Separate formulae are readily obtained for the various methods; but it is more useful, in order to correlate such methods and compare their advantages and disadvantages, to treat them as special cases of a quite general relationship.

Let AB, *Fig.* 1, be a ray of monochromatic light incident on the first of two plane surfaces

which separate three regions in which the refractive indices for the wave-length of the light employed are μ_1, μ_2, and μ_3. We shall assume that the incident ray and also the normals to the surfaces lie in the plane of the paper.

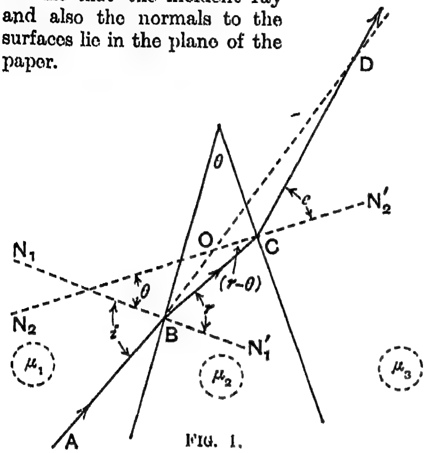

FIG. 1.

It is necessary to employ a definite convention with respect to the signs of angles in order to prevent confusion, and, in certain cases, ambiguity. *All angles will be considered positive when measured in a counter-clockwise direction from the appropriate reference directions.* For angles of incidence and refraction the reference directions are the normals to the respective surfaces; while, in considering the angle between two surfaces, the normal to the surface first encountered by the ray is the reference direction for the normal to the second surface. As regards the deviation of a ray, the initial direction of the ray is the reference line for the final direction.

Fig. 1 has been drawn so that all the angles with which we are concerned are positive on the above convention. The formulae obtained from it will of course differ in the signs of certain terms from those deduced in the text-books, in which the magnitude of an angle is alone taken into account.

Let the angle of incidence $ABN_1 = i$. The refracted ray BC in the second medium makes an angle $N_1'BC$, $= r$, with the normal at B, and finally enters the third medium, making an angle of emergence $N_2'CD$, $= e$, with the normal to the second surface at C. If the angle between the surfaces is θ, it follows from the geometry of the figure that $B\hat{C}N_2$, the angle of incidence at the second surface, $= r - \theta$, and that angle $C\hat{D}O = \theta + e - i$. But $C\hat{D}O$ is the angle by which the ray has been deviated by the two refractions, $= \delta$ say. Therefore the deviation, δ, $= \theta + e - i$.

$$\sin^2\theta = \{\sin r \cos(r-\theta) - \cos r \sin(r-\theta)\}^2$$
$$= \sin^2 r + \sin^2(r-\theta) - 2\sin r \sin(r-\theta)\cos\theta.$$

From the law of refraction

$$\mu_1 \sin i = \mu_2 \sin r\ ;\ \mu_2 \sin(r-\theta) = \mu_3 \sin e\ ;$$

therefore

$$\mu_2^2 \sin^2\theta = \mu_1^2 \sin^2 i + \mu_3^2 \sin^2 e - 2\mu_1\mu_3 \sin i \sin e \cos\theta. \quad (1)$$

Equation (1) is the starting-point from which all special cases may be deduced.

(i.) *Parallel Surfaces.*—If $\theta = 0$, equation (1) reduces to

$$\mu_3 \sin e = \mu_1 \sin i.$$

But this is the same relationship between i and e that would apply if the first and third media were separated by a single surface. The parallel plate of index μ_2 is therefore without effect on the final direction of the beam, which depends simply on the properties of the first and last media. If $\mu_1 = \mu_3$ the ray will be undeviated by passing through the plate.

(ii.) *Prism in Air.*—In this case $\mu_1 = \mu_3 = 1$ (approx.), and equation (1) becomes

$$\mu_2^2 \sin^2\theta = \sin^2 e + \sin^2 i - 2\sin e \sin i \cos\theta. \quad (2)$$

There are three special cases of practical importance, viz. $e = 0$; $i = 90°$; and the case in which the deviation is a minimum.

(*a*) When $e = 0$ the ray strikes the second surface of the prism normally. Equation (2) reduces in this case to

$$\mu_2 = \frac{\sin i}{\sin\theta} \quad . \quad . \quad . \quad (3)$$

(*b*) When $i = 90°$ the incidence is "grazing," the ray being refracted at the so-called critical angle.

Equation (2) reduces in this case to

$$\mu_2^2 = 1 + \left(\frac{\cos\theta - \sin e}{\sin\theta}\right)^2. \quad . \quad (4)$$

(*c*) When the deviation is a minimum the angles of incidence and emergence are equal. This is shown in all text-books and it is needless to prove it here. When this condition is fulfilled $i = -e$ and equation (2) becomes

$$\mu_2^2 \sin^2\theta = 2\sin^2 i(1 + \cos\theta),$$

or $4\mu_2^2 \sin^2(\theta/2)\cos^2(\theta/2) = 2\sin^2 i \,.\, 2\cos^2(\theta/2)$,

whence $$\mu_2 = \frac{\sin i}{\sin(\theta/2)}.$$

The deviation, δ, $= \theta + e - i$, $= \theta - 2i$, or $i = \frac{1}{2}(\theta - \delta)$; therefore

$$\mu_2 = \frac{\sin\frac{1}{2}(\theta-\delta)}{\sin\theta/2} \quad . \quad . \quad . \quad (5)$$

The reader may have observed that the sign of $\sin e$ in equation (4) and of δ in equation (5)

are different from the usually given forms. In the latter case, δ is invariably negative on the sign convention adopted in this treatment; so if $\bar{\delta}$ denotes the numerical value of the measured deviation, $\delta = -\bar{\delta}$ and

$$\mu_2 = \frac{\sin \frac{1}{2}(\theta + \bar{\delta})}{\sin \theta/2}, \quad . \quad . \quad (5a)$$

which is the usual form. In the case of equation (4) the formula is usually deduced in the text-books for a case in which e is negative, in which case, if the numerical value of $\sin e$ is denoted by $\sin \bar{e}$, the usual $+$ sign is obtained in the formula. However, in this method e is by no means always $-$ve. If θ or μ_2 is small, the emergent ray may lie between the normal and the refracting edge of the prism, in which case e is positive and the negative sign in equation (4) must be used. It is easier therefore, as in other optical problems, to remember the generalised forms of these equations, inserting the appropriate signs in practical cases, rather than to remember each case separately.

(iii.) *Prism with one Surface in Contact with another Refractive Substance.*—Suppose that in contact with the first surface of the prism there is another refractive substance. In this case $\mu_1 \neq 1$, and equation (1) becomes

$$\mu_2^2 \sin^2 \theta = \sin^2 e + \mu_1^2 \sin^2 i - 2\mu_1 \sin i \sin e \cos \theta.$$

The only case of practical importance is that of grazing incidence, or $i = 90^\circ$.

In this case the equation reduces to

$$\mu_1 = \pm \sin \theta \sqrt{\mu_2^2 - \sin^2 e} + \sin e \cos \theta.$$

The index μ_1 is positive and greater than unity, whereas the product $\sin e \cos \theta$ is necessarily less than unity; so that the positive sign before the square root must always be taken. Thus

$$\mu_1 = \sin \theta \sqrt{\mu_2^2 - \sin^2 e} + \sin e \cos \theta. \quad (6)$$

If μ_2 and θ are known, μ_1 can be determined from equation (6), the only measurement required being the angle of emergence e which the ray makes with the normal to the second surface of the prism.

§ (3) Angle of Incidence for a given Deviation.—In the preceding section the relations involved in the principal methods of refractometry have been deduced. In each case some particular value of i, e, or δ was chosen, the choice being dictated by the convenience of realising these particular conditions in practice.

It is sometimes desired to produce a given deviation by a given prism (in air), and an angle of incidence has to be chosen to give this deviation.

The general equation, (2), is

$$\begin{aligned}\mu_2^2 \sin^2 \theta &= \sin^2 e + \sin^2 i - 2 \sin e \sin i \cos \theta \\ &= \tfrac{1}{2}\{2 - (\cos 2e + \cos 2i)\} \\ &\qquad - \cos \theta \{\cos (e - i) - \cos (e + i)\} \\ &= \tfrac{1}{2}[2 - 2\{\cos (e + i) \cos (e - i)\}] \\ &\qquad - \cos \theta \cos (e - i) + \cos \theta \cos (e + i) \\ &= 1 - \cos (e + i)\{\cos (e - i) - \cos \theta\} \\ &\qquad - \cos \theta \cos (e - i).\end{aligned}$$

But $\quad e + i = \delta + 2i - \theta$, and $e - i = \delta - \theta$;

$$\therefore \mu_2^2 \sin^2 \theta - 1 + \cos \theta \cos (\delta - \theta) = -\cos (\delta - \theta + 2i)\{\cos (\delta - \theta) - \cos \theta\}$$

or

$$\cos (\delta - \theta + 2i) = \frac{1 - \mu_2^2 \sin^2 \theta - \cos \theta \cos (\delta - \theta)}{\cos (\delta - \theta) - \cos \theta}.$$

Since δ is always $-$ve, provided $\mu_2 > 1$, we may put $\delta = -\bar{\delta}$ where $\bar{\delta}$ is the numerical value of the deviation, and

$$\cos (2i - \theta - \bar{\delta}) = \frac{1 - \mu_2^2 \sin^2 \theta - \cos \theta \cos (\theta + \bar{\delta})}{\cos (\theta + \bar{\delta}) - \cos \theta}.$$

from which, since θ and μ_2 are supposed known, the value of i corresponding to a specified value of δ can be calculated.

§ (4) Sensitivity of Methods.—The equations of § (2), relating to various methods of refractometry employed in practice, tell us nothing about the relative advantages of the methods, and give no guidance as to which should be used in any particular circumstances. It is necessary to discuss the sensitivity of the methods, that is, the change in the measured quantity per unit change of refractive index, and also the extent to which the results are affected by errors in the values of the auxiliary constants, such, for instance, as the angle of the prism, or, in the case of the method to which equation (6) refers, the refractive index μ_2 of the auxiliary prism.

Taking first the most familiar method, the quantity measured is δ, the minimum deviation. The sensitivity S may be measured by the number of seconds which δ varies when the refractive index of the prism changes by one unit in the fifth decimal place. Thus

$$S = \frac{\partial \delta}{\partial \mu_2} \times \frac{57 \cdot 3 \times 60 \times 60}{10^5} = 2 \cdot 06 \frac{\partial \delta}{\partial \mu_2}.$$

From equation (5) above,

$$\frac{\partial \mu_2}{\partial \delta} = -\frac{1}{2} \frac{\cos \frac{1}{2}(\theta - \delta)}{\sin \theta/2}.$$

Whence $$S = \frac{-4 \cdot 12 \sin \theta/2}{\cos \frac{1}{2}(\theta - \delta)}. \quad . \quad . \quad (7)$$

Thus the sensitivity is a function of the deviation and of the angle of the prism. We can calculate its value for any values of μ_2 and θ, first finding the appropriate values of δ from equation (5).

For a given material (*i.e.* μ_2 constant) it is interesting to observe how the sensitivity varies for different prism angles. There is clearly a major limit to the permissible angle for any value of μ_2, which is reached when θ is such that both the angles of incidence and emergence are 90°. If θ is greater than this there is no emergent ray, the light being totally reflected at the second surface for all possible angles of incidence on the first.

If $i = -e = 90°$, $\delta = \theta + e - i = \theta - 180°$, and equation (5) reduces to

$$\mu_2 = \frac{1}{\sin \theta/2}.$$

The largest refractive index of which measurement can be made with a prism of given angle, or the largest angle which a prism of given index may have and still transmit light, is given by the above relationship.

If $\mu_2 = 1{\cdot}6$ the largest possible prism angle is $77\frac{1}{3}°$, while for the usual 60° prism the largest possible index is 2.

In *Fig.* 2 the sensitivity of prisms of refractive index 1·6 and 1·75 is plotted for different prism angles. The sensitivity increases as θ increases, the rate of increase being very rapid as θ approaches its greatest possible value, being infinite when that value is reached. The curve shows that for $\mu_2 = 1{\cdot}6$, which is about the average of the values encountered in practical work of high precision, an angle of 75° would give more than five times the sensitivity of the usual 60° prism.

Sensitivity is, however, only one factor in the accuracy of the measurements; and we shall see that there are other factors which prevent the utilisation of the large sensitivity which might be obtained by suitable choice of prism angle.

Leaving for the moment the case of minimum deviation, let us consider the method in which the incidence is grazing, and for which we found (equation (4))

$$\mu_2^2 = 1 + \left(\frac{\cos \theta - \sin e}{\sin \theta}\right)^2.$$

In this case the measured angle is e, and the sensitivity, in the same units as adopted for the last case, will be $S = 2{\cdot}06\,(\partial e/\partial \mu_2)$.

$$2\mu_2 \frac{\partial \mu_2}{\partial e} = -2\left(\frac{\cos \theta - \sin e}{\sin \theta}\right)\frac{\cos e}{\sin \theta},$$

or $$S = -2{\cdot}06\mu_2 \frac{\sin^2 \theta}{\cos e}\Big/(\cos \theta - \sin e). \qquad (8)$$

The quantity in brackets is always positive provided $\mu_2 < 1$, since, if μ_2 is unity, the ray is undeviated and emerges parallel to the 1st face, in which case $e = 90° - \theta$ and $\sin e = \cos \theta$.

This is the largest positive value e can have, so that if $\mu_2 > 1$, $\sin e < \cos \theta$. Thus $\partial e/\partial \mu_2$ is always −ve and the ray is always deviated farther away from the refracting edge for an increase in the refractive index.

Clearly the maximum value of θ for a given μ_2, or *vice versa*, is the same as in the minimum deviation method, since the case in which *both* i and $-e = 90°$ may be regarded indifferently as pertaining to either method.

As regards the sensitivity obtained with different angles for a given μ_2, the general features of the curve would be similar to *Fig.* 2,

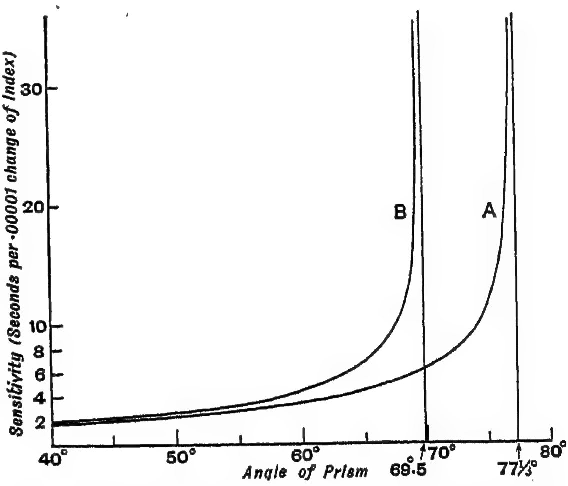

FIG. 2.—Sensitivity of Minimum Deviation Method for different Prism Angles.
A, $\mu = 1{\cdot}60$. B, $\mu = 1{\cdot}75$.

for it is easy to see from the form of equation (8) that as $\cos e$ approaches zero, that is, as the angle of the prism approaches the value for which the emergent ray is grazing, $\partial e/\partial \mu_2$ increases more and more rapidly, becoming infinity when the limiting value of the angle is reached. In this case as in the last, however, practical considerations prevent the highest sensitivity being fully utilised and, as we shall see, the balance of advantage for most ordinary purposes lies with the 60° prism.

If then we take the 60° prism as basis, it is useful to compare the sensitivities of these two methods throughout the range of refractive index usually encountered in practice.

These have been plotted in *Fig.* 3. The curves tell us the accuracy with which the direction of the emergent beam has to be determined in each method in order to have an error not exceeding 0·00001 in the refractive

index. The precision required is greatest for low indices. For indices below 1·5, an error of 3 seconds in the direction of the emergent ray will introduce an error of 0·00001 in the result with either method. At higher indices there is a slight improvement, particularly with the minimum deviation method. The region of high sensitivity (1·8 to 2·0) is not of great importance, as most substances employed in optical work have indices between 1·4 and 1·8, the great majority lying between

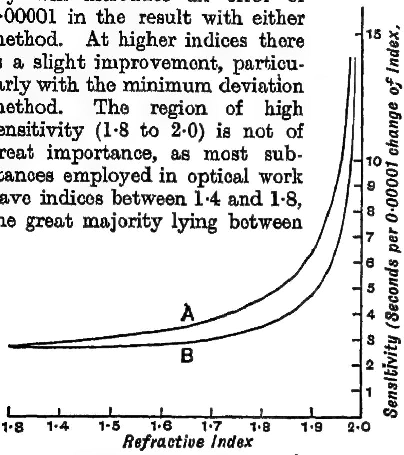

FIG. 3.—Sensitivities of Refractive Index Measurements for different Indices.

A, Minimum Deviation Method.
B, Grazing Incidence Method.

1·5 and 1·75. In the majority of cases, then, the sensitivity for the grazing incidence method is 3 seconds per 0·00001 change of index and for the minimum deviation method from 3 to 4 seconds.

The third method which it is of importance to discuss is that due to Wollaston,[1] in which the object is not the determination of the index of the prism but of a substance in contact with its first face, the prism merely filling an auxiliary rôle. Several commercial refractometers due to different inventors are made on this principle. The prism we may term the standard prism or standard block.

Equation (6) refers to this method, μ_1 being the index to be determined, μ_2 the index, for the wave-length in question, of the standard block, and θ its angle. The quantity measured is e, the angle of emergence from the second face of the block.

Differentiating equation (6) under the conditions that θ and μ_2 are constant, we obtain

$$\frac{\partial\mu_1}{\partial e}=\frac{1}{2}\frac{\sin\theta}{\sqrt{\mu_2^2-\sin^2 e}}(-2\sin e\cos e)+\cos e\cos\theta$$

$$=-\frac{\cos e}{\sqrt{\mu_2^2-\sin^2 e}}\{\cos\theta\sqrt{\mu_2^2-\sin^2 e}-\sin e\sin\theta\},$$

which, after transformation and substitution from equation (6), becomes

$$\frac{\cos e}{\sqrt{\mu_2^2-\sin^2 e}}\sqrt{\mu_2^2-\mu_1^2}.$$

Thus the sensitivity for measurements of μ_1, which we may denote by $S\mu_1$,

$$=2\cdot06\frac{\partial e}{\partial\mu_1}=\frac{2\cdot06\sqrt{\mu_2^2-\sin^2 e}}{\cos e\sqrt{\mu_2^2-\mu_1^2}}. \quad (9)$$

This quantity can be calculated for different values of μ_1, μ_2, and θ, the appropriate values of e being obtained from equation (6), which, for this purpose, can be reduced to a rather more convenient form, viz.

$$\sin e=\mu_1\cos\theta-\sin\theta\sqrt{\mu_2^2-\mu_1^2}. \quad (10)$$

In *Fig.* 4 a series of curves are drawn showing, for the case in which $\mu_2=1\cdot75$ (a usual value for this method), how the sensitivity, $S\mu_1$, varies with the index under test (μ_1) for prisms of different angles. The sensitivity is in all cases high for indices near that of the block, diminishing to a minimum value, which is lower, and occurs at a lower value of μ_1, the smaller θ becomes. Thus with a 90° block, the minimum sensitivity occurs when $\mu_1=1\cdot57$ approx., and is about 6 seconds per 0·00001 variation of μ_1; for $\theta=80°$ the minimum is at $\mu_1=1\cdot5$, and is under 5 seconds; for $\theta=60°$ the minimum is not reached until μ_1 is in the neighbourhood of 1·2, and is just over 3 seconds, while for $\theta=45°$ the minimum is never reached.

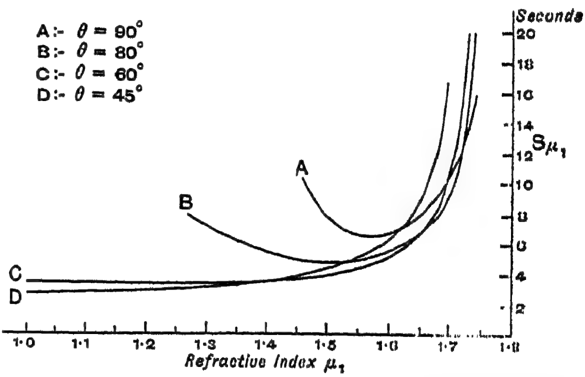

FIG. 4.—Sensitivity of Refractive Index Measurements by Wollaston Method.

§ (5) EFFECTS OF ERRORS IN AUXILIARY CONSTANTS.—In all the formulae which we have considered the angle, θ, of the prism occurs. This quantity has, in general, to be experimentally determined, and is therefore subject to possible error. The assumption of an erroneous value for θ in any of the

[1] *Phil. Trans.*, 1802, p. 365.

formulae for refractive index will lead to a corresponding error in the result. This error is clearly proportional to the partial derivatives with respect to θ of the expressions for μ.

For the minimum deviation method we obtain, by partial differentiation of equation (5),

$$\frac{\partial\mu_2}{\partial\theta}=\tfrac{1}{2}\frac{\cos(\theta-\delta/2)}{\sin\theta/2}-\tfrac{1}{2}\frac{\sin(\theta-\delta/2)}{\sin^2\theta/2}\cos\theta/2$$

$$=\tfrac{1}{2}\frac{\sin\delta/2}{\sin^2\theta/2}.$$

It is usually more convenient to express the result as the inverse of this, *i.e* the error in angle which will produce unit error in the calculated refractive index. We may call this the *Tolerance in prism angle* and denote it by T_θ, the factor 2·06 being introduced as before to give the result in seconds of arc per 0·00001 error in index.

Thus $$T_\theta=4{\cdot}12\frac{\sin^2\theta/2}{\sin\delta/2}. \qquad (11)$$

For the grazing incidence method by differentiation with respect to θ, of equation (4) we obtain

$$2\mu_2\frac{\partial\mu_2}{\partial\theta}=2\left(\frac{\cos\theta-\sin e}{\sin\theta}\right)\left\{-\frac{\sin\theta}{\sin\theta}-\left(\frac{\cos\theta-\sin e}{\sin^2\theta}\right)\cos\theta\right\}$$

$$=-2\left(\frac{\cos\theta-\sin e}{\sin\theta}\right)\left\{1+\cos\theta\left(\frac{\cos\theta-\sin e}{\sin^2\theta}\right)\right\}$$

$$=-2\{\sqrt{\mu_2^2-1}+(\mu_2^2-1)\cot\theta\},$$

$$T_\theta=2{\cdot}06\frac{\partial\theta}{\partial\mu_2}=\frac{-2{\cdot}06\,\mu_2}{\sqrt{\mu_2^2-1}+(\mu_2^2-1)\cot\theta}. \qquad (12)$$

In *Fig.* 5, T_θ is plotted for both of these methods for different prism angles, the refractive index being taken as 1·6. We see

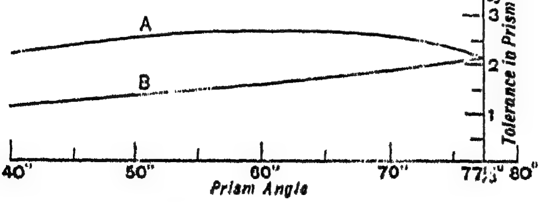

FIG. 5.—Tolerance in Angle of Prisms used for Refractive Index Determinations.
A, Minimum Deviation } μ=1·6.
B, Grazing Incidence }

from the figure that the effect of an error in the angle of the prism is much greater for grazing incidence than for minimum deviation, except near the limiting prism angle, in which

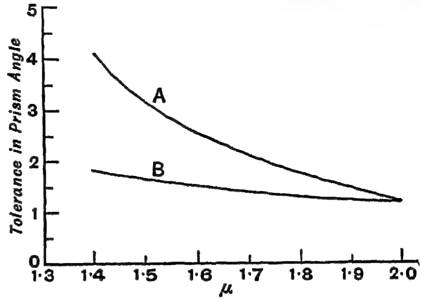

FIG. 6.—Tolerance in Angle of Prism used for Refractive Index Measurements.
A, Minimum Deviation.
B, Grazing Incidence.

case the two methods tend to become identical. In *Fig.* 6 is plotted the tolerance with a 60° prism, for different values of the index.

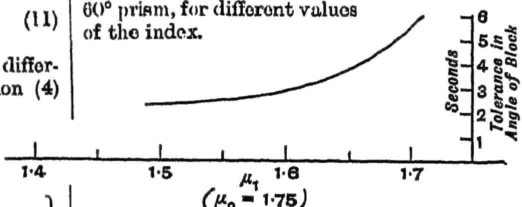

FIG. 7.—Tolerance of Angle of Block in Wollaston Method.

In the case of the Wollaston method we have, from equation (6),

$$\frac{\partial\mu_1}{\partial\theta}=\cos\theta\sqrt{\mu_2^2-\sin^2 e}-\sin e\sin\theta,$$

which reduces to $\sqrt{\mu_2^2-\mu_1^2}$.

Thus $$T_\theta=2{\cdot}06\frac{\partial\theta}{\partial\mu_1},=\frac{2{\cdot}06}{\sqrt{\mu_2^2-\mu_1^2}}. \qquad (13)$$

In this case, therefore, the tolerance in angle is independent of the angle of the prism, depending only on the values of μ_1 and μ_2. Assuming $\mu_2=1{\cdot}75$, *Fig.* 7 shows the value of T_θ for different values of the index under test. We see from it that the effect of an error in θ is less the higher the index under test. For substances of index about 1·5 an error of two seconds in the angle of the block will introduce an error of 0·00001 in the value of the index.

The accuracy of this method also depends on the accuracy with which μ_2, the index of the prism, is known. The error in μ_1 due to an error in the assumed value of μ_2 will be proportional to the partial derivative of the

The use of quartz jaws was suggested by the late Sir W. Crookes.[1] These are bevelled to a very sharp edge in the same way as the ordinary metal jaws. The edges therefore form prisms, and light which passes through the quartz is refracted towards the sides of the collimator tube, by which it is absorbed. Only the light passing between the edges reaches the lens of the collimator, just as in the case of opaque jaws. The advantage of quartz jaws is that they can be polished to a more accurate edge than metal. The disadvantage is that the edges are so extremely fragile. The jaws should therefore be mounted in such a way that the moving mechanism drags them forward by friction, so that there is no possibility of jamming them together in the event of the slit being accidentally closed. It is surprising that this method has not been generally adopted even for metal jaws, as it would greatly minimise the risk of damage to a valuable slit.

The slit is usually attached to a short tube which slides into the end of the collimator tube, and may be adjusted, preferably by rack and pinion, for focussing the collimator.

The body tube of the collimator should be lined with some corrugated material or fitted with a series of diaphragms to prevent light which falls on the side of the tube from being reflected as stray light through the lens.

The lens of the collimator should be a telescope objective of the finest quality. It should be free from all but the merest trace of spherical aberration. The lenses employed in spectrometers are almost invariably cemented doublets. There is therefore always considerable residual chromatic aberration, which is usually particularly manifest at the blue end of the spectrum. By the use of triple lenses the greater part of this could be obviated, and a very serious nuisance to the spectroscopist removed.

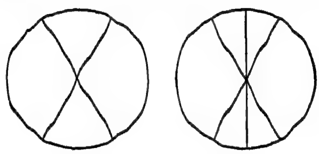
(ii.) *The Telescope.*—The requirements of this important part of the spectrometer have not, unfortunately, received the attention from makers which ought to have been devoted to them. As in the case of the collimator, telescopes are frequently fitted with object glasses made to an ordinary formula suitable for telescopes of surveying instruments, etc. The type of colour correction suitable for such instruments is entirely unsuited for spectroscopic work, in which the rays at the extreme ends of the spectrum are just as important as those in the more central regions. Here, as in the case of the collimator, it would be possible to get a much more satisfactory result from a triple lens than from the usual doublet.

As the telescope may sometimes have to be used with a micrometer eyepiece, the lens ought to be designed to give the best definition possible over a field of at least 2° on either side of the axis. Further, the field of view should be flat, otherwise the measurements with the micrometer eyepiece will be affected by distortion.

The power of the eyepiece employed may vary over a fairly wide range without appreciably affecting its usefulness; but a convenient power is one which gives a magnification of the telescope as a whole of 18 to 20 diameters for each inch of effective aperture.

An important feature of a spectroscopic telescope, and one which greatly influences the accuracy of the results obtainable with the instrument, is the cross-lines.

Considerable experimenting with settings of different types has been done by various workers, but there is very little doubt that the most suitable arrangement for general spectroscopic work is that in which the cross-lines are mounted diagonally as shown in *Fig.* 9 (*a*). The angle between the lines varies in different instruments from about 20° to 90°. Where possible the writer always mounts them at 60°. Such lines can be set with great accuracy on a vertical line as in *Fig.* 9 (*b*). As regards the thickness of the lines, there is no great advantage in having them excessively fine. Within reasonable limits, the thicker the lines the less fatiguing it is to keep them



(*a*) (*b*)

FIG. 9.

in sharp focus. With an eyepiece of about 1½ cm. focal length a convenient diameter of fibre to employ is from 4 to 8 μ.

In the case of a micrometer eyepiece, the best type is that in which the ocular can be moved as well as the cross-lines. If the ocular is fixed only small movements of the cross-lines are possible, since the definition falls off rapidly towards the edge of the field. But if the ocular can also be translated, so that the cross-lines always appear in the centre of the field of view, good definition is obtained over a much larger range.

(iii.) *The Axis and Scale.*—The considerations of §§ (4) and (5) show us that in order to measure refractive indices correctly to the fifth decimal place it is necessary that we should be able to determine angles to within a little over one second of arc. This requires most accurately turned centres and accurately divided scales; but even when the instrument-maker has done his very best, there is much to be done by the experimenter in discovering the peculiarities

[1] *Chem. News*, 1895, lxxi. 175.

right-hand side of equation (6) with respect to μ_2, θ and e being regarded as constant.

$$\frac{\partial\mu_1}{\partial\mu_2}=\frac{1}{2}\frac{\sin\theta}{\sqrt{\mu_2^2-\sin^2 e}}\cdot 2\mu_2=\frac{\mu_2\sin\theta}{\sqrt{\mu_2^2-\sin^2 e}}. \quad (14)$$

In the particular case when $\theta=90°$, this reduces to μ_2/μ_1. In *Fig.* 8, $\partial\mu_1/\partial\mu_2$ is plotted for different prism angles for two values of μ_1.

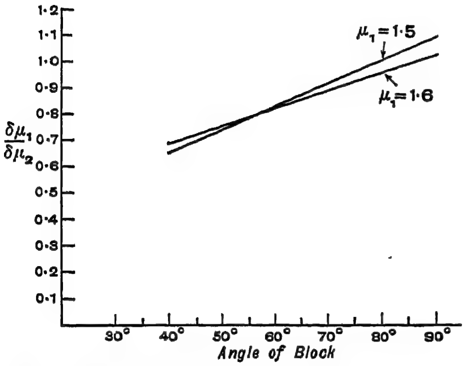


FIG. 8.—Wollaston Method. Effect of Errors in Index of Standard Block.

It will be noticed that the smaller the value of θ the smaller is the effect of an error in μ_2.

II. The Spectrometer

§ (6).—The spectrometer in its simplest elements consists of a collimator, an adjustable table on which a prism or other dispersing apparatus may be placed, a telescope which rotates about an axis concentric with the table, and a circular scale on which the angular position of the rotating telescope may be determined. It is necessary to be able to rotate the table itself about the same axis as the telescope rotates; and, except in the simplest instruments, means are provided for reading the angular position of the table, either on the same circle as used for the telescope or on a separate circle.

The former arrangement is the more generally useful, since it enables rotations of the table to be determined with the same accuracy as rotations of the telescope. Where a separate circle is provided for the table it is rarely of the same accuracy as the other.

(i.) *The Collimator.*—This consists simply of a narrow slit at the focus of a lens. The rays from each point of the slit are therefore rendered parallel by passage through the lens. The necessity for collimation is due to the fact that unless the slit were virtually at infinity, rays from any point of it would meet different parts of the prism at different angles of incidence and would therefore be deviated to different extents. If the slit is at infinity, all the rays from any point of it which reach the prism are deviated equally and can be recombined at a single point in the focal plane of the telescope. A sharp image of the slit is the result. The slit is usually formed between two jaws of untarnishable metal. The edges are bevelled on the side which faces the lens and are ground perfectly sharp and straight. The method of mounting the jaws varies in different designs; but there is invariably provision for opening or closing the slit by means of a screw of fine pitch, which is usually provided with a divided drum so that the slit width can be set at definite values. In the majority of cases one of the jaws is fixed, and the slit opens and shuts unsymmetrically. In some of the more expensive slits both jaws move simultaneously, so that the centre of the slit remains in the same position whatever the slit width. Some workers have a preference for symmetrical slits; but except when the instrument is used as a monochromatic illuminator, it is doubtful if there is appreciable advantage in their use. On the other hand, with an observer who is apt to take an instrument on trust, they may be a source of danger. When precise measurements are in question it must never be assumed that the centre of the slit has exactly the same position for different widths. It is not therefore satisfactory to vary the slit width when dealing with spectrum lines of different brightnesses as advocated by some writers. If some lines are too bright with the slit width necessitated by the faintness of others, their brightness should be diminished by placing absorbing glasses between the slit and the source, removing these when working on the faint lines. There is no slit mechanism sufficiently perfect to enable one to assume an absolutely symmetrical opening and closing of the slit to the very high degree of accuracy of which a well-designed spectrometer is capable.

Whether symmetrical or unsymmetrical, a good slit will also have provision whereby the exact parallelism of the jaws may be adjusted. In certain classes of work extremely fine slit widths, as little as 0·01 mm. for instance, are used. It is only with the most accurate adjustment for parallelism that slits of such fineness are possible.

When a good slit has been obtained it should be treated with the utmost care. To close the jaws completely is almost invariably fatal, and it is rare to find a slit which has been in general laboratory use for any length of time which will close down to a very narrow width without showing streaks across the spectrum due to some parts of the jaws being in contact.

of the instrument and the errors to which it is liable, and in devising means for their elimination or correction. The proper attitude to adopt to any instrument is one of distrust and suspicion; and it should not be regarded as accurate in any particular until it has been carefully verified by tests as many and varied as possible.

For working to anything less than ten seconds verniers are unsatisfactory, and the scale has to be read by two or four micrometer microscopes. The need for an even number of microscopes arises from the very probable existence of "centering error." This error is due to the scale not being exactly concentric with the axis of rotation.

Suppose C_1, *Fig.* 10 (*a*), is the centre of the scale, and C_2 is the axis about which the moving portion of the instrument rotates. Let C_2V be the arm carrying the vernier or micrometer. Then the reading will be at R, where C_2V intersects the scale. Let the line of excentricity EE_1 make an angle θ_0 from the zero point Z of the scale and let $C_1C_2 = e$. It is clear that if the scale reading is θ_0, that is, when the radius bar lies along EE_1, the reading is independent of the displacement e, and is therefore the same as if e were zero. When the bar is in any other position the angle through which it has been rotated from EE_1 is $R\hat{C}_2E_1$. But the angle recorded on the scale is $R\hat{C}_1E_1$. The recorded angle is therefore too small in the case shown by $C_1\hat{R}C_2 = e \sin \theta/r$, r being the radius. For any scale reading ϕ, therefore, there is an error of $-(e/r)\sin(\phi - \theta_0)$. This is of maximum value when the vernier arm is perpendicular to EE_1, and is zero when it is parallel to EE_1. The curve of error will be a sine curve of the form shown in *Fig.* 10 (*b*). The actual error between two readings ϕ_1 and ϕ_2 is the algebraic difference between the ordinates of the curve at these readings. It may therefore vary from zero to $2(e/r)$ depending on the values of ϕ_1 and ϕ_2.

We notice, however, that the ordinate at any point of the curve is equal and opposite to that at a point 180° from it. Thus if there are two verniers 180° apart the errors of one will always be equal and opposite to those of the other, and the mean of their readings will give the true angle.

Thus centering error can be eliminated if the mean reading of two verniers (or micrometers) 180° apart are taken. Spectrometers, except of the most elementary type, are therefore fitted with two or four verniers (or micrometers) equally spaced round the circle.

This, however, while it eliminates centering error where the direction and magnitude of the eccentricity is constant, does not eliminate every possibility of error from defective centres. If in the course of rotation the relative position of C_1 and C_2 alters, which is certain to happen to a greater or less extent unless the bearings are perfect in the literal sense of the term, the errors in each vernier reading need not follow the simple sine law

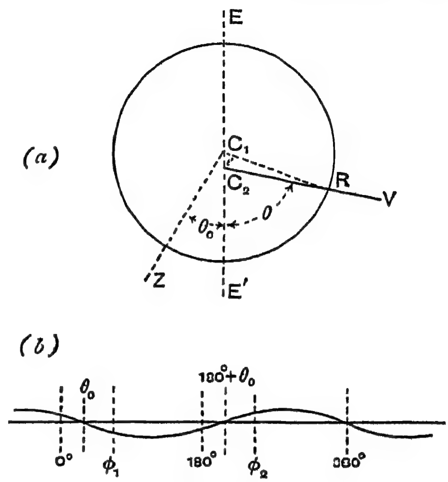

FIG. 10.

and will not necessarily be eliminated by taking the mean of readings 180° apart. An instrument, even if perfect when new, is certain to develop erratic centering errors of this type in the course of time, unless the rotating portion is very carefully balanced so as to press uniformly at all points of the bearing. If the contact is heavier on one side than another, the axis will be worn slightly elliptical in use, work being more concentrated in some ranges of angle than in others, and therefore e will change both in magnitude and direction for different readings.

Apart from centering errors, the scale divisions may themselves be non-uniform. There may be gradual variations of the size of a division due to unsuspected centering errors in the dividing engine with which the graduations were cut, or there may be irregular displacements of the division lines owing to imperfect working of the engine.

To calibrate the circle for every division is a very tedious business, and is not at all easy to perform with great accuracy except where special apparatus exists for such tests. On this account it is usual in the best instruments to provide means for altering the orientation of the scale with respect to the verniers or microscopes, in order that a particular measurement may be repeated, using different graduations distributed round the scale. In this way, if sufficient measurements are made, the graduation errors tend to average out.

The foregoing considerations apply both to

the measurements of the rotation of the telescope and rotation of the table. A serious defect in the design of most spectrometers is that the axis of rotation for the table is much less satisfactory than for the telescope; consequently measurements of table rotations, even when made on the same circle as those of the telescope rotations, are liable to much greater errors due to defective action of the centre. This is a serious matter in the general use of such instruments where, for certain purposes, such as the measurement of prism angles, for instance, it is necessary that the table rotation should be measurable with the very greatest accuracy.

There is one more important point about the centering arrangements of the spectrometer. The two moving parts should be mounted on a single axis, the table being, of course, uppermost; and the clamping devices and fine motion fittings should be so arranged that there is no frictional connection whatever between the two rotatable parts. If this is not secured the usual result is that the part, which in a given experiment is supposed to remain fixed, suffers a slight drag by the moving part in the direction in which the latter is moved.

(iv.) *A Standard Spectrometer.*—In *Fig.* 11 is shown a spectrometer designed in its essentials by the writer and in detail by Messrs. E. R. Watts, Ltd., of London, who made the instrument for the Optics Department of the National Physical Laboratory. The diameter of the base is 30 inches, which gives the scale of the figure.

The aim in the design was to avoid all sources of error which could be foreseen and to render easy the detection and elimination of such unforeseen and unavoidable errors as might still be present in the completed instrument.

The base is a circular iron plate, strengthened with radial and concentric webs on the lower side, and provided with two concentric slots of ⊥ section in the upper face. These are shown at 1 in the figure. The collimator, 2, is of 3½-inch aperture, and can be clamped to the base in any azimuth by four bolts, the heads of which are in the broad portion of the ⊥ slots. The telescope, 3, of 2½-inch aperture is mounted on an accurately balanced arm. In order to reduce the weight on the centres to a minimum, light alloys were employed wherever mechanical considerations permitted. A second telescope, 4, the uses of which are indicated later, is provided. This telescope is identical with 3, except that it stands on a pillar which can be clamped in any position round the base in the same way as the collimator. When not required it can be removed. Both telescopes and collimator are provided with adjustments for horizontality of axis, which are carefully designed to give great rigidity without the introduction of strain in the tubes.

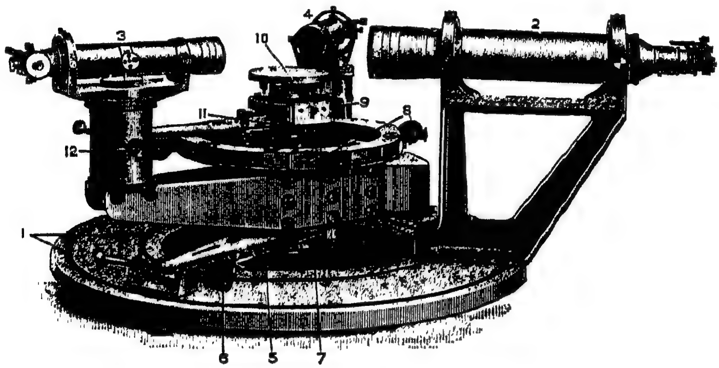

FIG. 11.

The centre consists of a strong tapering pivot. About the lower portion of this the telescope rotates, fine adjustment being obtained by means of the clamping collar, 5, and tangent screw, 6. A ring, 7, is screwed on a thread at the lower end of the pivot. This ring supports a ball-bearing, which in turn supports the weight of the moving telescope system. By adjusting 7, the moving system can be slightly raised or lowered to vary the tightness of the centre and secure proper freedom of rotation.

On the upper half of the central pivot, a second moving system, consisting of the table and graduated circle, rotates. The circle, which is of 15 inches diameter, is completely enclosed by a dust-proof cover. The scale is read by four micrometer microscopes, 8, reading directly to half-seconds and by estimation to less. These are attached

to a ring associated with the lower moving system and can be fixed in any position relative to it. The table itself can rotate for adjustment purposes independently of the circle. For this motion it is actuated by an endless tangent screw, 9, which can be thrown in or out of gear by a paul, 10.

When using the instrument for purposes in which rotation of the telescope is to be measured, the upper moving system has to be clamped to the pivot, thus fixing the position of the circle. The clamping device employed is such that no radial force whatever is exerted on the system. There is therefore no possibility of centering error being introduced by the process of clamping. When measuring rotations of the table, the telescope being fixed, the upper moving part is unclamped from the centre. Fine motion of the circle relative to the telescope is obtained by means of the clamping collar, 11, and tangent screw, 12. This collar can be removed entirely when not required, thereby removing any danger of a slight frictional drag on the circle and table when rotating the telescope. If desired, the tangent screw, 12, can be transferred to the support of the additional telescope, 4.

This instrument, it will be seen, can be used with equal accuracy for all purposes for which a spectrometer can be employed.

§ (7) The Prism.—In the last section the principal features and requirements of a spectrometer designed for the most accurate refractometry (and goniometry generally) were indicated. We shall now look at the requirements of the prism on which such measurements are to be made. In the first place, we must decide to what angle it should be cut. In discussing the sensitivity of the two principal methods available for determining the index of the prism, viz. the minimum deviation and grazing incidence methods, we saw that the sensitivity considerations alone would lead us to employ the largest angle for which light would still be transmitted by the prism. Further, from *Fig.* 4, the extent to which an error in the angle of the prism affects the result is seen to be nearly the same for all prism angles for the minimum deviation method, while it diminishes appreciably as the angle increases in the case of grazing incidence. This would also lead us to use as large an angle as possible.

There are other considerations, however. It is clear that the more nearly grazing the emergent ray is, the narrower is the transverse aperture of the beam which enters the telescope. This results in loss of definition. Up to a certain extent this is found to be without effect on the precision of the settings; but when carried too far some accuracy is lost, particularly in the method of grazing incidence, in which, as we shall see later, the setting is unsymmetrical. This consideration would lead us to use small angles. The final consideration, and the decisive one in the present stage of angular metrology, is that angles which are submultiples of 360°, such as 30°, 45°, 60°, and 90°, can easily and conveniently be measured with greater accuracy than those of intermediate value.[1] This fact leaves the balance of advantage with the 60° prism. Not only so, but if the substance is isotropic, or if it is a uniaxial crystal with its axis perpendicular to the principal plane of the prism, so that it has the same refractive index in any direction in the principal plane, it is possible, if all three faces are polished, to make measurements with each angle in turn. Glazebrook has shown[2] that if the individual angles of an approximately equilateral prism do not differ too much from 60°, the mean of the deviations when each angle is used in turn is equal to the deviation corresponding to a prism angle of exactly 60°. It must be borne in mind, however, that this result assumes that the prism is a true prism, *i.e* the three edges are supposed to be accurately parallel. By the assumptions on which the formulae of prism refraction are based, the angle of the prism is the angle between the two plane faces at which refraction occurs. If the prism is pyramidal, the sum of the angles between the faces taken in pairs exceeds 180°, and the mean deviation corresponds not to 60° but to $60°+\xi/3$, where the sum of the three angles is $180°+\xi$. It is shown in the article on "Goniometry," where the methods of measuring prism angles are dealt with, that for a 60° prism, $\xi=0{\cdot}279P^2\times10^{-5}$ seconds, where P seconds is the inclination of an edge of the prism to the opposite face. Thus if the pyramidal error of the prism is 10 minutes, the sum of the angles is 180° + 1 second.

While it is necessary to bear this in mind, and to test for pyramidal error, no prism which is otherwise good enough for precision determinations is likely to have more than a few minutes' pyramidal error at the outside, in which case the excess of the angles over 180° can be neglected.

Thus with a 60° prism it is possible to dispense altogether with a precise knowledge of the angles, thereby eliminating about half of the possible experimental error of the index determinations.

A prism which is to be used for determinations of great accuracy must be in the highest degree homogeneous and have its surfaces very accurately plane.

The total effect of defects of surface and

[1] See article on "Goniometry," § (3).
[2] See footnote to paper by Gifford, *Roy. Soc. Proc.*, 1902, xx. 230.

non-homogeneity on the transmitted wave-front, and also the planeness of the surfaces themselves, can be tested by interference methods (*vide* "Interferometers: Technical Applications," § (4)), and from these results the departures from homogeneity of the material can be deduced. The great skill with which surfaces can now be polished renders it easy to get prisms with surfaces of almost perfect flatness; but it is by no means easy to obtain a prism of satisfactory homogeneity. In fact the homogeneity of the material is what sets the limit at present to the accuracy to which it is worth while attempting to push refractometric measurements.

Theoretically, by increasing the mechanical perfection of the spectrometer, and by using telescopes of greater aperture and power, the precision of the angle measurements could be increased very considerably beyond what is necessary for fifth place accuracy in the index measurements; but the useful size of the telescopes is limited by the size of prism which can be obtained of satisfactory homogeneity. It is of little use at present to attempt to use prisms of more than 2-inch side.

§ (8) Adjustment of Spectrometer.—There are two principal adjustments which have to be made before a spectrometer is ready for use. The collimator and telescope have to be focussed for parallel light, and they have also to be adjusted so that their optic axes are perpendicular to the axis of rotation of the instrument. There are various ways of performing these adjustments; but by far the most convenient makes use, in each case, of an auxiliary telescope. Since such an auxiliary telescope is of the greatest convenience in many methods of using the spectroscope, particularly for goniometry (*vide* "Goniometry," § (2)), the experimenter should always provide one for his instrument. The telescope should be similar to that of the spectrometer, though it need not have a micrometer eyepiece, and should be mounted on a rigid stand with adjustable feet as described in the article just quoted.

The adjustment for collimation is very simple. First one telescope and then the other is focussed on the slit of the collimator. The two telescopes are then placed in line with each other, and the cross-lines of one of them illuminated by means of a lamp placed behind the eyepiece. If on looking through the other the cross-lines of the first appear in sharp focus, the collimation is correct. If, however, the collimator was not in correct adjustment to start with, the telescopes would each be focussed for an object either within or beyond infinity. Suppose the latter, *i.e.* the telescope cross-lines, are nearer the objective than the true focus, then if the light passes in the reverse direction, rays from a point in the plane of the cross-lines will leave the objective as a divergent beam. Thus when the first telescope is employed as a collimator with respect to the second, the rays from it *diverge*, whereas the second telescope is focussed for *converging* rays, and so the cross-lines of the first are not seen in sharp focus. Half the adjustment necessary to bring them into focus should be made with *each* telescope, after which both will be correctly collimated. Either can then be directed towards the collimator and the latter adjusted to bring the slit into focus.

If the initial error of collimation is great, the process should be repeated; a very few repetitions will secure perfect adjustment.

Apart from spectroscopic work, any three telescopes or collimators can be focussed for infinity in a very short space of time by adjusting them in this way until they will focus on each other in pairs.

In the case of the spectroscope the collimation must be adjusted for the wave-length of the light with which the instrument is about to be used, since the chromatic aberration of the lenses is always appreciable near the extremities of the spectrum.

The adjustment of the optic axes of the telescope and collimator to be perpendicular to the axis of rotation of the former is also most conveniently performed with the aid of the auxiliary telescope. The method is as follows:

The rotating telescope is turned to an oblique position, such as T_1, *Fig.* 12, and a prism is set on the table and adjusted so that one of its faces reflects the light from the collimator into the telescope. It is necessary to mark the approximate centre of the slit. This is usually done by stretching a fine wire or fibre across it; but it is much better to employ two such fibres, separated by about 0·5 to 1 mm. The point half-way between these, which can be judged with ample accuracy, is taken as the centre of the slit. This obviates making settings where the slit is crossed by the fibre. The prism is levelled by means of one of the adjustment screws of the table so that the centre of the slit comes on the cross-lines of the telescope. The latter is now rotated out of the way and the auxiliary telescope, T_2, set up in its place. The latter is adjusted by means of its own levelling screws until the centre of the slit is exactly on the cross-lines. It will be clear that by this process we have placed the auxiliary telescope with its axis in exactly the same direction as that of the telescope T_1 in its initial position. The prism is now removed, and T_1 is swung into a position in line with T_2. A lamp is placed behind the eyepiece

of the latter to illuminate the cross-lines, which are then visible in the field of T_1. If the adjustment is correct, so that the axis of T_1 generates

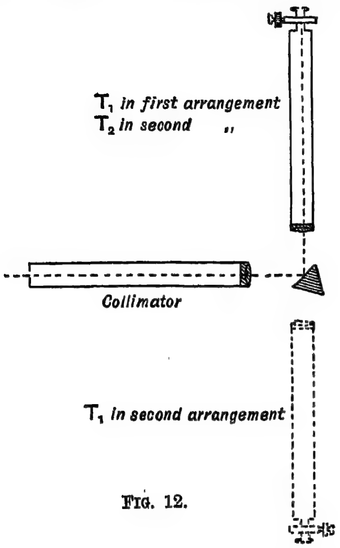

FIG. 12.

a plane on rotation, it is evident that the cross-lines of T_2 and those of T_1 itself will be at the same height in the field. But if the optic axis of T_1 is not perpendicular to the axis of rotation, it generates a cone, and in this case there is a vertical displacement between the cross-lines of T_2 and those of T_1. Obviously the angular extent of this displacement is twice the amount by which the axis of T_1 departs from perpendicularity to the axis of rotation. T_1 is therefore adjusted to reduce the vertical displacement by one-half, when its axis should be in correct adjustment. It is then brought into line with the collimator and the latter adjusted with respect to it. It is advisable to repeat the process if the initial error is large.

This method of axis adjustment can be performed quite quickly in practice, and is much less tedious and also more accurate than the customary spirit-level methods.

§ (9) THE USE OF THE SPECTROMETER FOR REFRACTOMETRY. MINIMUM DEVIATION METHOD.—The prism of which it is intended to measure the refractive index is placed on the table. Let F_1 and F_2, *Fig.* 13 (*a*), be the faces which are to be employed in the measurement; one of them, F_1, should be placed approximately perpendicular to the line *ab* joining two of the adjustment screws of the table. The telescope is put in any convenient position, say T, *Fig.* 13 (*b*), and the table rotated so that an image of the slit is seen by reflection in F_1. The centre is brought to the level of the cross-lines by the screw *a*, *Fig.* 13 (*a*). The table is then rotated until F_2 is in the position previously occupied by F_1, and the height of the image adjusted by the adjustment screw *c*. Since this does not affect the previous adjustment of F_1, both F_1 and F_2, and, therefore, also the edge in which they intersect, are now parallel to the axis of rotation. The prism is then in adjustment for making the index measurements. The minimum deviation method is carried out as follows:

The prism table is rotated so that the light transmitted by the prism is deviated to one side as in *Fig.* 13 (*c*). The table is rotated, and the image followed with the telescope until the deviation is a minimum. Many observers use special methods for determining when the deviation is a minimum; but it is quite easy to obtain the correct position without them. In case of doubt, however, the best method is to note the two positions of the table for which the deviation has a particular value just a little in excess of the minimum, and then set it half-way between these positions. If the telescope is provided with a micrometer eyepiece the best method of determining the position of the telescope is to clamp it in the approximately correct

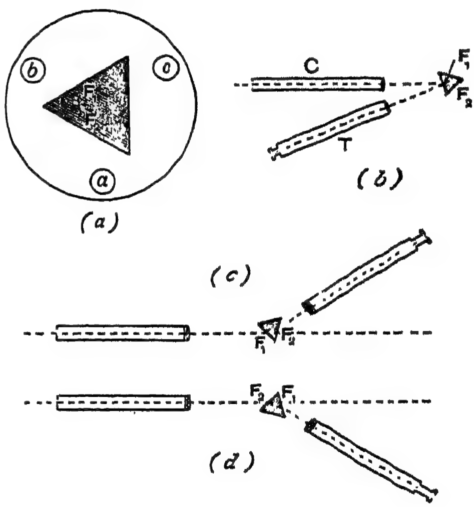

FIG. 13.

position and note the scale reading. This should be left fixed and the series of actual settings on the spectrum line made by means of the micrometer eyepiece. The individual settings will usually be of greater precision, and consequently fewer will be required to attain a given accuracy of the mean than if the telescope is moved bodily at each setting.

Having determined the direction of the refracted ray in this position, the prism table

is rotated so that the deviation is to the other side, *Fig.* 13 (*d*), and the same process of measurement is performed. The difference in the scale readings for the two cases, corrected for the difference in the micrometer means, is twice the angle of minimum deviation.

The necessity of doubling the angle by employing the two positions of *Fig.* 13 (*c*) and (*d*) arises from the difficulty of taking the zero reading with the telescope and collimator in line. These are focussed up for the wave-length of the monochromatic radiation for which the determination is being made. If a direct zero reading were attempted the light in the image of the slit would comprise all the components emitted by the source, and in general the settings could not be made without readjustment of focus.

Such, in outline, is the minimum deviation method. There are various matters of technique which must receive attention, however, if the highest accuracy is aimed at in the results.

(i.) *Position of Prism on Table.*—This must be so adjusted that in both positions, *Fig.* 13 (*c*) and (*d*), the light comes from the same area of the collimator lens and enters the same area of the telescope lens. If, for instance, the prism is arranged with its centre coincident with the axis of rotation, this condition will not be fulfilled. Thus in *Fig.* 14 the portion of the apertures used is mostly to one side of the axis in (*a*) and to the other side in (*b*). The errors which may arise from such an arrangement, on account of imperfect focussing or spherical aberration, are discussed in another article.[1] The prism must be moved towards its base so that it employs the apertures centrally, as in *Fig.* 14 (*c*). To make this adjustment, examine the exit pupil of the telescope with a magnifier. The illuminated aperture of the prism will be seen within the circular aperture of the telescope. Move the prism until its illuminated face appears symmetrical with respect to the telescope lens, taking care to keep the bisector of the refracting angle above the axis of rotation. When this is done the prism aperture will be symmetrical with respect both to the telescope and collimator axes in both positions, *Fig.* 13 (*c*) and (*d*). Needless to say, the parallelism of the refracting edge to the axis of rotation should be checked after the prism is in its final position.

(ii.) *Adjustment of the Light.*—The source of light has to be adjusted so that the aperture of the collimator is evenly filled with light. With broad sources such as flames it is sometimes good enough simply to place them at a little distance from the slit. With vacuum tubes or other small sources it is essential to form an image of the source on the slit. The source should be placed at some distance from the slit and adjusted until the rectangular

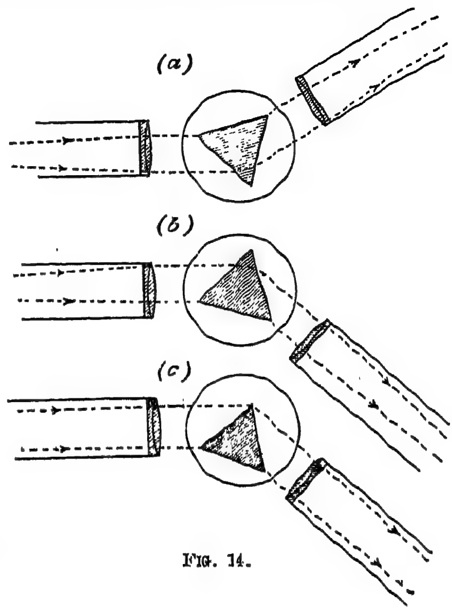

FIG. 14.

patch of light, which will be seen falling on the collimator lens, is at the centre of the latter. A lens is then interposed and adjusted until an image of the source is formed on the slit. The aperture and focal length of the lens should be such that the cone of rays which it concentrates on the slit just fills the lens of the collimator. If a wider cone is supplied some of the light is scattered from the sides of the collimator tube and may ultimately reach the field of view, adding to the stray light which is always to be found there.

(iii.) *Illumination of the Cross-lines.*—It is necessary in order to make comfortable and accurate settings that the cross-lines should be clearly seen. Further, it is necessary, particularly towards the blue end of the spectrum, to illuminate them with light of the same wave-length as the spectrum line on which measurements are being made. If this is not done very serious troubles arise, due to chromatic parallax, which make accurate settings an impossibility. The peculiarities of chromatic parallax, which arises from the chromatic aberration of the eye and the restricted size of the exit pupil of the telescope, are explained in another article.[2]

There are several methods of eliminating chromatic parallax,[3] but the most convenient for refractometric work, and in fact for any

[1] "Goniometry," § (1).

[2] "Eye, The" § (27).

[3] Guild, *Proc. Phys. Soc.*, 1917, xxix. 311.

spectroscopic work except when there are numbers of lines closely packed together, is to use a wide slit, say 1 to 2 mm., with a fibre, similar to those used for the cross-lines, stretched along its centre. Each spectrum line then gives rise to a band of light with a black line down the middle. The band serves as a background for the cross-lines, and settings are made on the central line. Suitable fibres of quartz or glass can be mounted on large washers, together with a horizontal pair to mark the centre of the slit, and protected with microscope cover glasses. These can then be affixed in front of any spectroscope slit with wax. It will be found useful to prepare a number of such fibres of varying thickness, say from 5 to 10 thousandths of a millimetre, and employ that which gives the greatest comfort under the circumstances of the observation. The collimation has of course to be adjusted with the fibre in position.

This arrangement has several advantages in addition to the elimination of chromatic parallax. Every worker with a spectroscope has realised the difficulties of setting cross-wires accurately on a fine spectrum line. Even when the general field illumination is satisfactory and the cross-lines are distinctly visible there is an annoying uncertainty as to the exact point of superposition. Diffraction effects make themselves evident in a wavering and loss of definition at the point of intersection, which is very trying. With the arrangement described there are no such effects at the moment of contact. Everything appears as distinct and clear as if it were a diagram drawn on paper. Secondly, the tiresome fluctuations of accommodation, to which the eye is subject when using faintly illuminated cross-lines, are practically absent. Thirdly, the full brightness of the line is utilised. With a fine spectrum line the field illumination has to be low enough to give a satisfactory contrast. With faint lines this involves working at illuminations for which the acuity of vision is not great. With the wide slit method the full brightness of the line is utilised as background for the cross-lines, so that the maximum use is made of the available light.

The method can be used with advantage for all cases in which there are not several lines packed close together. With sodium light, for instance, the slit images for D_1 and D_2 are superposed, but the central line of each is quite clearly defined. It is only when the bands of *several* close lines overlap that the individual images of the fibre become difficult to see.

(iv.) *Elimination of Scale Errors.*—When determining the scale reading by means of the micrometer microscopes, settings should be made on several consecutive rulings. This tends to reduce errors due to local irregularities. To eliminate progressive errors of ruling it is necessary to repeat the whole determination, say half-a-dozen times, with the scale shifted through about 60° in relation to the microscopes each time.

(v.) *Careful Manipulation.*—In general the greatest care in handling the instrument in the course of a series of observations is essential. No spectrometer will give consistent readings if subjected to strains and flexures. In particular the rotation of the telescope from one position to another must be made slowly and with the careful avoidance of sudden accelerations; and the manipulation of the micrometer eyepiece must be performed without any tendency to push or pull the eyepiece in the direction of measurement.

§ (10) CRITICAL ANGLE METHOD.—The essential condition for this method is that a converging beam of light should fall tangentially on one face of the prism, *Fig.* 15. The

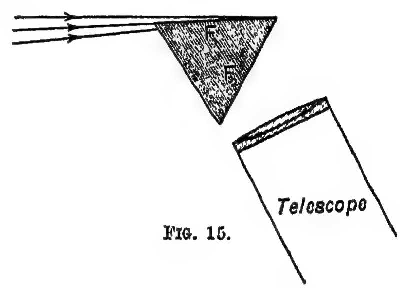

FIG. 15.

rays are refracted into the prism and fall obliquely on the second face, at which they are refracted into the air and may be received by a telescope suitably placed. It is clear that all rays which have the same angle of incidence will be deviated equally by the prism and will combine in the focal plane of the telescope to form a fine line parallel to the refracting edge of the prism. Actually the line will be slightly curved (as in the case of the image of a slit) on account of the fact that the deviation for rays which are inclined to the principal plane of the prism is greater than for rays in the principal plane. In practice, if the adjustments of the prism have been properly carried out, we are only concerned with rays in the principal plane.

We have, then, a fine line in the field of the telescope corresponding to each angle of incidence present in the converging beam. The resulting effect will be a band of light. It is evident that the incidence angle is sharply delimited at 90°, when the rays are just grazing. There are therefore no rays for which the angle of refraction is greater than for those at grazing incidence, and the band of

light in the telescope must terminate abruptly at the line corresponding to these rays. Thus the band will have a sharp edge; and if the cross-lines are set on this edge the inclination of the telescope axis to the normal of the face F_2 will be the angle of emergence, e, in the formulae which were developed in § (2) for the case of grazing incidence.

To make a determination by this method, the prism is mounted on the spectrometer table and levelled as described in the preceding paragraph. The source S is placed in line with one of the faces, *Fig.* 16 (*a*), and a lens L inserted to produce a converging beam. The distances of S and L should be such that an image of S is formed about an inch or so beyond the prism.

The telescope is rotated until the critical edge is on the cross-lines and a series of settings made. As in the case of minimum deviation, it is preferable to make these settings with the micrometer eyepiece, leaving the telescope clamped in one position throughout.

Having determined the reading for the critical edge in the position shown, the source and lens are shifted to S′ and L′ so as to bring the illumination from the other side of the prism. The telescope has then to be moved to the dotted position and the settings repeated. If ϕ is the angle between the two positions of the telescope, and e is the angle of emergence (the sign of e being given in accordance with the convention adopted in § (2)),

$$2e = \phi + \hat{C} - 180^\circ.$$

It has to be noted that the angle of emergence in the first position corresponds to a refracting angle $\hat{A}$, while in the second position the refracting angle is $\hat{B}$. If these differ the angles of emergence are not equal in the two cases. However, if they do not differ greatly, the value of e given by $\frac{1}{2}(\phi + \hat{C} - 180^\circ)$ will correspond to the mean of the angles $\hat{A}$ and $\hat{B}$. Clearly, if the measurements are made with the light incident on each of the faces in turn, giving three nearly equal values, ϕ', ϕ'', ϕ''', for the rotation of the telescope, we can put $e = \frac{1}{2}\{(\phi' + \phi'' + \phi''')/3 + 60^\circ - 180^\circ\}$; and the value of e so obtained will correspond to a prism angle of exactly 60° (assuming no pyramidal error).

The order of magnitude of ϕ is about 60°, more or less. This method, therefore, involves the measurement of a fairly large angle. An alternative arrangement, which only involves measuring a small angle, is shown in *Fig* 16 (*b*). It requires the use of the additional telescope on a separate stand, to which reference has already been made (§ (8), p. 765). The light is incident along the two faces which contain the refracting angle. The telescope T_1 is rotated so as to receive one of the emergent beams. The auxiliary telescope T_2 is placed so as to receive the other. The method of making the measurement is as

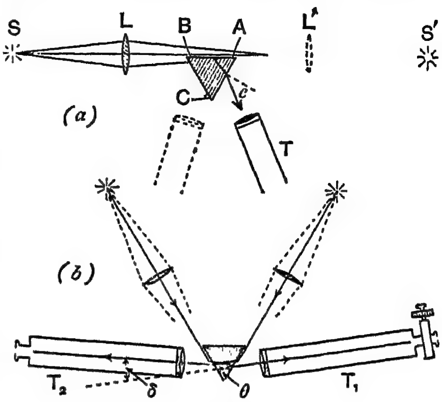

FIG. 16.

follows: The critical edge in the field of the fixed telescope T_2 is brought on the cross-lines by means of the tangent screw which rotates the table; then the telescope T_1 (or its micrometer eyepiece) is adjusted so that its cross-lines are set on the other critical edge. *Both* settings should be repeated several times, the telescope reading being noted each time. If δ is the angle between the axes of the two telescopes when they are both correctly set on the respective critical edges, $2e = \delta - \theta$. If the process is repeated with each angle of the prism in turn, giving three nearly equal values, δ', δ'', δ''', then $2e = (\delta' + \delta'' + \delta''')/3 - 60^\circ$, where e is the angle of emergence corresponding to a prism angle of 60°.

To measure δ we illuminate the cross-lines of T_2 and treat it as a collimator with respect to T_1, which should be rotated until the two sets of cross-lines coincide. The angle through which it has to be moved is the angle δ.

In order that all the observations may be made without removing the prism from the table, it is convenient to arrange the height of the latter (or of the telescopes, if this is more convenient) so that the lower half of the telescope objectives are utilised for the critical angle measurements, while the upper half are above the level of the prism top and are available for the collinear measurements.

As regards the latter there are one or two precautions to be observed. In the first place, it is not satisfactory to attempt to set the two cross-lines in exact coincidence. Such a setting is very insensitive. The telescope axes should be very slightly out of line in the *vertical* direction, so that one cross is a little above or below the other. Then when the axes are in line horizontally the two sets

of wires form a small symmetrical rhomboid. If a suitable vertical displacement is chosen, this rhomboidal setting can be made with great precision. In repeating the determinations *ab initio*, the cross-lines, which in the first case were lower, should be the higher next time, and so on. In this way any error due to want of exact parallelism of the two sets of wires is eliminated, and a true setting corresponding to exact coincidence of the axes is secured.

As in the case of the minimum deviation method, the final accuracy of the result depends on the care with which the manipulation is performed, and on the arrangement of the apparatus so that the processes involved in the actual measurements are rendered as few and as simple as possible. In the critical angle method the success or failure largely depends on the illumination arrangements. If these are satisfactory the method is easy and accurate; but if they are otherwise, as may very easily be the case, or if they require readjustment in the course of a determination, the greatest trouble may be encountered. It is undesirable, for instance, to have to shift the source so as to illuminate first one face of the prism and then the other. Two sources must be set up to begin with; or, what is better still, an arrangement should be adopted by which one source may be employed to illuminate both faces simultaneously.

A convenient and easily constructed illuminator for this purpose is shown in plan in *Fig.* 17. D is a hole of about 3 mm. diameter a little outside the focus of a condensing lens L. The source, if it has appreciable width, is placed behind D, or an image of it is formed at D by another lens, as if D were the slit of a spectroscope. The light leaves the lens L in a slightly converging beam. It then meets a 60° prism, which should be of clear colourless glass polished on all three sides, but which need not otherwise be of good quality. This splits the beam, by internal reflection, into two beams which emerge in the directions shown. These beams, when they have separated to an extent of 15 cm. or so, meet a pair of right-angled prisms so placed as to make them reconverge at an angle of 60°. The various parts can be mounted permanently on a single stand. The supports of the right-angled prisms should be capable of rotation, as this facilitates adjustment.

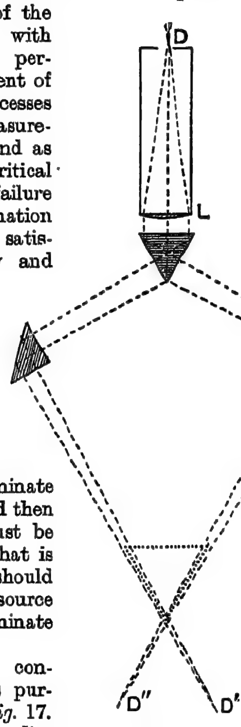

FIG. 17.

The illuminator is so placed in relation to the spectrometer that the prism under test occupies the position which is shown dotted in the figure.[1] The lens L should have a power of about 10 diopters, and the distance of D from it should be such that images of D are formed at D′ and D″, about two inches beyond the apex of the prism. When the illuminator has been placed approximately in the correct position, a slight rotation of the right-angled prisms will usually be sufficient to give satisfactory bands with sharply defined edges.

If the source is rich in light of other wave-lengths than that for which the measurement is being made, stray light of these wave-lengths almost always appears in the field, and may give rise to chromatic parallax troubles. To overcome this difficulty filters must be used in front of D to cut out or reduce the objectionable rays.

In determining δ, the suitable illumination of the cross-lines of T_2 may present some difficulty. It is evident that when the telescopes are sharply focussed on the critical edge of the refracted beams they are collimated for the wave-length of the light employed. In the presence of the usual amounts of chromatic aberration, they will not be in correct focus for other wave-lengths. If the refracted light is in the yellow or green part of the spectrum it will generally be quite satisfactory to put a table lamp behind the eyepiece of T_2 with, possibly, the interposition of a colour filter to approximate the colour to that for which the telescopes are focussed. If, however, the refracted light is not near the middle of the spectrum it is not usually possible to get sharp enough focus with colour filters, and it is necessary to employ light of the wave-length for which the index determination is being made. An arrangement which proves convenient, except with faint lines, is to mount a small mirror close up to the eyepiece of T_2 and adjust it so that it sends the refracted light which emerges from the eyepiece back into it to illuminate the cross-lines. This adjustment has to be made with some nicety,

[1] Particulars of this method are given in a paper by Guild and Dale, *Trans. Optical Soc.*, 1920, xxii. pt. 3.

so it is expedient to mount the mirror on the end of a lever, pivoted on a suitable stand. It can then be swung out of position when it is desired to look into the eyepiece of T_2, and swung back to position for the collinear measurement, without upsetting its adjustment. In this way the difficulty of securing light of the same wave-length for all the measurements involved can be overcome.

Special Case of $\mu = 1{\cdot}53$.—From equation (4), § (2), if $\mu_2 = 1{\cdot}528$ the emergent angle is $-30°$, and the two critical rays are collinear, provided $\theta = 60°$ exactly. Thus for indices near this value δ is very small, and can be measured on the micrometer eyepiece without rotation of the telescope at all. For such indices we thus have a useful check on the accuracy of more general methods; since we eliminate completely the axis of the instrument and any undetected peculiarities it may possess.

It is this feature of the method which invests it with importance in precise refractometry. It is not in itself quite so easy to perform as the minimum deviation method, and is not suitable at all except for bright spectrum lines; but the fact that it can be made to involve only very small rotations of the telescope or, in a particular case, no rotation at all, makes it highly useful as a check to be used in conjunction with other methods which depend for their accuracy on the accurate measurement of comparatively large rotations.

It is desirable therefore to investigate the errors to which the results may be liable on account of the unsymmetrical nature of the setting. There are two points which require attention. In the first place, on account of the phenomenon of irradiation, the bright area will encroach on the dark area and the edge will be displaced on this account. The magnitude of this error can easily be determined experimentally. As the observer should always determine it for himself with the telescope to be used for the measurement, a method of doing so may be described.

A prism P, *Fig.* 18, is placed at the focus of a long focus telescope objective L with one of its faces approximately at 45° to the axis. A glass plate A is placed a little behind the prism, also inclined at 45° to the axis. A source of light S_1 and a sheet of ground glass G_1 are placed so as to illuminate the face of the prism, and a second source S_2 and ground glass G_2 are placed where they will illuminate the plate A. The observing telescope is placed at T and focussed sharply on the edge E of the prism. If S_1 is turned on and S_2 is off, the field will be bright on one side of E and dark on the other; while if S_2 is on and S_1 is off, the bright and dark sides are reversed. If, then, the cross-lines are set on the edge when first one side and then the other is bright, the difference in the micrometer readings will be twice the error due to irradiation. When such measurements are made it is found that the error amounts to about 40 seconds divided by the magnification of the telescope. Thus for a telescope of power 20 the error is only about 2″. Further, this is found to be independent of the brightness over a very wide range, and also of the colour. Thus one may find very precisely the correction to be applied to critical angle readings on account of irradiation. It will be clear, of course, that this correction includes any other "personal equation" error which may influence the setting in addition to irradiation.

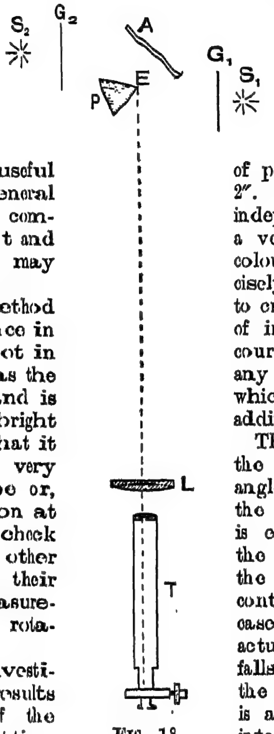

FIG. 18.

There is one particular in which the conditions in the actual critical angle setting differ from those in the arrangement just described. It is evident that in the latter case the intensity is uniform right up to the edge, and that a sudden discontinuity occurs there. In the case of the critical edge there is no actual discontinuity. The intensity falls off more and more rapidly as the critical angle is approached, and is actually zero at that point. The intensity curve can be calculated from Fresnel's equations for refraction and reflection, correction being made for the fact that the rays in the refracted beam are compressed more and more closely as the critical angle is approached. These curves have been calculated by Kruess,[1] and in *Fig.* 19, the intensity curve for a band 1° wide is given for $\mu = 1{\cdot}6$, and $\mu = 1{\cdot}05$. What will the eye adopt as the "edge" of such a band? There is reason for believing that the "edge" will be that part at which the intensity is diminishing most rapidly. While it is not evident from *Fig.* 19, on account of the scale on which it is drawn, the slope of the intensity curve increases continuously

[1] Hugo Kruess, *Zeit. f. Instk.* xxxix., March 1919, p. 73.

up to the critical angle, and is therefore greatest at this point. Therefore, if the above supposition is correct, the same setting should be made as if the brightness were uniform up to the edge and suddenly dropped to zero.

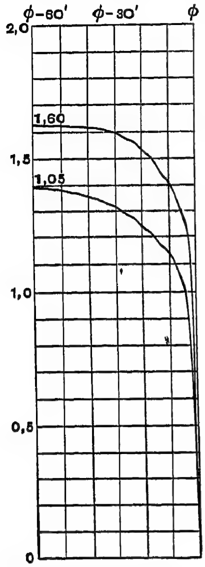

FIG. 19.—Intensity in neighbourhood of Critical Angle. ϕ=Critical Angle.

That this somewhat unexpected result is correct to a high order of accuracy has been demonstrated experimentally.[1] Consequently the critical angle setting only requires the easily determined correction, mentioned above, for irradiation and personal equation. The results of the method may therefore be employed with confidence for comparison with those obtained by the minimum deviation method.

III. REFRACTOMETERS

§ (11).—The methods which have been described in some detail in the preceding paragraphs are those suitable for the most precise absolute determinations. They involve a considerable amount of time to carry out completely, and also require carefully worked prisms of fairly large dimensions. They are even more troublesome when applied to the case of liquids; as the liquid has to be contained in a hollow prism, built up of accurately plane parallel pieces of glass, which has frequently to be taken to pieces for thorough cleaning.

There is a large amount of refractometry, which has to be done in connection with various industries, for which the very highest accuracy is not demanded, and for which the time and trouble involved in such determinations would be unjustifiably expensive. For such purposes a number of instruments have been devised, most of which are largely empirical in their results, but which are very rapid in use, and require a minimum of material and labour for the preparation of the necessary specimens.

§ (12) ABBÉ'S AUTOCOLLIMATION SPECTROSCOPE.—This instrument employs a modification of the minimum deviation method in which the telescope also serves as collimator. In the upper half of the focal plane of the eyepiece is a slit. The light enters by a hole in the side of the tube and is reflected through the slit by a small 45° prism. In the lower half of the field is a sharp pointer. The prism employed for the test is cut with an angle of 30°. The prism table is rotated until the light refracted at the first face of the prism meets the second face normally, and is returned along its path to form an image of the slit in the focal plane of the telescope. When this image coincides with the pointer, the normality of the beam to the second face of the prism is exact.

The angle of refraction is then equal to the angle of the prism. The angle of incidence, i, is found by rotating the telescope until it is normal to the first face of the prism, and the refractive index is obtained from the formula

$$\mu=\frac{\sin i}{\sin \theta}.$$

The method is not very convenient for accurate determinations of the refractive index, since the value of θ must be determined; but it gives quite accurate values for the dispersion. It has the advantage for commercial work of requiring only half as much glass as a 60° prism, but has the disadvantage over some of the empirical refractometers, described later, of requiring two first-class surfaces instead of only one.

§ (13) PULFRICH REFRACTOMETER.[2]—This employs the *Wollaston* method discussed theoretically in §§ (2) to (5). The main feature of the instrument is a block, A, *Fig.* 20, with one polished face horizontal and another vertical. The substance whose index it is desired to determine is placed in contact with the horizontal surface and a convergent beam of monochromatic light, L, is directed along the interface. In *Fig.* 20 (*a*) the arrangement employed for liquids is illustrated. A circular glass tube, C, is cemented to the block with a cement or wax which is not soluble in the liquid to be examined, some of which is poured into the cell thus formed. A portion of the incident light is refracted from the liquid into the block, ultimately emerging from the vertical face into the air, and is received by a telescope. As in the case of the critical angle method for determining the index of the prism itself, a band of light is produced in the field of view which has a sharp edge corresponding to the direction of emergence of a ray incident at grazing incidence on the first face. The angle of emergence, e, which this ray makes with the normal to the vertical face of the block is determined. In order to set the telescope normal to the face of the

[1] Guild and Dale, *Trans. Optical Soc.*, 1920, xxii. 13.

[2] C. Pulfrich, *Zeits. Instrumentenk.*, 1888, viii. 47; and 1895, xv. 389.

block it is provided with an autocollimating device, consisting of a small 45° prism fixed behind a portion of the cross-lines. This prism can be illuminated by a lamp placed to the side of the instrument. When the telescope is approximately normal to the face

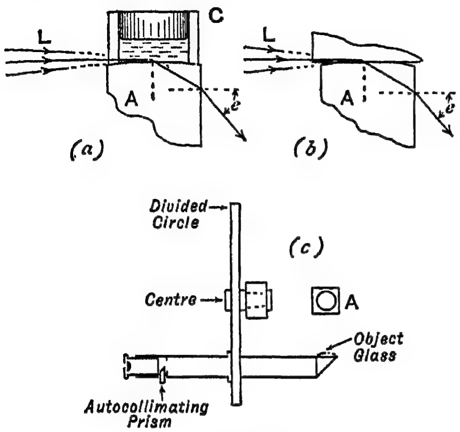

FIG. 20.

of the block a reflected image of the illuminated face of the little prism is seen at the side of the field opposite to the prism itself. It is crossed by images of the parts of the cross-lines which are in front of the prism. When the actual cross-lines are brought into coincidence with those images the axis of the telescope is normal to the face of the block.

To avoid having to place the head in inconvenient positions, the telescope is constructed as in *Fig.* 20 (*c*), with a right-angled prism behind the object glass, so that the main body of the telescope is always horizontal.

The circle is usually divided so as to read to minutes by means of a vernier. It is provided with a radius arm and micrometer tangent screw by means of which it may be moved through a range of 5° or 6°, for which readings can be taken on the drum of the tangent screw to 0·1 minute. Thus the actual values of e can be determined to about 1 minute, which, from the curves of *Fig.* 4, corresponds roughly to 1 unit in the fourth decimal place, whereas the differences of readings within the range of the tangent screw may be accurate to 0·1 minute, corresponding to about 1 unit in the fifth place. The quantities usually wanted in practice are the refractive index for some wave-length near the brightest part of the spectrum and the dispersion, *i.e.* the differences in refractive index for a series of lines spread throughout the spectrum. The lines almost universally used are C, D, F, and G′, the first, third, and fourth being obtained from the vacuum tube spectrum of hydrogen, and the second being the well-known sodium line. The procedure usually followed is to bring the tangent screw to the beginning of its range, and rotate the telescope so as to bring whichever of these lines corresponds to the smallest value of e, usually C, to the middle of the field. The circle is then clamped to the radius arm and the settings on the various bands made by means of the tangent screw. By noting the circle reading which corresponds to some reading on the tangent screw, and correcting for the reading which corresponds to the normal ($e=0$), the values of e for the various lines will be obtained correct to 1 minute, but mutually consistent to a much higher degree.

For determining the indices of solids, the arrangement of *Fig.* 20 (*b*) is employed. The specimen requires to have two polished faces, one of them two to three cm. long and accurately flat. The other, which should be approximately at right angles to the first, need only be a few millimetres deep, and its quality is immaterial provided it intersects the first surface in a clean sharp edge without trace of bevel.

In order to obtain optical contact, so that refraction from the specimen to the block may occur, it is necessary to interpose a film of liquid of higher refractive index than the specimen. If the film is parallel-sided—which can always be secured by examining the interference bands at the interface—the presence of the film does not affect the ultimate direction of the rays, which is the same as if the specimen were in optical contact with the block.

For this refractometer, in which the angle of the block A is 90°, equation (6), § (2), becomes

$$\mu_1^2 = \mu_2^2 - \sin^2 e.$$

For convenience in computation the instruments are usually supplied with tables giving the indices corresponding to values of e, increasing by intervals of 10 minutes, for each of the lines C, D, F, and G′. The values for intermediate angles are obtained by proportionate interpolation.

Unfortunately such tables as issued are rarely sufficiently accurate for any but the roughest approximation. The actual angle of the block usually departs appreciably from 90°; and the values adopted for the indices of the block are those determined for a specimen of the melting used for a number of blocks, and may differ considerably from those actually possessed by any one of them.

The angle should always be measured, and the true indices of the block deduced from careful determinations with a substance whose indices have been determined by an accurate absolute method; or, if this is not available, with a specimen of quartz, for which the

values are reasonably well established. Having obtained this information a new set of tables can be computed; but it is much simpler to employ the erroneous tables and apply corrections.

For instance, suppose the angle of the prism is $90° - \delta\theta$, where $\delta\theta$ is a small quantity.

$$\mu_1 = \bar{\mu}_1 - \frac{\delta\theta}{T_\theta}$$

$$= \bar{\mu}_1 - \frac{\delta\theta \sqrt{\mu_2^2 - \mu_1^2}}{2{\cdot}06} \text{ (from 13),}$$

where $\bar{\mu}_1$ is the value given by the tables. The tabulated value, $\bar{\mu}_1$, has to be diminished to give the true value if the angle of the block is less than 90°, and increased if the angle is greater than 90°. The correction can be calculated for a series of values of $\bar{\mu}_1$, say 1·5, 1·55, 1·6, 1·65, etc. It will not be necessary to tabulate it for smaller intervals unless the error in angle is unusually large.

A similar small correction can be applied to the tables for errors in the assumed values of μ_2. This of course has to be done for each wave-length. Let $\bar{\mu}_2$ be the assumed value used in computing the tables, and μ_2 the true value. Also let $\bar{\mu}_1$ be the value of the index under test as given by the tables, and μ_1 the true value.

$$\mu_1 = \bar{\mu}_1 - \frac{\partial\mu_1}{\partial\mu_2}(\bar{\mu}_2 - \mu_2)$$

$$= \bar{\mu}_1 - \frac{\mu_2}{\mu_1}(\bar{\mu}_2 - \mu_2).$$

This correction can also be tabulated for a series of values of $\bar{\mu}_1$ for each wave-length. If there is also an error in the angle of the block, the two corrections, being small, can be obtained separately as above and added to give a single correction.

The total correction for values of $\bar{\mu}_1$ increasing by intervals of ·01 can be got out in a comparatively short time. The corrections should be computed to the sixth decimal place to prevent accumulations of small errors mounting up to 1 in the fifth place.[1]

§ (14) THE ABBÉ REFRACTOMETER. — This instrument is of lower accuracy than the Pulfrich refractometer and gives results which are only reliable to a few units in the fourth decimal place.

The essential parts of the instrument are shown diagrammatically in *Fig.* 21, the arrangement of parts being that followed in the instrument made by Bellingham and Stanley of London, which has various advantages over the Zeiss model. P_1 and P_2 are two prisms of dense glass. Surfaces 1, 3, and 4 are polished; surface 2 is matt. The prism P_1 is hinged at H, so that it can be swung away from P_2 and removed altogether if desired.

In determining the index of a liquid, a drop of the latter is placed on surface 2, which is then closed up into contact with surface 3, the liquid being squeezed out into a thin film. Light from a suitable source is directed towards the prism system by a mirror M. It

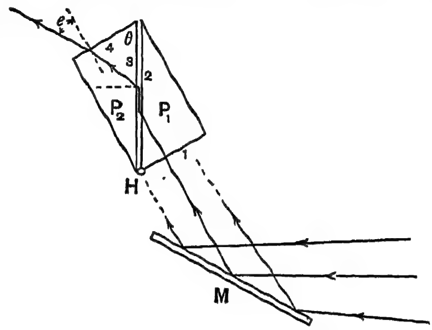

FIG. 21.

strikes the matt surface 2, and is scattered into the liquid film and the prism P_2. Since no ray can enter P_2 with a greater angle of refraction than that of the ray at grazing incidence, the emergent rays when collected by a telescope will all converge to points on one side of a line in the focal plane. The field will therefore be divided into dark and light portions, the edge of the bright portion corresponding to the value of e for the critical rays, as in the similar cases previously discussed.

The rotation of the telescope is registered on a graduated arc which reads refractive index directly. In practice the instrument is used with white light. To compensate for the dispersion of the system, and at the same time get a rough measure of the dispersion of the substance under test, the ingenious device is adopted of introducing a reverse dispersion by means of two direct vision prisms. These are mounted one above the other in front of the object glass of the telescope, and are geared so that by turning a milled head they may be rotated in opposite directions. They are so oriented to start with that their planes of dispersion are parallel to each other and to the principal plane of the prism P_2, their dispersions being additive. If k is the angular dispersion of one of the prisms between the C and F lines, the total dispersion in this position is $2k$. If now the prisms are rotated at equal rates in opposite directions, the resultant dispersion is still parallel to the principal plane of P_2, but is diminished. For any orientation, ϕ, from the initial position the resultant dispersion is $2k\cos\phi$. When ϕ is 90° the dispersion due to the prisms is zero, and when ϕ exceeds 90° it changes sign, and increases to $2k$ in the reverse direction.

In using the instrument the critical edge as

[1] For a discussion of the possibilities of the Pulfrich Refractometer and the limitations of existing patterns of the instrument, see Guild, *Proc. Phys. Soc.* xxx. part 111, p. 157.

first observed will probably be spread out into a short spectrum. The compensating prisms are rotated until the colour disappears and a sharp achromatised edge is obtained. The cross-lines are set on this edge; the reading on the arc then gives the index for sodium light. The orientation of the compensating prisms gives, by reference to a set of tables supplied with the instrument, a rough value of the dispersion, from C to F, of the substance under test.

To use the Abbé refractometer to determine the indices of solids, the prism P is removed, and a specimen similar to that employed with the Pulfrich refractometer placed against face 3, optical contact being obtained by a film of liquid, as described in connection with the latter instrument.

§ (15) ABBÉ'S CRYSTAL REFRACTOMETER.[1]—This instrument is designed for the convenient examination of crystals in different orientations. The block is in this case hemispherical, *Fig.* 22, and is fitted with a cell to contain

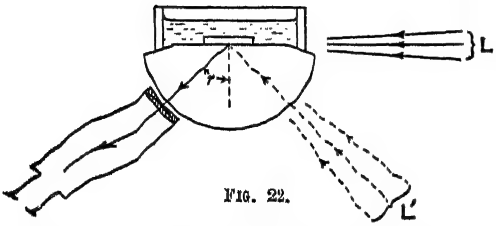

FIG. 22.

liquids. The crystal specimen is placed on the surface, immersed in a liquid of higher refractive index. The axis of rotation of the telescope passes through the centre of the hemisphere, so that the optic axis is always normal to the latter. The front surface of the object glass is close to the hemisphere and parallel to it, thereby neutralising the effect of the curvature of the block on the focus of the emergent beam. There is evidently no deviation of the beam on leaving the block, so that when the telescope is set on the critical edge it measures r, the angle of refraction of the critical ray into the block. The index of the specimen, $\mu_1 = \mu_2 \sin r$.

It is possible to rotate the hemisphere about a vertical axis, thereby altering the orientation of the crystal with respect to the direction of the light. The illumination may either be supplied at grazing incidence, as in the Pulfrich refractometer, or the beam may be incident from within the glass as shown dotted at L′. In the latter case the critical edge divides the field into regions of total and partial reflection, the critical direction being the same as for grazing incidence. The arrangement is advantageous with specimens whose edges are irregular or not approximately perpendicular to the face in contact with the block of the instrument; but the edge is not so sharp nor the contrast so good as with grazing incidence. In order to pass readily from one method of illumination to the other, the source is mounted in line with the axis of rotation of the telescope, the light being reflected in the direction L or L′ by a mirror mounted on an arm which rotates about the same axis. Thus, by swinging the mirror, the light can quickly be adjusted for either type of illumination.

[1] See S. Czapski, *Zeits. f. Instrumentk.*, 1890, x. 246, and Feussner, *Zeits. f. Instrumentk.*, 1894, xiv. 87.

§ (16) THE DIPPING REFRACTOMETER.—This instrument is designed for the refractometry of liquids available in fairly large quantities. It is only suitable for use over a small range of index and is therefore mainly used for special purposes, such as the estimation of alcohol, wines and beers, sea and mineral waters, etc. The principle of the apparatus will be clear from *Fig.* 23. P is a cylinder of glass on which a plane surface inclined at about 30° to the axis has been ground and polished. The end of the instrument is immersed in the liquid, which is contained in a vessel with a glass side so that light reflected from a diffusing reflector, R, may enter the vessel. The critical edge is viewed in the focal plane of the eyepiece, in which there is also a scale divided to read refractive indices directly. A is a direct vision prism which compensates the

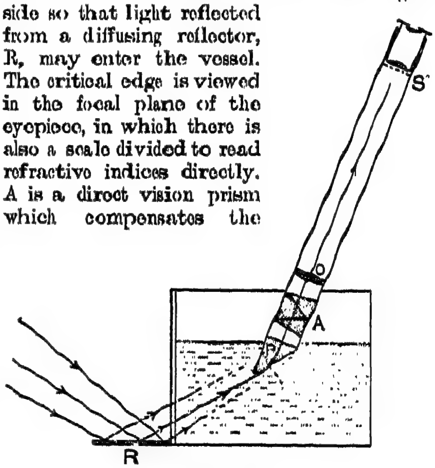

FIG. 23.

dispersion and ensures a sharp achromatic edge. The instrument is usually supplied with several nose-pieces of different glass to render it suitable for different ranges. The most usual range is 1·325 to 1·365.

IV. EFFECTS OF TEMPERATURE AND PRESSURE

§ (17). In the preceding paragraphs we have concerned ourselves with the methods of determining refractive indices as accurately as possible, *under the circumstances which prevail during the determination*. For the results to

be of value it is necessary to state them in such a form that they can be compared with those made under other conditions. In the first place, the quantity measured by all the methods employed in practice is the *relative* index, *i.e.* the absolute index of the substance with respect to vacuum divided by the refractive index of air. If $\bar{\mu}$ is the absolute index and μ the observed index, $\bar{\mu}=\mu n$, where n is the refractive index of the air during the observation. Both $\bar{\mu}$ and n are affected by temperature, and n is also affected by pressure. An observed value of μ is therefore only correct for the particular temperature and pressure for which the determination was made.

As regards the variation of $\bar{\mu}$, this may be taken as linear over the usual range of laboratory temperatures, so that $\bar{\mu}_t=\bar{\mu}_{t'}+\mu a(t-t')$, where a is the temperature coefficient of absolute index, and is taken as positive when the index increases with temperature.

The variation of n with temperature and pressure follows Gladstone and Dale's law that $n-1$ is proportional to the density of the gas. Thus

$$n_t^p-1=\left(n_0^{760}-1\right)\frac{p}{760}\cdot\frac{273}{273+t}$$

$$=\beta\left(1+\frac{\delta}{760}\right)\left(1-\frac{t}{273}\right)=\beta+\beta\frac{\delta}{760}-\beta\frac{t}{273},$$

where $1+\beta$ is the refractive index of air at 0° C. and 760 mm. pressure, and δ is the *excess* of pressure above 760 millimetres.

Let μ_t^δ be the observed relative index at t° C. and $760+\delta$ mm. pressure, then

$$\bar{\mu}_t=\mu_t^\delta n_t^\delta=\mu_t^\delta\,(1+n_t^\delta-1)$$

$$=\mu_t^\delta+\mu\beta+\mu\beta\,\frac{\delta}{760}-\mu\beta\frac{t}{273}. \quad \text{(i.)}$$

This gives $\bar{\mu}_t$ in terms of the observed relative index. Similarly, for observations at any other temperature and pressure,

$$\bar{\mu}_{t'}=\mu_{t'}^{\delta'}+\mu\beta+\mu\beta\,\frac{\delta'}{760}-\mu\beta\,\frac{t'}{273}. \quad \text{(ii.)}$$

Subtracting (ii.) from (i.) and rearranging, we get

$$\mu_{t'}^{\delta'}=\mu_t^\delta+\mu\beta\frac{\delta-\delta'}{760}-\mu(t-t')\left(a+\frac{\beta}{273}\right). \quad \text{(iii.)}$$

Equation (iii.) gives the relative index at any temperature and pressure in terms of the relative index at the temperature and pressure of the observation. It is evident that the temperature coefficient of the *relative* index is $a+\beta/273$.

These relationships enable us to express a result either as *absolute* index at a standard temperature, or as *relative* index at a standard temperature and pressure. The most useful in practice is the latter, and, where possible, results should be expressed for a temperature of 17° C. and a pressure of 760 mm.

The values of β can be obtained from the results of Kayser and Runge,[1] Scheel,[2] and others. Kayser and Runge's formula for *damp* air at 0° C. and 760 mm. pressure is

$$\beta=10^{-7}\left(2878\cdot7+13\cdot16\frac{1}{\lambda^2}+0\cdot316\frac{1}{\lambda^4}\right),$$

where λ is the wave-length of the light. For dry air 3×10^{-7} should be added. This difference is negligible for our present purpose. The following table gives the indices for dry air for various spectrum lines:

Designation in Solar Spectrum.	Approximate λ.	β.
A	7590 AU.	·0002905
B	6870 „	·0002911
C	6560 „	2914
D	5890 „	2922
E	5270 „	2933
F	4860 „	2943
G	4310 „	2962
H	3970 „	2978

From these figures the reduction of the results to standard pressure can always be performed; and, if a is known, the reduction from one temperature to another. The coefficients both of absolute and relative index are given for a typical series of optical glasses in Hovestadt's "Jenaer Glas." For the ordinary flint glasses a varies fairly regularly with μ, and the value for any glass of this type can be found sufficiently accurately for correction purposes by interpolation. For the more complex glasses, however, the data are insufficient for interpolation, except for glasses which are very near one of the type glasses, and it may be necessary to determine a. In doing this it is safest to avoid attempts to heat the prism. It is very difficult to obtain reliable results in this way. In most laboratories there is some room or rooms of which the temperature can be varied over a range of at least 10° C., so that measurements can be made, with the whole apparatus at a uniform temperature, over a sufficient range to give the necessary accuracy in a for correcting over a smaller range.

V. Special Varieties of Spectroscopes

§ (18). The type of spectrometer discussed in § (6) is really in principle the simplest and earliest form of spectroscope, elaborated in mechanical detail so as to enable the measure-

[1] *Abhandl. d. Berl. Akad. Wiss.*, 1893.
[2] *Berl. Verh. d. Physik. Ges.*, 1907, ix.

ments involved in refractometry and goniometry to be made with the utmost accuracy. Except for these specific purposes, however, such an instrument would rarely be used. It would find no place, for instance, in the equipment of a modern spectroscopic laboratory, where the primary object of the work is the identification and accurate measurement of wave-lengths. Such determinations are always made by interpolation between adjacent lines of known wave-length, and the spectroscopist is never concerned with any but quite small angular measurements. This being so, the instrumental requirements are somewhat different. Not only so, but the development of photographic methods has practically ousted the spectro*scope* as an instrument of spectroscopic research.

Thus the beautifully designed instruments, with long trains of prisms intended to give very high resolving power, which were formerly features of spectroscopic laboratories, are now rarely if ever employed; they are replaced by spectrographs, which not only are capable of greater accuracy, but have the inestimable advantage of giving permanent records of the observations. The visual spectroscope is only used for the identification of simple known spectra, or for other work for which great accuracy is not required. The special needs of the spectroscopic laboratory are beyond the purview of this article, which deals primarily with the requirements of the "applied" rather than the "pure" physicist; but a certain amount of spectroscopic equipment, suitable for general work, is essential in an optical laboratory.

§ (19) The Direct Vision Spectroscope.—This instrument, which is suitable for the examination of light sources to ascertain the general nature of their spectra, has all its parts mounted in one straight tube, and is therefore easily directed to the light when simply held to the eye. Its essential element is a compound prism, P (*Fig.* 24), which consists of a

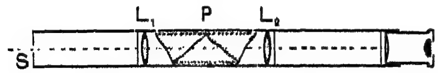

Fig. 24.

prism of dense flint glass cemented with Canada balsam between two prisms of crown glass. The refractive index of the denser glass will be about 15 per cent greater than that of the other, but its dispersion may be twice as great. Consequently, if the prisms be cut to such angles that the total deviation for, say, the sodium light is zero, rays at the blue end of the spectrum will be deviated towards the base of the dense prism, and those at the red end will be deviated in the opposite direction, on account of the preponderating dispersion of the flint glass.

The collimating and telescope lenses, L_1 and L_2, have usually a focal length of 2 to 3 inches. In some instruments the slit, *s*, is fixed, and the positions of lines in the spectrum are read on a scale in the focal plane of the eyepiece. This is only convenient for instruments of small dispersion. If the dispersion is large the whole spectrum cannot be seen in the field of view at once. In a convenient form of instrument made by Hilger the slit can be moved across the end of the tube by a tangent screw. By this means different parts of the spectrum can be brought to the centre of the field of view, which is marked by a pointer.

Larger and more ambitious types of direct-vision spectroscope can be obtained; but for anything except the roughest of purposes it is better to employ—

§ (20) The Hilger Constant Deviation Spectroscope.—This is an exceptionally convenient instrument for general laboratory use. *Fig.* 25 (*a*) is a diagrammatic plan. The collimator C and telescope T are permanently fixed at right angles to each other. The prism P is clamped to a table which may be rotated through a small angle by means of a tangent screw. The nut in which the tangent screw works is attached to the fixed part of the stand, and its movement is registered by a drum D with spiral scale. The special feature is the prism, which can be regarded as built up of three prisms arranged as shown in *Fig.* 25 (*b*). If a ray of light is incident at such an

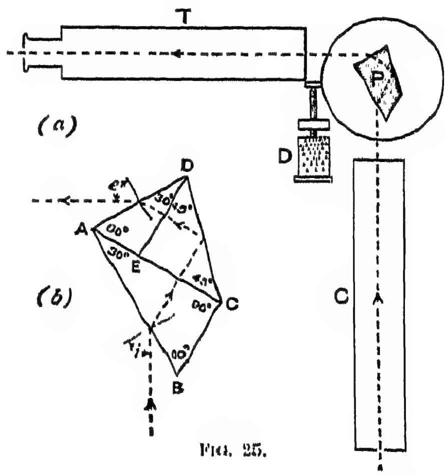

Fig. 25.

angle on AB that it is refracted parallel to BC it will be parallel to EA after internal reflection at the hypotenuse face of the 45° prism CED. It is therefore incident on AD with an angle of incidence equal to the angle

of refraction at AB, and so emerges from the prism at an angle, e, which is equal to the angle of incidence i. Since $D\hat{A}B=90°$ and $i=e$, the incident and emergent rays are at right angles. But we may regard ACB and ADE as two halves of a 60° prism, so that a ray which travels parallel to BC and EA suffers minimum refraction.[1] This applies to any ray which traverses the prism and emerges at 90° to its initial direction. Clearly the shorter the wave-length, and, consequently, the greater the refractive index of the prism, the greater the angle i will have to be in order that the refracted ray should be parallel to BC. Thus as the prism is rotated by the tangent screw, thereby altering the angle of incidence of the beam from the collimator, the spectrum will pass across the field of view, each wave-length being at minimum deviation, in the restricted sense indicated in the footnote, at the moment when it occupies the centre of the field.

The advantages of this instrument over an ordinary 60° prism spectroscope are, firstly, that both telescope and collimator being fixed extreme rigidity and permanence of adjustment are obtained; and, secondly, no readjustments of the prism are necessary in order to get minimum deviation for all measurements. The drum is graduated to read wave-lengths directly; and all that is necessary is to adjust the cross-lines of the eyepiece occasionally so as to make the instrument read correctly for some known wave-length.

§ (21) Monochromatic Illuminators.—It is frequently necessary to obtain monochromatic light, either from a source giving a continuous spectrum, or by isolating a particular line in a line spectrum. Any spectroscope can be used for this. It is only necessary to replace the eyepiece by a second slit in the position normally occupied by the cross-lines. If the collimator slit is illuminated by white light, or light containing more than one spectrum line, the light which passes through the second slit can only contain the wave-length of that part of the spectrum which falls on it. Either the direct vision spectroscope described above, or the constant deviation spectroscope, make excellent monochromatic illuminators. The former is particularly suitable for separating the green line of the mercury spectrum from the other lines. If the slit widths are chosen as wide as possible without including any of the nearest yellow line, the resulting illumination is very bright, and suitable for such purposes as polarimetry where an intense light is required. For use with white light greater dispersion than that of the direct-vision instrument is required, and the constant-deviation spectroscope is better. Hilger makes a special form of the instrument for use as a monochromatic illuminator. The telescopes are shorter and of larger aperture, thus securing a greater amount of light, and both slits open symmetrically. On account of the fixed direction of the emergent beam, the Hilger instrument is specially suitable for purposes in which it may be necessary to vary the wave-length during an experiment. The importance of being able to do this will be realised in reading the article on Immersion Refractometry.

There is one precaution which must be borne in mind in using monochromatic illuminators for work, such as polarimetry, in which complete exclusion of other wave-lengths is essential. There is always a proportion of the light which passes through any spectroscopic system scattered irregularly at the surfaces of the lenses and prisms, and even within the material. This is due to imperfect polishing, minute air-bubbles, and to any dust particles that may be present. Some of the scattered light, which contains all wave-lengths present in the light from the source, passes through the slit in addition to the rays which are properly focussed there. Thus, in separating the green line of mercury, if the light from the monochromatic illuminator is examined by another spectroscope it will be found to contain an appreciable quantity of the yellow and blue radiations. For most purposes this is immaterial, but for polarimetry it is fatal, on account of the rapid variation of optical rotations with wave-length. It is necessary in this case to pass the light from the first illuminator through a second, which reduces the scattered residuum to a negligible amount.

J. G.

[1] The total deviation, which is due not only to refraction but to reflection at DC, is never a minimum. It is only the portion due to refraction that has a minimum value; but under these conditions the magnification is unity, as in the case of a 60° prism at minimum deviation. It is only in this restricted sense that the term minimum deviation can be employed in connection with this instrument.

SPECTROSCOPY, MODERN

§ (1) Apparatus and Methods of Observation.—In the classical researches of Bunsen and Kirchoff, one of the chief functions of the spectroscope appeared to lie in its use as a tool in chemical analysis and in the discovery of new elements, and indeed it may be said that many of the chemical elements would probably not have been detected or isolated without the help of the spectroscope. In addition to the spectroscopic detection of elements, by examination of the radiations which they emit when in the state of luminous gases, the spectroscope has proved of signal service in the identification of compounds, particularly in organic chemistry, by observation of the radiations which they absorb, either in a pure state or

when dissolved in appropriate solvents. At the present time, however, the main uses of the spectroscope are in its application to physical problems, in which it has proved one of the most powerful methods of attack in many widely differing fields of investigation. In its simplest form the spectroscope consists essentially of a slit on which the image of a luminous source is projected, the rays which traverse the slit being made parallel by means of a lens, known as the collimating lens, and after passing through the dispersing system, consisting of one or more prisms, being brought to a focus by means of a telescope lens, the spectrum being either observed visually with an eyepiece or recorded permanently on a photographic plate. This simple system forms the basis on which the modern spectrometer has been developed, and can be used in this form for preliminary visual observation and approximate measurement of wave-lengths. In recent years, however, visual observations have been almost entirely superseded by photographic methods, for the latter have numerous advantages both in regard to accuracy of measurement, the range of wave-lengths which can be recorded, and owing to the fact that a considerable portion of the spectrum can be photographed at the same time on the plate, thus obviating the instrumental displacements which are liable to occur when consecutive measurements are made. Spectrographs were formerly designed with trains of prisms of relatively small aperture and lenses of short focal length, but in recent years there has been a tendency towards single prism instruments of large aperture, the required dispersion being obtained by the use of lenses of greater focal length. In the design of all forms of spectrograph, rigidity of all the parts is an essential feature, since exposures often extending over many hours have to be made, and any displacement of the apparatus would give rise to serious errors in measurement or loss of definition. In designing a spectrograph for a particular purpose it is generally necessary to arrive at some compromise between dispersion and light-gathering power, the former attribute being essential for the accurate determination of wave-lengths and the latter for recording faint spectra which would require impracticably long exposures with an instrument of low light-gathering power. For the accurate determination of wave-lengths either concave gratings or plane gratings mounted with lenses of long focus are to be preferred, though good results can be obtained with prism instruments of adequate dispersion. For the photography of faint spectra it is often essential to use prisms of large aperture and lenses of relatively short focal length with a consequent sacrifice of dispersion. For the visible spectrum and the ultra-violet spectrum down to about 3600 Å. the lenses and prisms are usually made of glass, but for the more refrangible rays down to 1800 Å. both lenses and prisms are made of quartz, since glass is opaque to these radiations. In the latter case the quartz prisms are made up of two halves of right- and left-handed quartz respectively, and the collimating and camera lens are also made of right- and left-hand quartz in order to obviate the doubling of the image which would otherwise occur. An instrument which is now widely used and which has many advantages is known as the Littrow spectrograph. This mounting, in which the principle of autocollimation is used, is applicable both to gratings and prisms and is essentially similar to the Abbé spectrometer. In the determination of wave-lengths a spectrum containing a sufficient number of lines of known wave-lengths is photographed in juxtaposition to or superposed on the spectrum to be measured. The wave-lengths of the unknown lines are determined by measurement of their positions with respect to the standard lines and subsequent reduction by appropriate formulae. In all accurate work the utmost care must be taken to ensure correct superposition of the spectra and to guard against instrumental displacement between successive exposures. A great deal of attention has been paid to the photographic plates used for spectroscopic purposes, and whereas ordinary plates are insensitive to wave-lengths greater than about 5000 Å. it is now possible to obtain plates which have been bathed in appropriate dyes which render them sensitive as far as the extreme visible red, and by the use of dicyanine bathed (1) plates it has recently been found possible to extend the sensibility of the photographic plate to about 9600 Å. In the regions of shorter wave-length the ordinary plate is sensitive to about 2000 Å., but beyond this limit its sensibility falls off rapidly owing to the absorption of the more refrangible rays by the gelatine of the plate. Plates are now made on a commercial scale in which this difficulty is overcome by following the special methods of preparation devised by Schumann (2), in which the gelatine is reduced to a minimum, and such plates have recently been used successfully by Millikan down to a wave-length of 360 Å. It should be mentioned that a number of special methods, notably that of Abney (3), have been devised for the purpose of extending the sensibility of photographic plates into the infra-red, but the technique of these methods is exceedingly difficult and laborious and they have not come into general use. In spectrographs in which lenses of single material (not achromatic lenses) are used, it is necessary to incline the plate, so that the rays do not fall on the plate at an angle perpendicular to its surface, and in such cases

it is essential that backed plates should be used to eliminate the reflection from the back of the plate, though it is desirable to use backed plates in all cases in which the most critical definition is required. For the photography of the ultra-violet regions below 1800 Å. it is necessary to use specially designed spectrographs from which the air can be exhausted or which are filled with pure helium, since air absorbs these radiations strongly. For the examination of the infrared regions of the spectrum which are beyond the range of sensibility of photographic plates special spectrometers are used. In these instruments glass must be eliminated and either gratings, or prisms of rock-salt or sylvin, are used. Lenses are usually replaced in these instruments by concave reflectors of metal, and a second slit is placed at the focus of the telescope reflector. Radiations which traverse this second slit are detected and their intensity is measured by means of a thermopile or a bolometer which is fixed behind the slit.

§ (2) Classification of Spectra.—Luminous spectra can be divided into two classes, namely continuous spectra, which result from the radiation of heated solids, and discontinuous spectra, which are in general peculiar to luminous gases, though in some cases continuous spectra can be observed from luminous gases, and solids may under certain conditions give rise to spectra which cannot be described as continuous. Discontinuous spectra may be subdivided into line and band spectra, the former consisting of lines distributed at intervals through the spectrum in a manner in which certain mathematical relations can frequently be found, though the existence of such relations is not immediately apparent; band spectra usually consist of complex groups of lines arranged in a manner in which some regularity is obvious, these groups repeating themselves at intervals in the spectrum. The regularities in these two classes of spectra are discussed in a later section.

§ (3) The Production of a Spectrum. (i.) *Flame Spectra.*—One of the most striking phenomena in spectroscopy is to be found in the variation in the spectrum of an element under different conditions of excitation. The spectrum of substances introduced into the Bunsen flame consists generally of a certain number of lines due to the element together with bands due to compounds of the element with oxygen or with other elements with which it has been introduced into the flame. Thus in a spectrum of calcium chloride introduced into the Bunsen flame we have, in addition to the characteristic flame lines of the element, bands due to calcium oxide and other bands due to calcium chloride, the spectrum of calcium bromide being thus similar as regards the lines and oxide bands but showing bands peculiar to calcium bromide in place of those due to calcium chloride. The efficacy of flames, as a method of producing spectra, can be greatly enhanced by introducing the substances in a finely divided state, most conveniently in the form of a spray (4), but the method is in general limited to the more volatile elements.

(ii.) *Arc Spectra.* — The spectra of less volatile elements can be conveniently produced by burning an electric arc between poles of a metal under investigation or between carbon poles impregnated or filled with the substance in the case of non-metallic bodies. When the arc burns between metallic poles the spectrum is found to consist of lines due to the element and sometimes also of bands due to the oxide; but in the case of substances introduced into the carbon arc there are a vast number of lines due to impurities in the carbon poles and bands which are attributed to cyanogen and other carbon compounds. The number of lines exhibited by different elements under these conditions varies widely, as also does the quantity of an element necessary for the appearance of its spectrum. The distribution of intensity amongst the lines in the spectrum of a given element depends also on the density of the radiating vapour, and it is found that the last lines to disappear from the spectrum when the quantity of a substance in the arc is gradually reduced are not necessarily the lines which are strongest when the density of vapour in the arc is greater (5). The recognition of the last lines to disappear under these conditions is, of course, a matter of importance for the detection of small quantities of a substance which is present as an impurity. The electric arc, burning between iron poles, is a source of radiation of great importance in spectroscopy, since its spectrum contains the lines selected as the international secondary standards of wave-length, and a special form of the iron arc, due to Pfund (6), has been chosen as the standard iron arc for this purpose on account of the fineness of the iron lines which it yields. Arc spectra generally contain, in addition to the "arc lines" proper, the lines characteristic of the flame spectrum and also a certain number of lines which belong more appropriately to the spark spectrum. A number of interesting changes occur when the arc is burnt in vacuo. Under these conditions the spark lines, which are relatively feeble in air, are greatly enhanced, and the oxide bands disappear and are often replaced by bands usually attributed to hydrides. The arc in vacuo thus represents a transition stage between the arc in air and the spark spectrum, and it has the advantage that the spark lines

are exceedingly narrow and therefore capable of measurement with a high degree of precision, which is unobtainable in spectra of condensed spark discharges, in which the spark lines, though relatively stronger in so far as their energy content is concerned, are so diffuse as to be unsuitable for measurement.

(iii.) *Spark Spectra.*—A striking change in the spectra of most substances is found when the arc spectrum is compared with the spectrum obtained when high potential discharges from an induction coil or transformer are allowed to pass between poles of the substance under investigation. With discharges obtained without the use of a condenser the spectrum consists mainly of bands due to air with feeble metallic lines in the neighbourhood of the poles, but when a condensed discharge is employed the spark spectra of the poles are obtained together with the characteristic spark lines due to the nitrogen and oxygen of the air. Whilst the latter lines extend uniformly across the spark gap the lines due to the poles are strongest in the immediate neighbourhood of the poles and extend to varying distances across the spark gap (7). Both arc and spark lines are present, the latter being greatly enhanced in intensity, and being in many cases found only in the immediate neighbourhood of the poles, whilst the arc lines extend to a considerable distance between the poles or right across the gap. The lines which extend furthest across the gap are precisely those lines which are the last lines to disappear when the amount of the substance in an electric arc is gradually reduced. The spark lines themselves extend to varying distances across the gap and can thus be classified into different groups. A remarkable change is observed when the period of the condenser is increased by the introduction of a self-induction coil in the circuit (8). Under these conditions the air lines disappear from the spectrum, which in other respects approximates closely to that of the electric arc, only the "longest" of the spark lines being visible in the immediate neighbourhood of the poles. The temperature of the poles also exerts an influence on the spectrum, the effect of cooling being in general to enhance relatively the intensity of the spark lines.

(iv.) *Tube Spectra.*—Gases can best be excited to luminosity by the use of vacuum tubes. Such tubes generally consist of two glass bulbs connected by a length of capillary tubing, each bulb being provided with an electrode which is usually made of aluminium. The tubes contain the gases to be investigated at relatively low pressures, generally in the neighbourhood of a few mm. of mercury, and can be excited by means of an induction coil or transformer. The preparation and filling of these tubes require a great deal of care, as the spectrum of the substance which it is desired to examine is often masked by impurities, notably compounds of carbon, with which the glass tube and the electrodes are frequently contaminated. In preparing these tubes they are usually exhausted to a very high vacuum, and there are several methods by which the desired gas can then be admitted into the tube in a sufficiently pure state, but special methods are usually required for different gases. As in the case of the spectra of spark discharges between metallic poles, the spectra of gases in vacuum tubes can be profoundly modified by the introduction of a condenser and spark gap into the electrical circuit. Nitrogen, for example, shows with an uncondensed discharge two band spectra, one of which is known as the negative band spectrum, and which appears in the neighbourhood of the cathode, whilst the other, the positive band spectrum, is brightest in the capillary portions of the tube. When the condenser and spark gap are introduced into the circuit the two band spectra disappear and are replaced by a bright line spectrum, which is the spark spectrum of nitrogen. This spectrum is itself capable of further modification, for when more powerful spark dischagres are employed certain of the lines are relatively enhanced. With these powerful condensed discharges, it is usual to find lines due to the constituents of the glass walls of the capillary. A very striking example of the change due to the introduction of the condenser and spark gap is afforded by the rare gas argon, which with the uncondensed discharge glows with a red light, which changes to a bright blue when the condensed discharge is used. In addition to spectra due to pure substances, it is common to find in vacuum tubes bands due to compounds. A large number of different types of vacuum tube have been designed for different purposes. For the investigation of the ultra-violet it is necessary to use tubes of fused silica, or glass tubes provided with a quartz window. For the investigation of some substances, *e.g.* metallic cadmium, which are not volatile at ordinary temperatures, it is possible to obtain satisfactory results by raising the temperature of the vacuum tube. In tubes containing mixtures of gases it frequently occurs that the gas which is present in smaller quantity dominates the spectrum, though it is often possible to reverse this state of affairs by a change in the conditions of electrical excitation. Thus in a mixture of helium and argon a small quantity of argon is sufficient to mask the helium spectrum when an uncondensed discharge is used, although the helium lines appear brightly when a condensed discharge is employed. Some gases are decomposed by the passage of the electric discharge, and

in these cases it is necessary to arrange for a continuous flow of the gas through the tube so that the products of decomposition are carried away. Changes in the spectrum of gases in vacuum tubes can also be brought about by changes in the pressure in the tube, and by the presence of impurities. Some of these changes are very striking and can be observed without difficulty, whilst others are discovered only when photometric measurements are made of the relative intensities of the lines.

(v.) *Other Methods of Production.*—Interesting results have been obtained by examining the spectra of substances at very high temperatures by enclosing them in graphite tubes heated by the passage of a very powerful electric current (9). In such cases the luminosity is probably due to temperature alone, but it resembles in general the spectra from electric arcs, although at the highest temperatures available a certain number of spark lines can be observed. In recent years attention has been paid to the spectra of fluorescent substances (10). In the case of solids and liquids, the spectrum usually consists of broad and somewhat indefinite bands, but in the case of fluorescent vapours the spectra are discontinuous and often exceedingly complex, the spectrum depending on the nature of the exciting light.

§ (4) Estimates of Intensity.—In recording a spectrum it is usual to give, in addition to the wave-lengths of the lines, an estimate of their intensities and an indication of any peculiar characteristics which they show. Thus, in a given spectrum some lines may appear perfectly sharp, whilst others are diffuse, either uniformly or in the direction of longer or shorter wave-length. It is usual to express intensities on an arbitrary scale from 0 to 10, the strongest lines being designated 10, whilst those which are just visible are given as intensity 0. This procedure, whether by direct visual observations or from photographic plates, is very inaccurate and is subject to considerable personal error on the part of the observer. In the infra-red regions of the spectrum where the thermopile or bolometer are used, the intensities can be quantitatively measured, and methods have been introduced recently by which quantitative measurements can also be made photographically in the visible and ultra-violet portions of the spectrum (11).

§ (5) Doppler's Principle.—There are a number of phenomena in spectroscopy which depend on the application of Doppler's principle. According to this principle a small change in the wave-length of a line is found when the observer or the source of radiation is in motion. If λ_0 is the wave-length observed when both the observer and the source are at rest, and if a is the velocity of the observer and b that of the source in the line of sight, V being the velocity of light, then λ, the observed wave-length when the observer or source is in motion, is given by the equation

$$\lambda = \lambda_0 \left\{ \frac{V \mp b}{V \pm a} \right\},$$

the upper sign being used in the case of approach.

Thus, if the displacement of a line is measured, the velocity of the moving source relative to the observer can be determined. This has been applied to the determination of the velocity of the positive rays in hydrogen and other gases (12). In such experiments, in addition to the displaced line, there is a line in the undisplaced position, the latter being due to particles made luminous in the path of the positive rays, whilst the former is due to the radiation of the moving particles themselves. According to the kinetic theory of gases the particles of a gas are in motion, and in consequence part of the radiation in a luminous gas will be from particles which are approaching the observer, and some from particles which are receding. The result of this is that spectrum lines are never infinitely narrow, but are broadened according to a law which depends on the distribution of velocities in the gas. These velocities are proportional to the square root of the absolute temperature, and inversely proportional to the square root of the masses of the radiating particles. According to the kinetic theory the distribution of intensity in a line which is broadened in this way follows a law of the form $y = e^{-kx^2}$. The width of a spectrum line is thus mathematically infinite, but it is usual to define it by the "half-width," which is the value of x when $y = \frac{1}{2}$. Lord Rayleigh (13) has shown that if $\delta\lambda$ is the "half-width" of a line of wave-length λ from a source at T° absolute, the masses of the radiating particles, in terms of that of the hydrogen atom, being m,

$$\frac{\delta\lambda}{\lambda} = 3{\cdot}57 \times 10^{-7} \sqrt{\frac{T}{m}}.$$

This affords a means of determining the masses of the radiating particles in luminous gases if the temperature is known, or the relative masses independently of the temperature in the case of mixtures of gases. By measuring the "half-widths" of the lines of the rare gases from vacuum tubes at ordinary temperatures, and when immersed in liquid air, it has been possible to show that the temperature of the radiating particles in a discharge tube is not appreciably greater than that of the walls of the tube, and that the measured "half-widths" of the lines are

in close agreement with the values deduced on theoretical grounds (14).

§ (6) Distribution of Intensity.—It has been found possible to measure the actual distribution of intensity in the lines, and the results have been found to be in accordance with theory. Investigations of this kind require the use of spectroscopic apparatus of very high resolving power, far exceeding that of any prism instruments and barely within the capacity of the largest gratings. The instruments usually employed for investigations of this kind are the Michelson or Fabry and Perot interferometers, the Echelon diffraction grating, or the Lummer-Gehrcke plate (15). The method of measuring the widths of lines with the interferometer consists in gradually increasing the distance between the plates until the interference fringes vanish, the "half-widths" of the lines being deducible from the optical difference of path when this occurs (13). By somewhat different methods the Echelon and Lummer-Gehrcke plate may also be used for measurements of the widths of lines. These instruments are of great value in all cases in which phenomena depending on small changes or differences of wave-length are concerned, though the largest gratings can also be used.

§ (7) The Zeeman Effect.—Amongst the phenomena included in this category may be mentioned the magnetic resolution of spectrum lines into components discovered by Zeeman in 1896 (16). Zeeman found that when a source of light is placed in a powerful magnetic field the lines are split up into components, some of which are polarised in a direction perpendicular to the magnetic field, whilst others are polarised parallel to the field, when the luminous source is observed transversely to the field. In the simplest case a line observed transversely is split up into three components, the outer components being polarised at right angles and the central component parallel to the lines of force. The separation of these two outer components is an important constant, from which the ratio of the electric charge to the mass of the electron has been deduced. It is found that $Zn = (\Delta\lambda/\lambda^2 H) \times 10^5$, where $\Delta\lambda$ is the separation of the outer components of a "normal" Zeeman triplet, λ the wave-length, H the magnetic field, and Zn a constant which, according to the most recent results, is equal to 9·385. When viewed along the lines of force the resolution in the simplest case is into two components of equal intensity which are circularly polarised in opposite directions. This simple case has been accounted for theoretically by Lorentz, but the phenomena are generally much more complex, many different types of resolution being now recognised. It has, however, been found that all lines belonging to the same spectral series exhibit the same resolution, and corresponding lines of different elements behave in the same way. Runge has shown that in many cases these complex separations may be expressed as simple fractions of the separation of the normal Zeeman triplet, but there are many complex types which do not appear to conform with this rule. The phenomena are even more complicated in the case of certain lines which exhibit dissymmetries and shifts, and complex phenomena are frequently observed in the resolution of lines which are themselves close doubles.

Many spectrum lines, when examined under a high resolving power, are found to possess a complex structure. This is most common in lines of the heavier elements, which are frequently accompanied by satellites. Certain regularities in the positions of these satellites have been observed, but their precise nature is not yet understood.

§ (8) Variations of Wave-length.—It has been found that the wave-lengths of lines are in many cases affected by the pressure of gas in the luminous source. The change in wave-length observed is usually very small, even when very great ranges of pressure are employed. These displacements appear to be directly proportional to the pressure and vary for different lines and for different elements. They are independent of the partial pressure of the luminous gas, but depend only on the total pressure. Recent investigations have shown that the pressure effect is an exceedingly complex problem.

It has been found that in electric arcs at atmospheric pressure minute changes of wave-length of some of the lines are to be found in the neighbourhood of the poles. This phenomenon, which is known as the Pole effect, is distinct from the change in wave-length due to pressure, and is of fundamental importance in the choice of standards of wave-length. The exact nature of the phenomenon is at present not fully understood.

Spectroscopic apparatus of very high resolving power is required in the investigation of the minute differences in wave-length which have been observed between the lines of the isotopes of lead.

§ (9) The Stark Effect.—Stark discovered in 1913 (17) that when certain spectrum lines are emitted in strong electric fields they are resolved into components, which, as in the case of the Zeeman effect, are polarised in different planes. This phenomenon differs from the Zeeman effect in the fact that the resolution is not the same for lines of the same series, the separation and number of the components increasing with the term number, though, as in the case of the Zeeman effect, the polarisation and number

of the components depend on the direction with respect to the field in which the observations are made. Stark's method of investigating the phenomenon was to observe the radiation of positive rays in a space between two metal plates which were kept at a suitable difference of potential in a specially designed vacuum tube, whilst Lo Surdo, who discovered the phenomenon independently at about the same time as Stark, found that the electric field in a vacuum tube in which the cathode was in a constricted part of the tube was great enough to exhibit the phenomenon. It has recently been found possible to investigate the electric resolution of the less volatile elements.

In some cases the resolution is symmetrical, whilst in others there is a marked dissymmetry of the components, both as regards their position and intensity. Lines of the diffuse series are affected to a much greater extent than those of the principal and sharp series. Stark has pointed out that the broadening of spectrum lines which occurs when powerful electric discharges are used is greatest for those lines which exhibit the greatest electrical resolution, and has suggested that the broadening in this case is due to the electric fields of neighbouring charged atoms on the radiating particles. Later investigations have confirmed this explanation of the broadening both qualitatively and quantitatively. It should be pointed out that this broadening by powerful condensed discharges, and also the broadening which results from an increase of pressure, is distinct from and superposed on the broadening which is due to the motions of the radiating particles in the line of sight. Whilst the latter effect imposes an inferior limit to the widths of spectrum lines, the former conditions can be varied from a negligible effect to a state in which the lines broaden to an almost continuous spectrum.

§ (10) Spectrum Series. (i.) *Balmer.*—It had been recognised for many years (18) that the lines in spectra were arranged in a manner which implied some definite relation between them, but the first successful representation of a series of lines was the formula of Balmer, which represents to a high degree of accuracy the chief series of lines in the spectrum of hydrogen. The word series is taken to mean a succession of lines the intervals between which become less from the red towards the violet and which degrade in intensity in the same direction. These series may consist of single lines, pairs or groups of more complex structure, and a spectrum usually comprises a number of such series. In the simplest case, that of hydrogen, Balmer expressed the wave-lengths of the lines (in reality complex lines) by the formula

$$\lambda = 3646 \cdot 14 \frac{m^2}{m^2 - 4},$$

where m takes a series of integral values 3, 4, 5, etc. The series therefore converges to a limit at $\lambda = 3646 \cdot 14$, but the limit of a series is never observed owing to the rapid degradation in the intensities of the lines, though in the case of hydrogen upwards of 30 members of the series have been observed in the chromosphere of the sun. In all the more recent work on spectrum series it has been found convenient to express the results in terms of the wave number, which is the reciprocal of the wave-length or the number of waves per centimetre. In terms of the wave number Balmer's formula reduces to

$$n = 27418 \cdot 75 - \frac{109675}{m^2}.$$

(ii.) *Rydberg, Kayser and Runge.*—Further regularities in spectra were recognised in the classical work of Rydberg and of Kayser and Runge. These investigators recognised the existence of three chief types of series which are now known (following Rydberg) as the Principal, Sharp, and Diffuse series, which are abbreviated P, S, and D respectively. Kayser and Runge expressed the wave numbers of the lines of series by the formula

$$n = A - Bm^{-2} - Cm^{-4},$$

where A, B, and C are constants, A being the limit of the series; but this method of representing the series is inferior to that of Rydberg, which not only expressed with success the wave numbers of the individual lines of series, but brought out the relation between the different series. Rydberg employed the formula

$$n = n_0 - \frac{N}{(m + \mu)^2},$$

where n_0 is the limit of the series, μ a constant peculiar to the series, and N the "universal constant," which is equal on Rowland's scale of wave-lengths to 109675, m taking successive integral values. A recent investigation of Curtis, in which the lines of the Balmer series of hydrogen were remeasured with great precision, has shown that on the international scale of wave-lengths the value N 109678·3 should be adopted. This "constant" is nearly the same for all series and all elements, and its interpretation in the light of the quantum theory is one of the most striking achievements of modern theoretical physics. The P, S, and D series differ physically in many important characteristics. Thus, of the three series, the P series, which usually contains the most prominent lines in the spectrum, shows the phenomenon of reversal most readily; in the S series, as its name implies, the lines are sharp under most conditions and are seldom reversed; whilst the lines of the D series are usually diffuse, and undergo a greater resolution in the electric field than the lines of the other series. Rydberg and Schuster discovered in-

dependently the important relation that the difference between the limit of the P series and that of the S series is equal to the wave-number of the first P line. The relations discovered by Rydberg can be seen from the following formulae, which represent the wave-numbers for the three series in the case in which each component of the series is a pair. Writing p, s, and d for the values of μ in the P, S, and D series respectively, and noting that the limit of the series n_0 in the simple Rydberg formula can be written in the form $N/(m+\mu)^2$, we have

P series,

$$n_1 = N\left(\frac{1}{(1+s)^2} - \frac{1}{(m+p_1)^2}\right),$$

$$n_2 = N\left(\frac{1}{(1+s)^2} - \frac{1}{(m+p_2)^2}\right);$$

S series,

$$n_1 = N\left(\frac{1}{(1+p_2)^2} - \frac{1}{(m+s)^2}\right),$$

$$n_2 = N\left(\frac{1}{(1+p_1)^2} - \frac{1}{(m+s)^2}\right);$$

D series,

$$n_1 = N\left(\frac{1}{(1+p_2)^2} - \frac{1}{(m+d)^2}\right),$$

$$n_2 = N\left(\frac{1}{(1+p_1)^2} - \frac{1}{(m+d)^2}\right),$$

n_1 in each case denoting the member of the pair of greater wave-number. The following important facts emerge from these relations:

(1) The S and D series converge to the same limit, but the separation of the components of the pairs remains constant.

(2) In the P series the separation of the components of the pairs decreases with the term number, converging to a common limit.

(3) If the more refrangible member of the pair is the stronger in the P series, the less refrangible member will be the stronger in the S and D series.

(iii.) *Ritz and Hicks.*—These relations are probably exact, though the wave-numbers of the individual lines of series may be more accurately represented by the formulae of Ritz and Hicks. The formula of Ritz may be written approximately

$$n = A - \frac{N}{(m+\mu+(a/m^2))^2},$$

while Hicks finds that the most accurate representation of the wave-number is given by

$$n = A - \frac{N}{(m+\mu+(a/m))^2}.$$

In the Ritz formula m takes integral values for the P and D series, but in the S series it assumes the values 2·5, 3·5, 4·5, etc. In the Ritz and Hicks formulae the values of μ and a for the P, S, and D series are expressed by the symbols $p\pi$, $s\sigma$, $d\delta$ respectively, and the relations between the series can be conveniently expressed by adopting the abbreviated forms due to Paschen, who writes, for example, mp, ms, and md, for the variable parts of the P, S, and D series; similarly $1p$ denotes the common limit of the S and D series. Similar relations to those given above are found in the case of series consisting of triplets. The above formulae require some amplification in the case of series which have satellites associated with the D series. It will be seen that every line in the scheme given above is represented as the difference between two wave-numbers, one of which is the limit of the series, and Ritz's important combination principle states that lines are often observed which can be represented by combining these wave-numbers in different ways. Thus in certain "combination" series, as they are called, the wave-numbers are equal to the differences between other observed wave-numbers. The validity of the combination principle has been established by the recognition of a great number of combination series. Of these combination series the most important is known as the Fundamental or F series, the wave-numbers of which can be expressed, in Paschen's notation, as $n_F = 2d - mf$. Ritz has suggested another representation of this series, but this does not appear to be fully established. The spectra of elements in the same group in the periodic table are similar, the separation of doublets or triplets being roughly proportional to the squares of the atomic weights.

§ (11) Arc and Spark Spectra (Fowler).—In a previous paragraph the terms arc and spark spectra were used to denote the lines which were relatively stronger in the spectra of electric arcs and spark discharges respectively. These terms have now assumed a new and more fundamental significance in the light of the important work of Fowler (19) on series in spark spectra. The fundamental difference in the spark and arc series lies in the fact that the "universal constant" N in the series formula is replaced by 4N in spark series, which is in accordance with recent theoretical investigations on the origin of spectra. The case of magnesium may be cited as an example. In the spectrum of this element there is a complete set of arc series with the "universal constant" equal to N, comprising a triplet system and a single line system, and also a pair system of spark lines in which the N is replaced by 4N. Both these sets of series are accompanied by combination series. These results are of fundamental importance in recent work on the origin of spectra in relation to atomic structure, but their discussion is beyond the scope of the present article.

§ (12) Band Spectra.—The existence of regularities is very apparent in the case of band spectra. Bands, which are usually associated with the spectra of compounds or molecules, consist of groups of lines which converge to definite heads, the head of a band being frequently, but by no means invariably, the strongest line in the band. These bands may be degraded either towards the red or towards the violet, and a large number of the lines composing them can often be enumerated, and bands of similar structure recur at intervals in the spectrum. Deslandres has shown that the wave-numbers of the lines composing bands may be expressed by a formula of the type $n = A + Bm^2$, where A is the wave-number of the head of the band, B a constant, and m takes a series of integral values 1, 2, 3, etc. In the same way it has been shown that the heads of the different bands may be arranged in series by a similar formula. The two formulae may be united into one, so that the complete representation of the lines in a series of bands is given by

$$n = Al^2 + Bm^2 + C,$$

where A, B, and C are constants and l and m are integers. These formulae are only approximate, and a number of more complex modifications have been proposed; but in the absence of any theoretical knowledge as to the origin of band spectra, it may be considered doubtful whether they are to be regarded as having greater significance than pure interpolation formulae. Band spectra are often exceedingly complex, several series frequently converging to the same head, and these different component series may show variations in their relative intensities under different physical conditions of excitation. Fowler (20) has recently observed a new type of band series associated with the spectrum of helium. In these bands the individual lines composing the bands are arranged in a manner which can be expressed approximately by Deslandres' formula, whilst the heads of the bands are arranged in series resembling those found in line spectra.

Spherometer: an instrument for measuring the curvature of the surfaces of lenses and mirrors. See "Spherometry," §§ (1) to (6).

SPHEROMETRY

§ (1) In the following paragraphs methods will be described which are suitable for the determination of the curvatures of the surfaces of lenses and mirrors. Only those arrangements will be treated which are of general applicability, and which will be found useful in determining the structural data of optical instruments. A complete compendium of all the arrangements employed by different experimenters would be quite beyond the space at our disposal; but the methods described will be found to cover satisfactorily the whole range of curvature encountered in practice,

from the minute radii of the high-power microscope objective to the long radii of nearly flat surfaces.

I. Mechanical Methods

§ (2) The Simple Spherometer.—For medium curvatures, provided the diameter of the surface is reasonably large, the determination of curvature is most easily performed with a spherometer. The simplest form of spherometer is shown in *Fig.* 1. Three rigid legs, terminating in points a, b, and c, are attached to a stout plate. Through the centre of the plate passes a micrometer screw, also terminating in a point d.

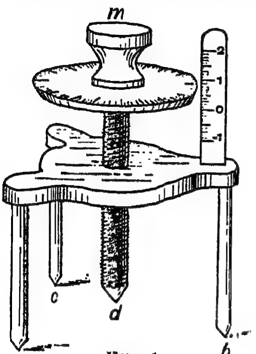

Fig. 1.

The three points a, b, and c are at the corners of an equilateral triangle, and d is equidistant from each of them. If the spherometer rests on a plane surface and d is screwed down so as just to touch the surface, the reading of the micrometer corresponding to zero curvature is obtained. If the instrument rests on a curved surface, and d is adjusted to make contact, the difference between the micrometer reading and that corresponding to zero curvature is a measure of the curvature. Suppose this difference is h, and that the radius of the circle on which the three fixed feet lie is ρ. In *Fig.* 2, $de = h$ and $eb (= ec = ea) = \rho$. From the geometry of the figure $ed \times ef = eb^2$, i.e. $h(2r-h) = \rho^2$, where r is the radius of the spherical surface. Therefore

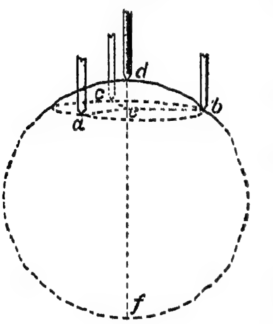

Fig. 2.

$$r = \frac{\rho^2}{2h} + \frac{h}{2}.$$

In order to determine the exact moment at which d makes contact, the usual method of using the instrument is to grip the milled head m, *Fig.* 1, lightly between the thumb and the first and second fingers, and screw up the micrometer, taking care to avoid bearing more heavily on one of the feet than on the others. So long as d is not touching, the spherometer remains quite steady; but as soon as d touches the surface any further rotation tends to raise the other feet from the surface and the whole spherometer rotates. With a little practice in handling the instrument, readings can be repeated to a surprising degree of accuracy by this method provided the span, 2ρ, is fairly large. This type of instrument is very useful therefore for large surfaces; but for surfaces of smaller diameter, where an instrument with the feet closer together must be employed, the precision of setting falls off considerably.

For the great majority of lenses the diameter is under two inches, and it is desirable to employ more accurate types of spherometer.

§ (3) The Abbé Spherometer.[1]—This spherometer, designed by Professor Abbé, gets over the difficulty of determining when contact is made by dispensing altogether with the micrometer screw and replacing it by a plunger which slides freely in guides and is pulled against the surface of the lens by a definite force. The degree of contact is therefore always the same. The position of the plunger is read by means of a microscope with micrometer eyepiece. *Fig.* 3 is a diagrammatic section of the instrument, from which its construction will be easily understood. B is a circular plate supported on two stout pillars, of which only one, P, is shown. The sliding rod R passes through the centre of B and through a lower guide G, which is attached between the two uprights. A counterweight W is attached to R by a string which passes over a pulley. This is slightly heavier than R, so that it tends to pull the latter upwards. A finely-divided scale is attached to the side of the plunger and is read by a microscope attached to the underside of P, fractions of a division being obtained by the micrometer eyepiece. The lens under test rests on a ring A which is concentric with the plunger. The ring is not bevelled to a single razor edge, but is ground to an annular plateau about $\frac{1}{2}$ mm. wide. Concave surfaces make contact with

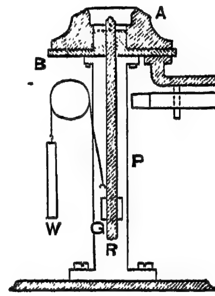

Fig. 3.

[1] See Pulfrich, *Zeits. f. Instrumentk.*, 1892, xii. 307.

the outer rim and convex surfaces with the inner. There is therefore a slightly different value for ρ, the radius of the ring, in the two cases. The reason for this arrangement is that with pointed feet, as in the simple spherometer first described, or with rings bevelled to a single razor edge, the points or edges become rounded in use and lenses of different curvature make contact at different distances from the centre. It is therefore impossible to ascribe an accurate value to ρ. With Abbé's arrangement the edges are much less acute and so do not round off readily. There are a number of rings such as A, but of different diameters, which may be fitted on the instrument so that lenses of various sizes may be measured.

§ (4) The Aldis Spherometer.—In this spherometer the lens rests on three steel balls instead of on points or rings. This appears to be the best method of support, inasmuch as the blunting difficulty is entirely eliminated; and, further, there is no tendency to scratch or mark the lens, a fault which some users allege against the ring support. With spherical supports the formula requires a little modification. Let AB, *Fig.* 4, be a convex surface of radius r resting on spheres of radius a whose *centres* are on a circle of radius ρ. The quantity which the spherometer measures is h, the vertical distance between the lowest point of the surface and the plane FG tangential to the spheres, the zero being obtained by the use of a flat surface in the ordinary way. This is equal to the vertical distance between the lowest point of A′B′, a curve concentric with AB but passing through the centres of the spheres, and the plane F′G′. Thus the ordinary spherometer formula, using the values h and ρ, would give the radius of A′B′ which equals the radius of AB plus the radius of the supporting spheres. Therefore

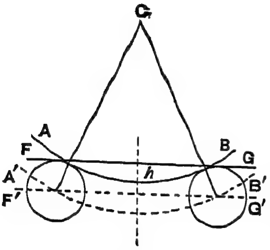

Fig. 4.

$$r=\frac{\rho^2}{2h}+\frac{h}{2}-a.$$

Similarly the formula in the case of a concave surface is

$$r=\frac{\rho^2}{2h}+\frac{h}{2}+a.$$

In the Aldis instrument, which is shown diagrammatically in *Fig.* 5, the lens is held down on the three-ball support by the weight of a plunger P, which slides smoothly in a hole in the superstructure. The micrometer screw is brought up from below. Before it makes contact the lens is held fairly firmly against the three peripheral spheres, and there is appreciable frictional resistance to rotation. When contact is made, however, the lens is practically held between the point of the micrometer and the plunger, and can be rotated freely.

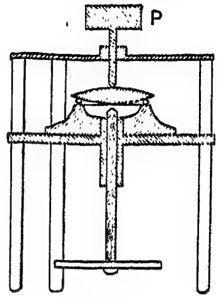

Fig. 5.

There are obvious defects in this arrangement for accurate work. The weight not only of the lens but of the plunger has to be supported on the sharp point of the micrometer. Quite an appreciable local depression is therefore produced before lifting occurs. This will occur to approximately the same extent in taking the zero reading, but the process is disastrous to any surface which undergoes it very often. The flat used for zero testing is soon ruined. The sensitivity with which the contact can be detected by rotating the lens is fairly high with large lenses, but for small lenses, such for instance as those in eyepieces, it becomes very low.

§ (5) The Guild Spherometer.[1]—This instrument is similar to the Aldis instrument as regards the arrangement of the micrometer parts and the use of three-sphere supports, but the method of detecting contact is quite different.

The micrometer screw, instead of terminating in a point, terminates in a small sphere of quartz (or glass). When this is nearly in contact with the surface of the lens under test, Newton's rings can be seen if a suitable arrangement for observing them be provided. From the behaviour of these rings as the micrometer is rotated the point of contact can be observed. The instrument is shown diagrammatically in *Fig.* 6. L is the lens under test resting on the three-sphere support (only two are shown). B is the small transparent sphere in which the micrometer terminates. A microscope M, with an ordinary vertical illuminator V fitted above the objective, is arranged for observing the Newton's rings formed between B and L. Illumination is supplied by a small 4-volt lamp on a suitable bracket. A piece of Wratten No. 25 gelatin filter (red) is mounted behind the aperture of the illuminator, and renders the

[1] Guild, *Trans. Opt. Society*, 1918, xix. 103.

light sufficiently monochromatic for several rings to be seen surrounding the point of contact.

The method of using the instrument is simple. Suppose that the small sphere B is gradually approaching the surface of L. When it comes within a short distance of it the Newton's rings become visible on suitably

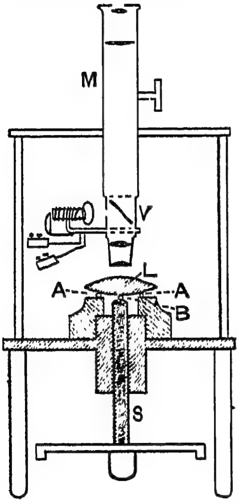

FIG. 6.

focussing the microscope. As the surfaces approach still closer the fringes expand outwards, a fresh one appearing at the centre for each half wave-length that the screw advances; but when actual contact is made the expansion of the fringes ceases abruptly, any further motion of the screw simply lifting the lens from its support. This point can be determined with certainty to less than one five-thousandth of a millimetre. It is better, however, to use as the criterion of contact not the point at which the expansion of the ring system ceases, but some easily recognised configuration *just before* this stage is reached. A convenient configuration is that in which the central black spot approximately trisects the diameter of the first black ring. This has the advantage that the appearance of the rings continues to alter for a little beyond the required setting, which is more satisfactory in practice than when the criterion adopted is one-sided. But the greatest advantage is that the surfaces are not in tight contact at this stage, and so no errors due to local distortion of the surface can arise.

With this instrument, exactly the same

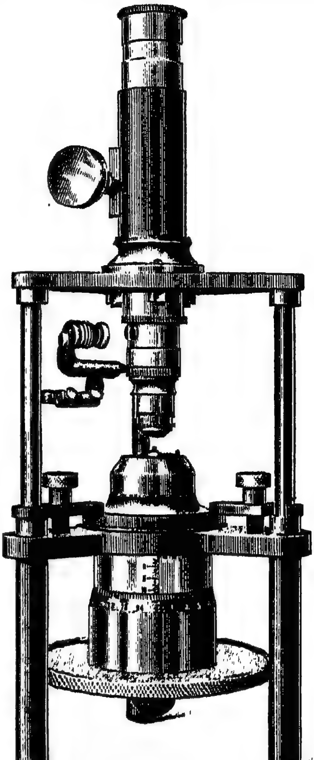

FIG. 6A.

accuracy in the micrometer settings is obtained with small lenses as with large. With a little practice readings of h can be repeated to a ten-thousandth of a millimetre, which is several times as sensitive as the best of the other existing types. An actual instrument is shown in *Fig.* 6A.

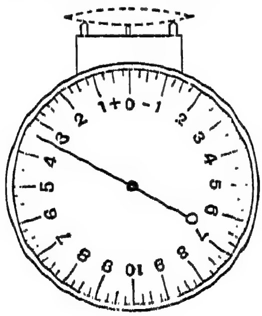

FIG. 7.

§ (6) THE WATCH-POCKET SPHEROMETER.—For very rough work, and for the rapid identification of surfaces, it is convenient to use a simple arrangement sold under the name of Dioptre-meter. In appearance it is similar to a watch, with three feet projecting from the rim (*Fig.* 7). The outer feet are fixed, and the central one can be pushed in against the pressure of a spring. When the feet are pressed against a lens surface, the central leg

is pushed inwards to an extent depending on the curvature of the surface. Its motion is converted into rotation of the dial pointer by toothed wheels.

As the instrument is principally used to measure the power of spectacle lenses, it is graduated to read the power of the surface in dioptres, assuming a refractive index of 1·52. Thus the actual reading gives the quantity $0{\cdot}52/r$, where r is the radius.

II. Optical Methods

§ (7) Newton's Rings.—For lenses at least 1 cm. in diameter, provided the curves are not too shallow, the curvatures can usually be most conveniently determined by means of an accurate spherometer. There are cases, however, in which the spherometer is inapplicable. For very small lenses, such as may be encountered in a microscope objective, or for lenses of shallow curvature for which the value of h would be very small, other methods have to be adopted. There are a great variety of such methods, but they are not all of satisfactory accuracy or convenience to be of practical value. We shall restrict ourselves here to a description of some of the methods which are of real utility in the optical laboratory. Of these the Newton's Rings method is the most suitable of any for convex curves of long radius; but by employing suitable arrangements it can be used down to quite small radii.

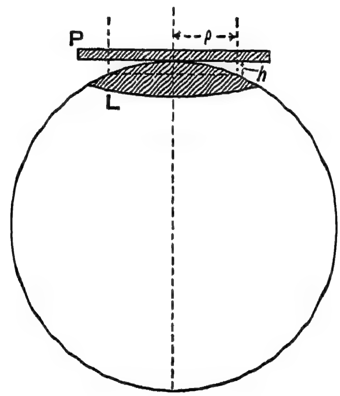

Fig. 8.

In *Fig.* 8 let P be a plate, of which the under side is accurately flat, resting on the surface of a lens L, and let a beam of monochromatic light fall on it from above. The lower surface of the plate forms with the lens an air film of which the thickness increases in all directions from the point of contact. Circular interference fringes surrounding the point of contact can therefore be seen if suitable observing apparatus is provided. Let us assume that the thickness of the film is zero at the centre. Since the ray reflected from the lower surface of the flat is incident from the glass side of a glass-air surface, it undergoes no phase change on reflection. The light reflected from the surface of the lens, being incident from the air side of a glass-air surface, undergoes a phase change of half a wave-length. Consequently, at the point of contact, where the thickness of the air film is zero, the rays annul each other by interference and produce darkness. There is therefore a black spot at the centre of the system. At any point away from the centre the illumination will be a maximum or zero according as the total retardation, which is equal to twice the distance between the surfaces + half a wave-length, is an even or odd number of half wave-lengths; that is, there will be a bright or a black ring at a distance ρ from the centre according as $2h$, *Fig.* 8, is an odd or even number of half wave-lengths. For purposes of measurement the black fringes are always used. These will be at such distances from the centre that twice the separation of the surfaces $=m\lambda$, where λ is the wave-length and m has successively the values 1, 2, 3, etc. If ρ_n is the radius of the nth ring, $2h$ for this ring $=n\lambda$. But $2rh-h^2=\rho_n{}^2$, where r is the radius of the curved surface. Since h is only a few wave-lengths, h^2 may be neglected in comparison with $2rh$, so that

$$\rho_n{}^2=2rh=rn\lambda,$$

$$\therefore \rho_n=\sqrt{rn\lambda}.$$

The radii of the rings are therefore proportional to the square roots of the natural numbers, and the fringes become closer together as we pass outwards from the centre. The width of a fringe is very approximately inversely proportional to its distance from the centre; for if

$$\rho_n{}^2=nr\lambda,$$

$$\rho_{n-1}{}^2=(n-1)r\lambda,$$

$$\therefore (\rho_n-\rho_{n-1})(\rho_n+\rho_{n-1})=r\lambda.$$

Approximately, therefore, the width of a fringe

$$=\rho_n-\rho_{n-1}=\frac{r\lambda}{2\rho_n}.$$

It is easier to measure the diameter of the rings than their radii. If D_n is the diameter of the nth ring,

$$r=\frac{D_n{}^2}{4n\lambda}. \quad . \quad . \quad . \quad . \quad (1)$$

This relation can be employed to determine the radius of curvature of the surface. It assumes, however, that the flat is geometrically tangential to the lens at the point of contact. In practice the nature of the contact is by no means definite. If the surfaces were to touch at one point only the pressure would be

infinite. There is always, therefore, a flattening of the curve and denting of the flat to spread the contact over an appreciable area. Owing to this deformation near the middle of the system the diameters of the rings will not be accurately given by the formula we have discussed. However, the *difference* in the diameters of rings at some distance from the centre will not be affected, and the radius of the surface will be correctly given by

$$r = \frac{D_{n2}^2 - D_{n1}^2}{4(n_2 - n_1)\lambda}, \quad . \quad . \quad . \quad . \quad (2)$$

where D_{n2} and D_{n1} are the diameters of the n_2th and n_1th rings respectively. In carrying out this method for lenses of long radii a travelling microscope, such as that employed for the measurement of spectrum photographs, etc., is essential. The lens is laid on the stage of the microscope, *Fig.* 9, with the surface to be tested upwards, and the flat plate laid on top of it. Unsteadiness can be prevented by little pellets of plasticene or soft wax near the periphery. The illumination should be supplied in a parallel beam at exactly normal incidence by means of an arrangement of the type shown in the diagram. A is a small aperture in a screen, behind which is placed a strong source of monochromatic light. The aperture is at the focus of a lens L. The light is reflected at a transparent glass reflector R, which is mounted in a bracket with universal adjustment attached to the framework which carries the microscope. By adjusting R the light can be brought to normal incidence.

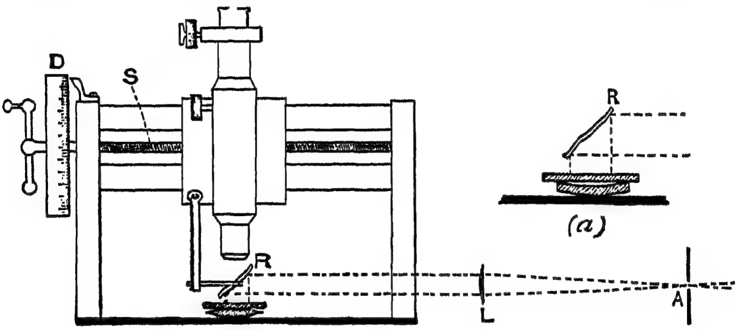

FIG. 9.

In making the actual measurements it is necessary, as we have seen, to measure the diameters of two rings, the n_1th and the n_2th. The accuracy of the final result will be greater the greater $n_2 - n_1$. It is not desirable, however, that *either* n_2 or n_1 should be small, as the rings near the centre being broad and diffuse the accuracy of setting is considerably less than for rings further out. The effect on the result of errors in D_{n2} and D_{n1} is readily deduced by differentiating equation (2) with respect to each of them separately. It requires D_{n2}/D_{n1} times as big an error in D_{n1} as it requires in D_{n2} to produce a given error in r. Thus the relative accuracy with which the diameters have to be measured is proportional to the diameters. We saw that the widths of the fringes were inversely proportional to their diameters, so that if settings were accurate to the same fraction of a fringe width the probable error in the result would be of the same order in each measurement. As a matter of fact the accuracy of setting does vary nearly in this way at some distance from the centre, but for the first few fringes the fringe width is varying rapidly and the judgement of the setting is affected by the want of symmetry. It is not desirable therefore to make measurements on rings of smaller order than the 6th or 7th. For the outer ring as large a value of n as possible should be taken. This involves working where the fringes are very close together, and it will be found of convenience to employ a micrometer eyepiece to the microscope. The microscope as a whole is moved slowly across the fringe system by means of the screw S, the fringes being counted as they pass the cross-lines. When the fringe is reached at which it is intended to stop, the reading on the drum D is taken. Several settings are then made by means of the micrometer eyepiece, and the mean of these readings used to correct the drum reading. The advantage of this process is that if the repeated settings are made with the screw S, the cross-lines have to be brought back several fringes each time in order to take up the backlash of the screw. It is very easy in doing this to get confused as to the fringe on which the measurement is being made. If the repetitions are made with the micrometer eyepiece, however, the screw being of finer pitch and the mechanism being more delicate altogether it is not usually necessary to retreat more than a fringe width to take up the backlash, and the chances of getting on the wrong fringe are minimised.

There are one or two details in the arrangement of *Fig.* 9 which differ from those usually described in text-books and papers, and which require some explanation. The lens is universally made to lie on the flat surface, and in consequence the fringes are seen *through* the lens, and are in general magnified. An object in contact with one surface of a lens is magnified, when observed through the lens, in the ratio f/f_b, where f is the focal length and f_b is the "back focal length," *i.e.* the distance from the principal focus to the surface of the lens. It is only in the special case of a lens in which the other surface is flat, and in which, therefore, the appropriate nodal point coincides with the curved surface, that $f_b=f$. In all other cases the distance traversed by the microscope has to be multiplied by f_b/f to give the true diameters of the rings. In the diagrams illustrating the method this point is always avoided by the convenient choice of a plano-convex lens; but in practice this is the exceptional case. The expedient of placing the flat uppermost, as in *Fig.* 9, overcomes this difficulty entirely.

The use of the illuminating arrangements described here, instead of the usual vertical illuminator above the microscope objective, ensures a parallel beam at normal incidence for all positions of the microscope. With the ordinary method of illumination, in which the light comes as a converging cone from the objective, fringes are only visible with extremely thin air films, and consequently the lens and flat must be in contact. This being so, the expedient is adopted, in dealing with concave surfaces, of measuring the difference in curvature between the surface and a convex surface of greater curvature which rests within it. This is an inaccurate arrangement except when the two curvatures are very nearly equal; as an error in the assumed value of the radius of the convex surface produces a greater percentage error in the result obtained for the concave.

Suppose h is the vertical distance between the two surfaces at a distance ρ from the centre. Let h_1 and h_2 be the respective distances of the convex and concave surfaces above a plane which is tangential to them at their point of contact.

Then if r_1 is the radius of the convex and r_2 that of the concave surface

$$\frac{1}{r_1}=\frac{2h_1}{\rho^2},\quad \frac{1}{r_2}=\frac{2h_2}{\rho^2},$$

$$\therefore \frac{1}{r_1}-\frac{1}{r_2}=\frac{2}{\rho^2}(h_1-h_2)=\frac{2h}{\rho^2}\doteq\text{constant};$$

$$\therefore \frac{1}{r_1{}^2}dr_1=\frac{1}{r_2{}^2}dr_2$$

or

$$\frac{dr_1}{r_1}\cdot\frac{r_2}{r_1}=\frac{dr_2}{r_2}.$$

Thus a percentage error dr_1/r_1 in the assumed value of r_1 gives rise to a percentage error dr_2/r_2, which is r_2/r_1 times as great. Since, except in special cases, r_1 has itself to be determined, and cannot be known to a greater percentage accuracy than is also desired for r_2, the method is not a good one.

With the method of illumination shown in *Fig.* 9 it is quite possible to get fringes with a large total path difference and to measure the radius of a concave surface directly against a flat. The flat is laid on the rim of the lens, as in *Fig.* 9 (*a*), and when the light is properly adjusted the fringes will be seen and can be measured in the same way as for a convex surface. The light has to be absolutely normal, and the angular aperture which the source subtends must be small. The reasons for these precautions need not be treated here; they will be understood from the treatment of interference by thick plates in another article. In making the adjustments the best method of procedure is to mount the lens L on a stand which has rack-and-pinion adjustments both horizontally and vertically. Remove L and adjust R by hand until the fringes appear as distinct as possible. Replace L, and adjust it horizontally and vertically until the rings are equally distinct in all parts of the field. A guide to the correct adjustment will be found in the size of the rings near the centre. Since for normal incidence the retardation is a maximum, the rings shrink to a minimum size when the incidence is normal. The movements of the rings with slight changes in the adjustment of the light give rise to the impression that the results obtained depend entirely on the adjustment. This is not so, however, as the *relative* positions of different parts of the ring system are affected by the adjustment of the light to exactly the same extent as if the surfaces were in contact as in the ordinary method.

The necessity of employing as small a hole as possible at A necessitates the use of a very bright source of light. The green line of mercury is the most useful to employ, and should be obtained from a quartz arc made specially for interference work.[1] The other lines in the spectrum are much less intense than the green line, and only detract slightly from the blackness of the fringes, the positions of which are determined by the green line. The best type of aperture to use at A is a small iris diaphragm, which can be adjusted to give the best compromise between brightness and distinctness.

In employing Newton's Rings for medium and steep curves, the travelling microscope ceases to be satisfactory on account of the smallness of the radii of the rings. It is better in this case to use an ordinary microscope with

[1] Guild, *Proc. Phys. Soc.*, 1920, xxxii. 341.

a micrometer scale in the focal plane of a Ramsden eyepiece, and to measure up the rings on this scale. An objective should be chosen of such power as to give an image of the ring system of suitable size. With steep curves, the objective requires to be of too high a power to allow the interposition of the vertical illuminator shown in *Fig.* 9, and an ordinary vertical illuminator above the objective must be employed. The arrangement cannot then be used for concave surfaces. However, for medium and steep curves the method is no more accurate and is much more tedious than several other methods which will now be described.

§ (8) Microscope Methods.—The following methods require a good microscope stand with mechanical stage and a universal sub-stage with centring adjustments. A vertical illuminator of the ordinary inclined cover glass type is mounted above the objective.

(i.) *For Concave Surfaces.*—The lens is mounted on a support attached to the sub-stage fitting, which can be raised or lowered by the rack and pinion P, *Fig.* 10 (*a*), and centred by the screws *ss*. A piece of thin cover glass on which some easily recognisable markings have been scratched is placed on the stage, and the microscope is focussed on these, vertical illumination being supplied by the lamp L. The sub-stage is then racked up or down until the image of the markings formed by reflection at the concave surface is also seen in sharp focus. By means of the screws *ss* the image is centred with respect to the object, which is then at the centre of curvature of the surface. The cover glass is removed and the microscope racked down until some lycopodium grains sprinkled on the surface of the lens are in focus. The distance the microscope has been moved is the radius of curvature required. The method is accurate to about 0·05 mm.

(ii.) *For Convex Surfaces.* For this case the arrangement is somewhat more complicated. The microscope is initially racked down so that the objective is about the level of the stage. The sub-stage is adjusted until some lycopodium grains on the surface of the lens are in focus. The surface is then at the object point[1] of the microscope. A piece of silvered glass with a number of scratches cut on it is placed at O, and its distance from the vertical illuminator is adjusted until an image of the scratches is seen simultaneously with the lycopodium. Under these circumstances light from the scratches, after reflection at the vertical illuminator and passage through the objective, converges towards the object point of the latter. The sub-stage is then racked upwards until an image of the scratches is again in focus. This happens when the rays converging from the objective meet the surface normally — that is, when the object point of the microscope coincides with the centre of curvature of the surface. The microscope is now racked up-

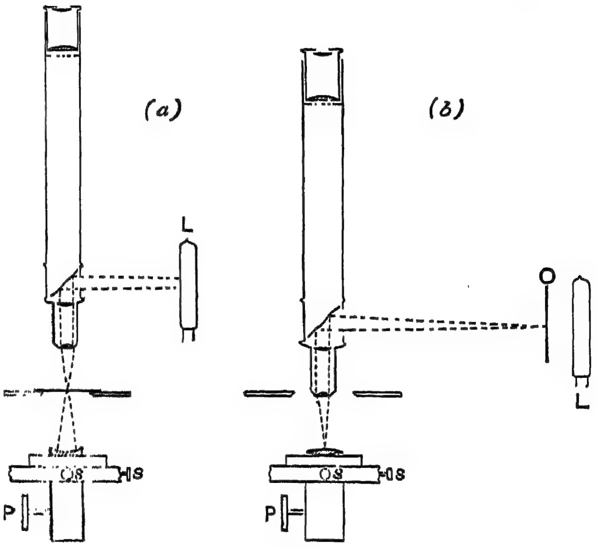

Fig. 10.

wards until the lycopodium is again in focus, and the distance moved is the radius of the surface.

This method is frequently described in an inaccurate manner. By following the procedure outlined above, it will be observed that all adjustments involving the image of the scratches are made with the microscope and the object O in a fixed relative position. This is clearly an essential condition to accuracy. The results are reliable to about 0·05 mm., as in the case of the previous method; but the range of curvature for which it can be used is limited by the working distance of the objective which is available. In the previous method the range was limited only by the range of vertical traverse of the microscope.

(iii.) *Magnification Method for very large Curvatures.*—For large curvatures such as are met with in some of the lenses of microscope

[1] For convenience of description we may use this term to denote the point conjugate to the centre of the focal plane of the eyepiece. To fix the position of this plane a graticule should be fitted.

objectives, none of the methods so far mentioned are satisfactory. The following method is at once extremely simple and extremely accurate; and has the great advantage that the percentage accuracy is practically independent of the curvature. Suppose (*Fig.* 11) that we employ as object a suitable mark on the front lens of the object glass of the microscope, and so adjust a reflecting surface M that an image of this object is seen in sharp focus in the focal plane of the eyepiece. It follows that the image I formed by reflection in the surface is situated at the object point of the microscope and is therefore at a fixed distance from O, $=k$ say, whatever the curvature of the surface may be. From the magnification of the image the curvature can be deduced. Let u be the distance from the surface to the object, v the distance from the surface to the image, and r the radius of the surface. Then $1/u+1/v=2/r$, quantities being regarded as positive when measured against the incident light. $k=\text{IO}=u-v$. The magnification of the image at $\text{I}=-v/u,=m$ say. Hence

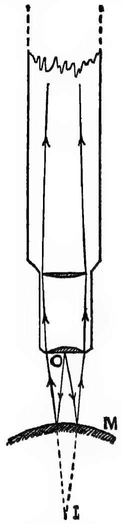

FIG. 11.

$$1-m=\frac{2v}{r},\ \ 1-\frac{1}{m}=\frac{2u}{r},$$

$$\therefore m-\frac{1}{m}=\frac{2k}{r} \quad . \quad . \quad . \quad \text{(i.)}$$

or

$$r=\frac{-2mk}{1-m^2}. \quad . \quad . \quad . \quad \text{(ii.)}$$

From (i.) we see that in general there are two distances of the mirror from the object which satisfy the condition of the experiment, namely the value of u which gives a magnification m, and another value u' for which the magnification is m', where $m'=-1/m$. In the case of a convex surface one of these values is negative and so is experimentally inadmissible. The other value is such that the magnification is $+ve$ and numerically less than unity.

For a concave surface, both values of u are positive. In one case u is less than $r/2$ and the magnification is positive and greater than unity. In the other case u is greater than r, and the magnification is $-ve$ and numerically less than unity.

This method can be employed over a large range of curvature; but the best experimental conditions differ for different ranges.

For very short radii the arrangement of *Fig.* 12 is convenient. The microscope is fitted with a vertical illuminator, preferably of the type shown, in which the reflecting cover-slip is just under the eyepiece. Light is supplied by a small 4-volt lamp, attached for convenience to the microscope. The illuminated aperture of the lens itself serves as the object. The curve C to be measured is placed centrally on the stage, and, on racking the microscope up or down, a circular disc will be seen which is the image by reflection in C of the aperture of the objective. This is sharply focussed and its diameter measured on a micrometer scale in the focal plane of the eyepiece. The actual dimensions depend of course on the magnification of the microscope as well as the magnification m of the reflected image. However, for a given objective and tube length, the measured diameter is proportional to the magnification m. The instrument is calibrated by measurements on a series of the steel spheres sold as ball-bearings. These can be obtained of diameters ranging from $\frac{1}{32}$ of an inch to 3 inches by small steps. The sizes up to about an inch make excellent optical standards, and a complete set should be available in any laboratory. They can be measured with a micrometer gauge; but it will be found that they are invariably so close to their nominal values that for optical purposes these values can be taken as substantially correct.

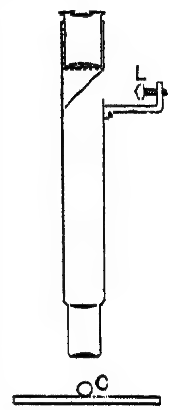

FIG. 12.

The accuracy with which the diameter of the luminous disc can be measured depends of course on its size. An objective should be employed which gives an image of at least 4 mm. on the eyepiece scale. The size of the image depends not only on the power of the objective but also on its working distance and the linear dimensions of the aperture. However, it is easy to find a series of three or four objectives which between them will cover the range from the smallest radii encountered in microscope work up to radii of about 10 mm. If, by means of the steel balls, calibration curves are drawn for each objective for the range in which it is to be used, they will be found to be practically straight lines within the accuracy of observation. This follows at once from the relation $r=-2mk/1-m^2$ when m is very small, as is the case with surfaces of such short radii. Thus the scale reading is proportional to the

radius. By a single reading the radius of any surface can be obtained from the calibration curve. It is safer, however, to make check measurements on one or two of the spheres each time the apparatus is reassembled, to ensure that the constant of the instrument has not been altered.

It is evident that the calibration curve obtained with the spheres will do equally well for the measurements of concave curves, the real image formed being of the same magnification as the image obtained with a convex curve of the same radius.

It will be observed that if suitable objectives are employed, the diameter of the disc to be measured is of the same order of magnitude (40 to 100 scale divisions), however small the radii tested may be. Since it is easy to read to ·1 scale division (with a good quality micrometer scale), the average sensitivity of the method is about 1 part in 700. Further, the method is virtually one of substitution, and all aberrational effects of the observing microscope are eliminated.

Thus there is no source of error other than the accidental errors of measurement, and the accuracy is equal to the sensitivity.

In practice the definition is improved by using a light green filter to cut out the extremities of the spectrum, as, if white light is used, chromatic aberration tends to spoil the sharpness of the image.

(iv.) *Magnification Method for Medium Curvatures.*—It is not convenient to use the method in the form described above for radii much over 1 cm., because the disc becomes too large to be contained in the field of view even with the lowest power objectives.

For larger radii it is better to use as object a scale, similar to that employed in the eyepiece, attached to the front of the objective with soft wax or plasticene. An image of this scale is seen when the object is at the correct distance from the surface. By measuring the dimensions of a suitable number of graduations, the magnification can be obtained from a knowledge of the magnification of the microscope. We may, if we choose, determine k, and calculate the radius directly from formula (ii.) above. To measure k a flat surface, preferably silvered, is laid on the stage and the microscope focussed on some scratches on the silver. On racking downwards, an image of the scale comes into focus. The distance which the microscope has been moved is clearly $\frac{1}{2}k$.

As in the case of very small radii, however, it is better to calibrate the instrument empirically. Unfortunately, there are no easily available standards such as the ball-bearings employed in the former case; but points on the curve can be obtained from measurements on lens surfaces which have been determined accurately with a spherometer. If sufficient of such standards are available to determine the calibration curve accurately, an unknown radius can be obtained directly from the curve; but it is usually better to measure m for the surface in question and also the corresponding value for the *nearest* standard, and deduce the unknown radius from the formula

$$r=r_1\frac{m(1-m_1^2)}{m_1(1-m^2)}.$$

In the case of concave curves, if the radius does not exceed two or three centimetres, it is easy to obtain the real and diminished image, and in this case the convex standards apply to concave curves as well. With shallower curves, however, the real image is too far from the lens to be within the range of vertical traverse of ordinary microscopes; and it is necessary to work with the virtual image, for which, as we saw earlier, m is greater than unity. A separate set of concave standards is necessary for those. Unfortunately, as the magnification increases the image of the scale becomes very faint, and the measurement is somewhat difficult with magnifications greater than unity. The range of curvature for which the diminished real image can be utilised may be increased by mounting the lens on the sub-stage or even on a separate support below the microscope.

Except with comparatively small radii the 4-volt lamp L (*Fig.* 12) will not give a sufficiently bright field. It is better to employ a 100 c.p. "Pointolite" lamp, or any similarly intense source, behind a ground-glass screen situated about 30 cm. from the microscope and on a level with the aperture of the illuminator. Except for the ground glass the lamp should be entirely enclosed.

The scale employed as object should not be too fine. A $1\frac{1}{2}$-inch objective with a working distance of about an inch will give satisfactory results over most of the range for which the method is applicable.

There are a variety of other magnification methods; but they involve the measurement of two magnifications and are inferior in convenience and accuracy to that just described.

§ (9) Direct Location of Centre.—For concave curves of radii above 20 cm. this method may be employed provided the ratio of the diameter of the surface to the radius of curvature is not too small. The principle of the method is that if an object and its image by reflection in the surface are coincident, or in close juxtaposition in a plane perpendicular to the axis of the surface,

they are located at the centre of curvature. The method as usually described, in which the image is formed on a card, is not, however, very sensitive; and if the best possible accuracy is required in the result the following arrangement will be found much better. A microscope slip is silvered or platinised on one side, and a network of very fine scratches is made with a sharp needle. The slip is mounted on the stage of a microscope which is turned back so that the microscope tube is horizontal. The scratches are illuminated by means of a small prism P, *Fig.* 13 (*a*), and a "pointolite" lamp S. The concave surface M is arranged so that an image is formed on the slip a little microscope more critically than almost any other type of object, and the depth of focus is reduced to a minimum. The accuracy depends on the ratio of diameter to radius of curvature. It is about 0·1 millimetre for a ratio of 1 : 20.

The direct location of the centre is unfortunately impossible with convex surfaces. The method in which an auxiliary lens is used to produce a convergent beam, which meets the convex surface normally and is reflected back through the lens and focussed in the vicinity of the object, is valueless for work of any accuracy on account of the aberrations of the lens.

§(10) Foucault's Shadow Method.—This

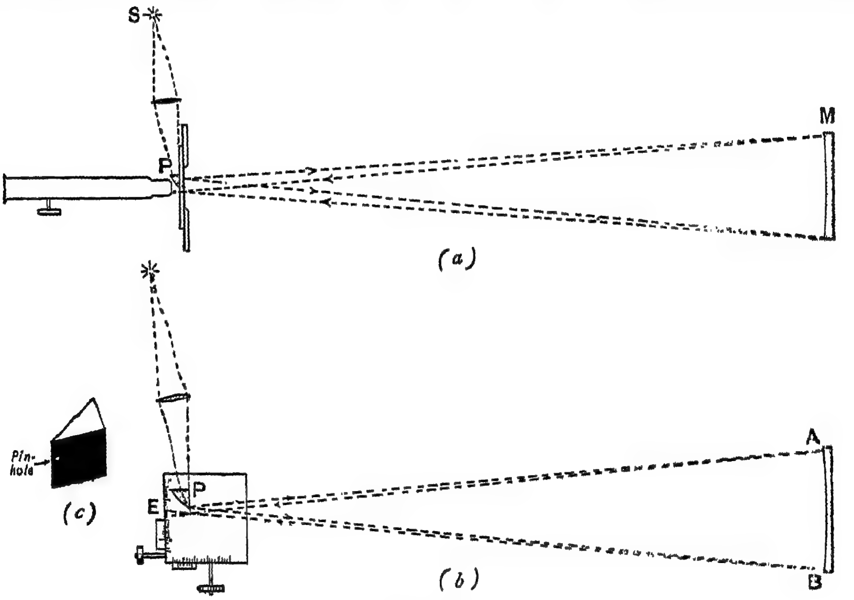

Fig. 13.

to the side of the illuminating prism P. In this region the plating should be almost all scraped off, a few streaks being left on which to focus the microscope. When the adjustment is correct, these streaks and the reflected image of the illuminated scratches will be simultaneously in focus. The plated side of the slip should be towards the mirror, and the distance between them can be measured in any convenient manner. It is advantageous in practice not to attempt precise adjustment of the mirror, but to get it approximately correct and measure the error by racking the microscope so that first the surface of the slip is in focus and then the reflected image. Half the distance between the two positions is the correction to be applied to the distance from slip to mirror. The edges of a silvered film can be focussed up with a is another useful method for concave curves. It forms at the same time a sensitive test of the sphericity of the surface. A convenient arrangement is shown in *Fig.* 13 (*b*). P is a small 45° prism with clean sharp edges. One of the square faces is covered with tinfoil in which a fine hole has been pierced with a needle close up to one of the 45° angles, *Fig.* 13 (*c*). This prism is mounted on a platform capable of fine adjustment in two directions. A good mechanical stage of a microscope will do. The pinhole is illuminated by focussing on it a very bright source, *e.g.* a "pointolite" lamp. A beam of light spreads out from the pinhole, and the mirror AB is placed so that an image of the pinhole is formed just a little to the side of the prism. The eye is placed just behind the prism at E so as to receive the reflected light. Since

this comes from all parts of the surface the latter appears uniformly bright all over. If, now, the prism is moved laterally, so as to bring the pinhole closer to the axis of the mirror, a point is reached at which the edge of the prism cuts into the reflected beam and shuts off some of the light reaching the eye. Assume first that the surface is truly spherical so that all rays corresponding to one point of the object converge to one point in the image. If P is exactly at the centre of curvature it will cut the beam exactly at the image, and the surface will darken uniformly all over. If P is inside the focus the rays from A are intercepted before those from B and a shadow comes over the surface from A to B. If P is outside the focus the shadow starts from B. The stage is moved longitudinally until the lateral movement produces a darkening of the whole surface simultaneously. The distance from the pinhole to the surface is then the radius of curvature. As a test of the surface this method is valuable. If there are any parts of it from which rays do not converge to the same point as from others, the surface will not darken uniformly in any position of P. If, for instance, the focus for the peripheral zone is farther out than for the central zone, and P is at the focus of the latter, the central zone will darken uniformly, but the rays from A will be cut off, while those from B will not. A crescent-shaped region near A will therefore remain bright after the remainder of the surface is obscured. If P is at the focus of the marginal rays the regions near A and B will darken simultaneously; but rays from the side of the central zone nearest A will pass the edge of the prism and this region will appear bright.

The effect of local irregularities is to give a patchy appearance to the field. The exact path of the rays from different parts of the surface can be determined, for the place where the rays from any two parts, say the centre and any other region, intersect the same vertical plane parallel to the axis is found by adjusting P till the two parts in question darken simultaneously. By making observations with AB in azimuths differing by 90° the paths of the rays may be completely determined.

§ (11) Summary. The methods of curvature measurement described in the preceding sections provide complete equipment for curvatures of all possible magnitudes. Where to leave off one method and use another depends largely on the predilections of the observer, as their ranges of utility overlap. As the intention was to give only those methods which are of general application, description has had to be omitted of various useful methods, suitable for works practice, where the possession of both the convex and concave curves of any radius is assumed.[1] J. G.

SPIRIT-LEVELS

§ (1) General.—Spirit-levels are used to determine the direction of the horizontal, or vertical, at any point, and sometimes to measure small angles from the horizontal. The usual form consists of a glass tube shaped so that the longitudinal section of its upper internal surface is the arc of a circle. The tube is nearly filled with liquid, so that a bubble of vapour is left. The bubble rises to the highest portion of the tube, and when at rest the line joining the two ends is horizontal. The tube is generally graduated on its upper surface. The graduations are generally single or double millimetres, $\frac{1}{10}$ths or $\frac{1}{20}$ths in., or in older instruments Paris lines (2·26 mm.), and may be continuous or have the centre marks omitted. The line joining the ends of the bubble, when those ends are equidistant from the centre of the tube as shown by the graduations, may be called the axis of the bubble. The glass tube is generally fixed in a metal tube, cut away to enable the bubble to be seen, and this tube is again adjustably fixed to some mount. For rough work it is sufficient to fix the bubble tube so that the instrument to which it is attached is level when the bubble is in the centre of its run, and trust to the adjustment remaining constant. The bubble is in adjustment when its axis is parallel to the base of its mount, or to the surface which it is desired to level. A tubular bubble will obviously only indicate the horizontal in the direction of its length, and if a surface has to be levelled two bubble tubes are required at right angles to each other.

§ (2) Circular Bubbles.—For rough work a circular bubble is often convenient. In this case the upper surface of the vessel containing the liquid is a portion of a sphere, and dislevelment in any direction is shown by the one bubble. *Fig.* 1 shows two forms of circular

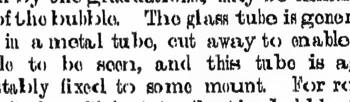

Fig. 1.

bubbles. A has the vessel containing the liquid formed of a completely sealed-up glass vessel, B has only the top of glass; it is more compact than A, but it is difficult to ensure that there shall be no slow leakage.

§ (3) Tubular Bubbles.—Where the horizontal is required with an error of less than a minute or so of arc, tubular bubbles are

[1] See, for instance, S. D. Chalmers, *Trans. Opt. Soc.*, 1915-16, xvi. 168.

almost always used, and they must be made so that they can be reversed end for end in order to check the adjustment.

For levelling a plane surface the under surface of the level mount is also a plane surface. If this now rest on a flat surface, which is tilted as necessary till the bubble lies in the centre of its run, the surface is level in the direction of the length of the bubble tube, provided the bubble is in adjustment. The adjustment is checked by reversing the bubble tube end for end. If the bubble still lies in the centre of its run the adjustment is correct. If it has moved it is brought back half-way by tilting the surface and the rest of the way by the adjusting screws on the bubble mount. The whole is then checked by reversal. It is not necessary for the bubble to be in adjustment; if the bubble remain in the same position in the tube after

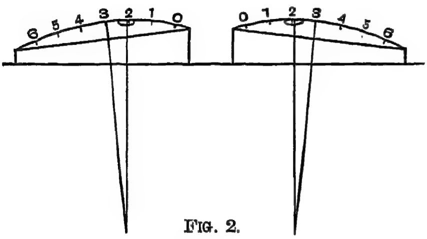

FIG. 2.

reversal, the surface is level. A consideration of *Fig.* 2 will make this clear.

§ (4) STRIDING LEVEL.—For levelling the axis of a cylinder, such as the telescope of a collimator or the horizontal axis of a transit, the level is mounted as shown at Q in *Fig.* 3. This is known as a striding level.

§ (5) USE OF LEVEL FOR MAKING A VERTICAL AXIS VERTICAL.—In order to make the vertical axis of rotation of any instrument (*e.g.* a theodolite) truly vertical, a bubble tube is fixed to the rotating portion of the instrument at right angles to the axis. If the bubble axis is truly at right angles to the vertical axis it is only necessary to set the bubble by means of the instrument levelling screws, in two positions at right angles to each other. In practice the instrument is rotated till the bubble tube is parallel to two of the levelling screws of the instrument, and by their means the bubble is set, *i.e.* brought to the centre of its run. The instrument is then rotated through 180°. If the bubble remain set the bubble is in adjustment; if not, the bubble is brought back half-way to its original position by means of the levelling screws, the instrument is again rotated through 180° into its original position, when the bubble should retain the mean position at which it was last set. The instrument is then rotated through 90° and the bubble set to the mean position as found above by means of the third levelling screw. The bubble should now take up the same position however the instrument is rotated, and if this is so the vertical axis is vertical. It is usually necessary to repeat the reversals several times before this condition is obtained. If the mean position of the bubble is not the centre of the tube the

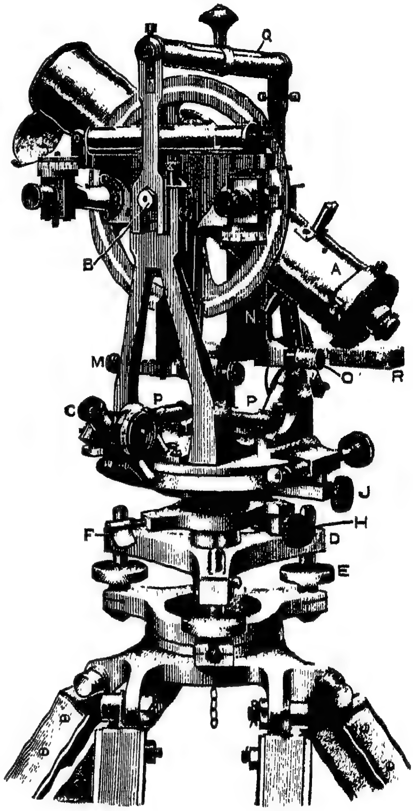

FIG. 3.

bubble can be brought into adjustment by means of the bubble-adjusting screws, but unless it is badly out of adjustment this is not worth while.

§ (6) THE SENSITIVENESS OF A BUBBLE, *i.e.* the amount the bubble will move when the tube is tilted through a small angle, varies directly as the radius of curvature of the tube, and is generally measured by the angle of tilt necessary to move the bubble through one division of the tube.

§ (7) THE ACCURACY OF A BUBBLE depends on other factors as well as on its sensitiveness, notably on the length of the bubble itself, and the method of illumination and viewing

adopted, and also of course on the accuracy of the figuring of the surface of the tube. When the tube is tilted and the ends of the bubble cease to be at the same level, a force due to this difference of level tends to move the liquid. This force is proportional to the specific gravity of the liquid and to the difference in level of the ends of the bubble. The difference of level or "head" is $l \sin a$, where l is the length of the bubble and a the angle of tilt. This force therefore varies as the length of the bubble, and is independent of the curvature. This force has to overcome the inertia of the liquid and the frictional forces. The more sensitive the bubble the greater the work that has to be done to move the liquid to its new position; hence the slower the movement.

The accuracy required in forming the surface of a sensitive bubble tube is very great. The following example gives some idea of the accuracy necessary. Suppose the tool used in forming the surface vibrates in such a manner as to superimpose a sine curve on the theoretical circle, and that the equation of this curve is $y = k \sin(2\pi x/p)$, where y is the linear departure from the true curve at any point whose distance along the curve is x, k is the maximum value of y, and p the period of the sine curve. For a displacement dx of the bubble the change of level of one end of the bubble is $(l\,dx/2R) + (y_1 - y_2)\cos\theta = h$, where l is the length of the bubble, R the radius of curvature, and θ the angle between the radius at the end of the bubble and the vertical. Thus $\theta = l/2R$, and $\cos\theta$ may be considered as unity. If h and h' are the changes in level at the two ends the corresponding angular tilt is $(h+h')/l = a$, whence

$$a = \frac{4k}{l}\sin\frac{\pi l}{p}\sin\frac{\pi dx}{p}\sin\frac{\pi(2x+l+dx)}{p} + \frac{dx}{R}.$$

The first term represents the error in sensitiveness at the point considered. This shows that in general the error is reduced with increase in l, but the term $\sin \pi l/p$ will vary from 1 to 0 as l varies. Applying this to a bubble with a mean sensitiveness of 10·3″ per millimetre (R = 20 metres) and an irregularity represented by k = ·0005 mm., p = 10 mm., length of bubble 35 mm., it is seen that the tilt necessary to move the bubble 1 mm. varies from 6·8″ to 13·8″. If the length of the bubble be increased to 40 mm. the error vanishes. If R = 100 metres (sensitiveness about 2″ per mm.) and the length of the bubble 65 mm., the tilt to move the bubble 1 mm. varies from 0·0″ to 3·9″, it will be difficult to set the bubble, and no accuracy can be obtained in reading small angles of dislevelment. The above shows that the tube must be very accurately shaped, especially if angles of dislevelment are to be read; it also shows that it is useless to attempt to calibrate a bubble tube, as the errors depend on the length of the bubble itself, and this is continually varying with changes in temperature.

§ (8) Effect of Temperature Changes.—If the temperature of the tube rises the liquid will expand and the bubble itself will contract. If the bubble become unduly short the level becomes unsatisfactory. To obviate this, sensitive bubble tubes are often made with a chamber as shown in *Fig.* 4, so that the length

Fig. 4.

of the bubble can be adjusted by allowing more or less of the air to be caught in the chamber. If the tube be unevenly heated it will become distorted, and the same will happen if the tube be mounted in a metal mount so that it is strained by unequal expansion of the glass and metal. If the liquid be unevenly heated the warmer portion will have its density reduced and will take up more room and so cause the bubble to move irrespective of tilt. A still more important effect of unequal temperature is probably that due to the alteration of the surface tension of the liquid with change of temperature. In general the surface tension is reduced by increase of temperature, consequently the stronger surface tension at the cooler end of the bubble will cause the air bubble to move towards the warm end. It is therefore important that sensitive bubbles should be carefully shielded from becoming unevenly heated, and it is advisable to enclose the bubble tube and its mount in an outer glass tube.

§ (9) Mounting the Bubble Tube.—The bubble tube is usually fixed in its metal mount by means of plaster of Paris, but this is not suitable for sensitive bubbles. Another method is for the tube to rest on two Y-shaped supports, and be held in place by springs; the Y's and springs may be lined with cork. Another method is to fix a metal cap on each end of the tube with wax. The caps are split and one portion turned up slightly to form a spring. The caps are then secured in the metal mount by means of three screws each, one of which presses against the sprung portion of the cap. The metal tube must also be mounted so that it can be adjusted without it being strained. One end must be capable of a small turning movement, while the other is fixed by two or four antagonising screws, or by a screw working against a spring.

§ (10) Method of Viewing the Bubble.—The accuracy of setting or reading the bubble depends not only on the sensitiveness and

accuracy of the tube itself, but also on the method of viewing and illuminating the bubble. In the usual method of mounting the bubble is both lit and viewed from the top. In this case the appearance of the bubble ends varies with the direction from which the light falls, and there is also a parallax effect depending on the thickness of the glass — this being specially noticeable with a long bubble. The best method of illuminating the bubble appears to be by transmitted light, the mounting tube being cut away below as well as above, and a suitable reflector provided beneath it. If the bubble be mounted in this way the edges and ends of the bubble are better defined if the sides of the bubble tube are blackened. In many instruments, *e.g.* engineers' levels and theodolites, the bubble is so mounted that it cannot be viewed by the observer from his position at the end of the telescope; he has to move round the instrument to see the bubble, and by this movement he may tilt the whole instrument unless it stand on an exceptionally firm base. This effect can be largely overcome by viewing the bubble in a mirror, but,

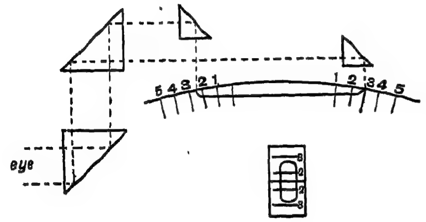

Fig. 5.

unless the mirror is at the correct inclination —and this varies according to the position of the eye,—parallax is not avoided, and the divisions of the scale at the two ends of the bubble being at different distances from the eye, they appear of different sizes. Both these effects are liable to introduce errors. A combination of reflecting prisms such as that shown in *Fig.* 5 avoids these errors, and also enables the ends of a long bubble to be viewed close together. The method of viewing the bubble shown in *Fig.* 6 (introduced by Messrs. Zeiss) entirely eliminates parallax, and enables the bubble to be set with very great accuracy. If the line *ab* of the prism is vertically over the centre line of the bubble, one half only of each end of the bubble is seen; and if the ends of the bubble are equidistant from *c*, the appearance is as shown in *Fig.* 6 (*a*). As the bubble moves to the right the two ends appear to move in opposite directions, and the appearance is as in *Fig.* 6 (*b*). The bubble is set by bringing the two ends into coincidence as shown in *Fig.* 6 (*a*). This arrangement more than doubles the accuracy of setting, as the separation of the two ends as seen in the prism is double the actual movement of the bubble, and it is much easier to bring the two ends into coincidence than to judge when the bubble is lying evenly between the marks on the tube. Another advantage of this arrange-

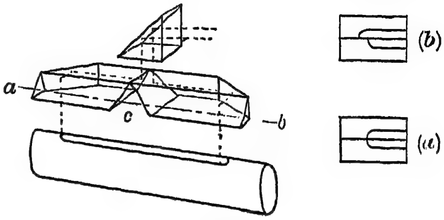

Fig. 6.

ment is that the bubble can be very easily adjusted, the final adjustment being made by shifting the prism box along the tube instead of tilting the tube itself; this is a far coarser and easier mechanical adjustment for a given angular adjustment.[1] This arrangement is probably the best so far devised for setting the bubble, but is not so suitable for use where it is required to read small angles of dislevelment. An attempt has been made to get the same facility of adjustment by marking the graduations on an outer glass tube instead of on the bubble tube itself; this method, however, increases parallax errors.

§ (11) Testing Bubble Tubes. — The "bubble tryer" shown in *Fig.* 7 is used for testing the sensitiveness and accuracy of bubble tubes. The bubble tube to be tested is placed on the Y's, the instrument is levelled laterally by the supporting screws on the right. The bar supporting the Y's can be tilted by means of the micrometer shown at the left. The dimensions of the instrument are calculated so that one revolution of the screw tilts the bubble by a definite number of seconds.

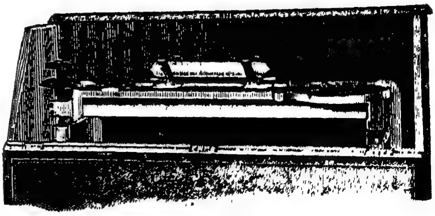

Fig. 7.

For sensitive bubbles a double lever arrangement can be used. By this means the angle necessary to move the bubble through any of the divisions of the scale can be found, hence

[1] *Fig.* 16 of article "Surveying and Survey Instruments" shows an instrument with this arrangement.

the mean angular value of a division and the constancy of this value. It will be seen from what has been said above that it is not possible to calibrate a bubble tube, as with an inaccurate tube the sensitiveness will vary with the length of the bubble itself.

STRINGS, VIBRATIONS OF

To investigate the transverse vibrations of a tense string or wire we take the axis of x along the undisturbed position and denote by y the transverse displacement at time t of that point whose equilibrium co-ordinate is x. If T_1 be the stretching force the transverse forces on the ends of an element δx are

$$-T_1 \sin\psi, \text{ and } T_1 \sin\psi + \delta(T_1 \sin\psi), \quad (1)$$

where ψ is the inclination of the curve to the axis of x. Hence if ρ be the line density, we have

$$\rho\delta x\frac{\partial^2 y}{\partial t^2} = \delta(T_1 \sin\psi). \quad . \quad . \quad (2)$$

This equation is accurate, but if ψ is everywhere small we may neglect the changes of tension, and further write $\sin\psi = \tan\psi = \partial y/\partial x$ with sufficient approximation. Thus

$$\frac{\partial^2 y}{\partial t^2} = c^2\frac{\partial^2 y}{\partial x^2}, \quad . \quad . \quad . \quad (3)$$

where $$c = \sqrt{\left(\frac{T_1}{\rho}\right)}. \quad . \quad . \quad . \quad (4)$$

The simplest, and naturally the most important, case is where the string is uniform, and c accordingly a constant. The general solution of (3) is then

$$y = f(ct - x) + F(ct + x). \quad . \quad . \quad (5)$$

It is easily verified, in fact, that this satisfies (3), and the arbitrary functions f and F enable us to satisfy prescribed initial and terminal conditions. For instance, in the case of an

unlimited string started from rest in the form $y=\phi(x)$ the solution is evidently

$$y=\tfrac{1}{2}\{\phi(x-ct)+\phi(x+ct)\}, \quad . \quad . \quad (6)$$

since this makes

$$y=\phi(x), \quad \frac{\partial y}{\partial t}=0, \quad . \quad . \quad (7)$$

when $t=0$.

If t be increased by any arbitrary amount τ, and x by $c\tau$, the value of the first term in (5) is unaltered. Hence this term, taken alone, would represent a wave-form travelling unchanged in the direction of x-positive with the constant velocity c. Similarly, the second term in (5) represents a wave travelling with velocity c in the negative direction. From the generality of the solution (5) we infer that any initial disturbance of the string resolves itself into two waves travelling in opposite directions. In the particular case where the string is started from rest, the formula (6) shows that the two waves are identical in form, and have at corresponding points half the original amplitude.

The kinetic energy of any portion of the string is given by

$$T=\tfrac{1}{2}\int\left(\frac{\partial y}{\partial t}\right)^2\rho dx, \quad . \quad . \quad . \quad (8)$$

the integral being taken over the portion in question. Since the length of an element is altered from ∂x to sec $\psi\delta x$, the work done in stretching it is

$$T_1(\sec\psi-1)dx=\tfrac{1}{2}T_1\left(\frac{\partial y}{\partial x}\right)^2\delta x,$$

to the second order. The potential energy is therefore

$$V=\tfrac{1}{2}T_1\int\left(\frac{\partial y}{\partial x}\right)^2dx, \quad . \quad . \quad (9)$$

the integral being taken over the disturbed portion. In a "progressive" wave, *i.e.* a wave travelling in one direction only, say

$$y=f(ct-x), \quad . \quad . \quad . \quad (10)$$

we have

$$\frac{\partial y}{\partial t}=-c\frac{\partial y}{\partial x}, \quad . \quad . \quad . \quad (11)$$

and therefore $T=V$, in virtue of (4). The energy is therefore half kinetic and half potential.

When the string is limited in one or in both directions reflection will take place. For instance, if the origin be fixed we must have, in (5), $f=-F$ for all values of the variable, and therefore

$$y=F(ct+x)-F(ct-x). \quad . \quad . \quad (12)$$

If we suppose the string to lie to the right of the origin, the first term represents a wave of arbitrary form travelling towards the fixed end, whilst the second represents the reflected wave. This is anti-symmetrical to the original wave, *i.e.* it is identical in form except that it is reversed in sign, and also end for end.

In Acoustics we are concerned with strings of finite length, fixed at both ends. Supposing these to be the points $x=0$, $x=l$, the formula (12) will apply, provided

$$F(ct+l)=F(ct-l) \quad . \quad . \quad (13)$$

for all values of ct. The function F is therefore unaltered whenever the variable is increased by $2l$, and the values of y and dy/dt will therefore recur exactly whenever t increases by $2l/c$. Hence, whatever the initial circumstances, the motion of the string is strictly periodic, the period $2l/c$ being the time a wave would take to travel over twice the length of the string. In this respect strings occupy an almost unique position among vibrating systems of multiple freedom. The only other acoustical instance is that of longitudinal vibrations of uniform rods or columns of air.

To treat the question by the more general procedure of the Theory of Vibrations we inquire what modes of vibration are possible in which the motion of each particle is simple harmonic with uniform period and phase. Assuming

$$y=u\cos(\omega t+\epsilon), \quad . \quad . \quad (14)$$

where u is a function of x only, we find that (3) is satisfied, provided

$$\frac{d^2u}{dx^2}+\frac{\omega^2}{c^2}u=0, \quad . \quad . \quad . \quad (15)$$

whence

$$u=A\cos\frac{\omega x}{c}+B\sin\frac{\omega x}{c}. \quad . \quad (16)$$

Since u is to vanish for $x=0$ and $x=l$, we must have $A=0$ and $\sin(\omega l/c)=0$, or

$$\omega=\frac{s\pi c}{l}, \quad . \quad . \quad . \quad (17)$$

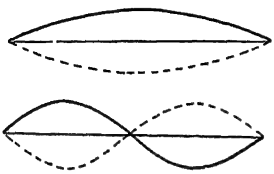
where s is integral. We infer that there is an endless series of normal modes (as they are called) of the type

$$y=B_s\sin\frac{s\pi x}{l}\cos\left(\frac{s\pi ct}{l}+\epsilon_s\right), \quad . \quad (18)$$

where the constants B_s and ϵ_s are arbitrary. The mode corresponding to $s=1$ is called "fundamental"; in it the form of the string at any instant is that of a semi-undulation of a curve of sines. In the next member ($s=2$) of the series the string forms a complete undulation, with a point of rest, or "node," at the middle point. In the mode corresponding to any other value of s there are $s+1$ nodes (counting the ends), and s intervening "loops," or points of maximum amplitude.

The frequencies ($\omega/2\pi$) of the successive modes form a harmonic series—

$$\frac{c}{2l}\times(1,\ \tfrac{1}{2},\ \tfrac{1}{3},\ \tfrac{1}{4},\ \ldots\ ).$$



This relation of frequencies has important consequences in Acoustics.[1] As is suggested by a remark already made, it is peculiar to strings and to one or two other ideally simple systems. Even in the case of a string the harmonic relation is at once violated if the density is not uniform, or if the flexural stiffness of the wire has to be taken into account.

The frequency of the fundamental mode, which determines the "pitch" of the note produced, is

$$\frac{c}{2l}=\frac{T_1^{\frac{1}{2}}}{2l\rho^{\frac{1}{2}}}. \quad . \quad . \quad . \quad (19)$$

It is lowered by increase of length or of line-density, and raised by increase of tension. These points have familiar illustrations in the structure and tuning of the pianoforte.

So far, the string has been supposed free from external force. To illustrate the case of "forced" vibrations we may imagine that a prescribed vibration

$$y=\beta\cos\omega t \quad . \quad . \quad . \quad (20)$$

is imposed at the point $x=a$. The two parts of the string are to be treated separately, since the equation (3) is violated at the point in question. The solution is

$$y_1=\frac{\sin(\omega x/c)}{\sin(\omega a/c)}\beta\cos\omega t, \quad . \quad (21)$$

for $0<x<a$, and

$$y_2=\frac{\sin\{\omega(l-x)/c\}}{\sin\{\omega(l-a)/c\}}\beta\cos\omega t. \quad . \quad (22)$$

Each of these expressions is seen to come under the form (5), whilst for $x=a$ the values of y_1 and y_2 agree with (20). The amplitude of y_1 or y_2 becomes very great whenever $\omega a/c$ or $\omega(l-a)/c$ is a multiple of π, *i.e.* when the imposed period approximates to a natural period of either of the two segments of the string. We have here an illustration of the principle of Resonance (see "Simple Harmonic Motion," Vol. I.), but it is to be remembered that when the amplitude exceeds certain limits dissipation forces become important.

It is to be remarked that the direct action of a string in starting air waves is quite insignificant. In the pianoforte, for example, the periodic pressures on the bridges near the ends of the string set the whole area of the sounding-board into vibration, and this is really the origin of the audible sound. There is, of course, a certain reaction on the string itself, but this is negligible except in so far as the loss of energy gradually brings the vibrations to an end.

SURVEYING AND SURVEYING INSTRUMENTS

I. Surveying in General

§ (1) Introduction.—Surveying consists in the application of physical measurement to the earth's surface, and furnishes a basis for its discussion. Land surveying may be divided roughly into three classes, cadastral, topographical, and geodetic, but there is no clear-cut division between them. Strictly speaking, a cadastral survey is concerned only with property boundaries, the topographical with natural features and physical objects, and geodetic with the shape of the earth. In any highly developed country a cadastral survey must be on a large scale, and any large scale survey is frequently called a cadastral survey. For example, the large scale Ordnance Survey maps of the United Kingdom are sometimes called cadastral maps, although they do not show property boundaries as such; they show

the physical divisions of the land such as hedges, walls, or ditches, which may or may not be the actual property boundaries. They are therefore, strictly speaking, topographical maps on an unusually large scale. On the other hand, a cadastral map is of little use if it does not include some topographical features. Generally speaking, a topographical map should show all the accidents of the surface which distinguish it from a featureless plane and which are of sufficient size to be shown legibly on the map. To satisfy these requirements on a scale larger than six inches to the mile (or about 1/10,000) would be very expensive and of little general use, and such large scale maps are only made of small areas for special engineering purposes. The smallest scale which can be considered a topographical map is about 1/500,000, maps on scales smaller than this become compilations or atlas maps. The scales most used for topographical purposes vary from 1/25,000 to 1/250,000. A geodetic survey does not in itself result in a map, but it is impossible to produce a good topographical or cadastral map of any considerable area without measurements which approach the accuracy required for geodetic purposes, and if the maps are to be on any but the smaller scales geodetic accuracy is necessary.

Land surveying is a very ancient art, and was carried out in Egypt as early as 3000 B.C., being required for laying out property boundaries on the land covered by the Nile floods, and for measuring the areas of holdings for revenue and land registration purposes.[1]

§ (2) Accuracy Required.—In deciding on the methods to be adopted in any given case it is necessary to consider on the one hand the precision of measurement and the elimination of errors of observation, and on the other the nature of the region to be surveyed and the purpose for which the results are required. Superfluous accuracy may lead to as unprofitable expenditure as an attempt to survey a large area without suitable means of controlling and eliminating the errors which must occur. For economical work there must be a proper adaptation of the means available to the end in view. The attainment of this requires a knowledge of the principles on which all survey work is based, and of the causes, and laws of accumulation, of the errors in the various processes.

The ideal accuracy is such that no error in fixing the position of any point is greater than the smallest amount that can be plotted on the largest scale map which is to be produced. While this limiting error should never be exceeded, it must be remembered that the final error in the position of a point depends not only on the immediate measurements made to it, but includes the errors of the points from which it is fixed. It is necessary therefore to provide a framework of points fixed with great accuracy, and with any errors that may appear, distributed in the best manner possible. These points are then used to control the detail of the survey, and prevent the accumulation of errors. By this means the bulk of the work can be done by rougher methods, and the most accurate, and therefore most expensive, work reduced to a minimum.

When commencing any new survey it is always economical in the long run to provide a framework, over the whole area to be surveyed, of the highest accuracy that is likely to be required in the future, and so to arrange it that it can be extended if and when the area is to be extended. If the framework is only just sufficiently accurate for a small scale topographical map, it will be useless for a larger scale, or more extensive, survey in the future. Limitations of time, or funds, available may necessitate a lower degree of accuracy, but it is generally false economy to hurry unduly or to starve the provision of this primary framework. If such an accurate framework is provided the points composing it must be marked in a permanent manner, so that they can be accurately identified at a future time; it is obvious that any failure in this respect makes the work useless for anything but the survey immediately in hand.

§ (3) Co-ordinates.—In all cases the general principles of fixing and defining the points are the same. The position of a point is defined either numerically or graphically by some system of co-ordinates, one co-ordinate being always measured vertically, *i.e.* in the direction of the force of gravity through the point. A surface which is everywhere at right angles to the vertical is a horizontal, or level, surface. The simplest example of such a surface is that of a lake or sea at rest, and the other two co-ordinates are generally measured on the surface represented by the mean level of the sea, supposed to be continued through the land. This surface constitutes the "Geoid," being the mathematical "figure of the earth" (see the article on "Gravity Survey," Vol. III.). The shape of the geoid approximates to an oblate spheroid having a semi-major axis of about 6,378,000 metres and an eccentricity of about 1/299. In surveys of large areas, such as countries or continents, it is necessary to take account of the spheroidal shape, and measurements are reduced to some selected "spheroid of reference." For smaller areas it is sufficient to consider the reference surface as a sphere whose centre lies in the earth's polar axis, and for still smaller areas the surface may be considered as a plane. The assumption that the surface is a sphere rather than a spheroid leads to the simplification that the vertical

[1] See H. G. Lyons, *Cadastral Survey of Egypt*, Cairo, 1908.

plane through a point A which also includes a point B is identical with the vertical plane through B which includes A, and that the level surfaces are all concentric spheres.

In commencing the survey of any area the reference surface is first selected, a point on this surface is then chosen as "Origin," and if the survey is to be connected to any other survey, the position of this point must be determined, either by connecting it to an existing survey, or by astronomical determination of its latitude and longitude. An azimuth must be similarly determined in order that the survey may be properly oriented. If the direction and distance from the origin of any other point is determined its position is fixed. Further points can be fixed in a similar manner, or by determining their directions from two points already fixed, or by determining their horizontal distances from two fixed points. In the latter case the height of the point must be determined separately, in the former case it is usual to measure horizontal angles only, and if this is done the height must also be determined separately. The system of horizontal co-ordinates to be adopted depends on circumstances. When an appreciable fraction of the earth's surface is to be considered the co-ordinates used are latitude and longitude.

§ (4) Latitude.—The latitude of a point is defined as the angle made by the vertical through the point with the plane of the equator. It is measured north or south from the equator. Strictly there are three different definitions of latitude—*astronomical latitude* as defined above and depending on the true vertical at the point; *geocentric latitude*, which is the angle the line from the earth's centre to the point makes with the plane of the equator; and *geographical latitude*, which is based on the supposition that the earth is a spheroid of known compression, and is the angle that the normal to this spheroid makes with the plane of the equator. It differs from the astronomical latitude only in being corrected for the local deviation of the plumb-line. It is this latitude which is used in mapping. The astronomical latitude of any point can be found direct by observation on the sun or stars, and can be found without much difficulty with an error of less than 0·3″ (corresponding to about 30 feet on the ground) using a 6-inch theodolite, and with greater accuracy by using special instruments. The astronomical latitude is not absolutely constant for any point, but varies through a range of about 0·5″ owing to the fact that the geometric axis of the earth does not coincide absolutely with the axis of rotation.

The angle between the true vertical at any point and the normal to the spheroid of reference is known as the deviation of the plumb-line, and in places where this (or rather its component in the meridian) varies the length of a degree of latitude as measured on the earth's surface will also vary irregularly; consequently astronomical latitudes are not suitable as co-ordinates for mapping purposes for large scale work. The deviation of the plumb-line may amount to over half a minute in exceptional cases,[1] and in the absence of a geodetic survey there is always an uncertainty of a few seconds. Geographical latitudes are corrected for this deviation, and therefore the length of a degree of geographical latitude does not vary irregularly. When the latitude of the origin, and the spheroid of reference to be used, have once been settled for any survey, the geographical latitudes can be calculated from the measurements and used for mapping purposes, but the resulting values will depend on the spheroid adopted and on the (necessarily unknown) deviation of the plumb-line at the origin. Consequently two surveys started independently cannot in general be expected to give the same values for the latitudes of any points common to both.

§ (5) Longitude.—The longitude of a point is the angle between the meridian plane through the point and some standard meridian plane, and is measured east or west from the standard. The meridian plane now almost universally adopted as standard is that of the transit instrument at Greenwich Observatory. The plane of the meridian may be defined in two ways, either as the plane through the earth's axis which contains the point, or as the plane parallel to the earth's axis which contains the vertical at the point. The first definition gives the *geographical longitude* and the second the *astronomical longitude*, the difference between them being the deviation of the plumb-line in the prime vertical (the plane passing through the vertical and perpendicular to the meridian). Geographical longitude is calculated in the same way as geographical latitude, but the determination of astronomical longitude is less simple. The difference in longitude between two points is a measure of the difference in the local times of the two points, one hour of mean time corresponding to 15° of longitude. Local time can be found by astronomical observations with an error of less than $\frac{1}{10}$ second without much difficulty, but to deduce the longitude Greenwich mean time must also be known. This is the most difficult part of the problem. Recent advances in wireless telegraphy have simplified this, and wireless signals can be recorded on a chronograph with a time lag of less than $\frac{1}{100}$ second, and there now appears no reason why astronomical longitudes should not be obtained in the field with the same accuracy as latitudes, and with nearly

[1] See de Graaf Hunter, *The Earth's Axis and Triangulation*, *Survey of India*, *Prof. Paper*, 16, Dehra Dun, 1918.

the same facility. In the past the only accurate method has been by exchange of telegraphic signals. This is only possible when arrangements can be made for the use of a telegraph wire between the field station and some station whose longitude is known. Transport of chronometers is not very satisfactory, as the rates of the chronometers are liable to change while they are being transported, but this has up to now been the best method available where triangulation or telegraphic determinations have not been possible. Recent improvements in chronometers, combined with the possibilities of rapid transport by aeroplane, have increased the accuracy possible by this method. A recent determination [1] of the difference in longitude between Paris and Greenwich shows the possibilities. In this Paul Ditisheim used 13 chronometers, and took in all five trips between Paris and Greenwich, giving sixty-one separate determinations. The mean for the sixty-one was 9 minutes 20·947 seconds ±·027, the probable error of one determination being 0·214 second. The mean of the French and British determinations by telegraphic methods in 1902 was 9 minutes 20·953 seconds.

Greenwich time can also be obtained by observations of the occultation of stars by the moon, or by observing or photographing the position of the moon among the stars, but such observations are neither simple nor accurate.

§ (6) "Figure of the Earth."—This is found by determining as accurately as possible the astronomical latitudes and longitudes of points connected by a geodetic survey, and the figure so found is that which makes the resulting deviations of the plumb-line a minimum for the stations considered. Naturally as geodetic surveys are extended more data become available, and fresh figures can be found which approximate more closely to the true geoid. For this reason surveys started at different times and in different countries have adopted different figures for their calculations, but these variations have little effect on the mapping of the various countries, and the labour of fresh calculations which would be necessitated by a change in the figure has not been considered to be justified by any gain in accuracy that would result. Inconvenience arises, however, when two such surveys connect up with each other,[2] and as the existing gaps in geodetic triangulation become filled up, the question of recalculation, so as to make a consistent whole, will have to be seriously considered.

[1] Monthly Notices, *Royal Astronomical Soc.* lxxx. 809.

[2] A striking example of the inconvenience caused by surveys which had not been reduced to a consistent whole, but which connected or overlapped, is given by the theatre of operations of the British Armies in France and Flanders in the late war. There were no less than five good, but conflicting, systems of triangulation in this area. See *Geographical Journal*, liii. 253.

§ (7) Rectangular Co-ordinates.—Instead of using geographical co-ordinates (latitude and longitude), it is frequently preferable to use rectangular co-ordinates, and these are invariably used in large-scale work. The position of any point on the earth's surface can be defined with reference to any other point chosen as origin by the intercept of the great circle at right angles to the meridian through the origin and passing through the point (x co-ordinate), and the distance along the meridian from the origin to the intersection of the great circle (y co-ordinate). Rectangular co-ordinates as thus defined are strictly accurate means of defining the position of points. Geographical and rectangular co-ordinates can be converted the one into the other.[3]

The rectangular co-ordinates of traverse points or trigonometrical points, whose latitude and longitude are not required, are generally calculated as follows.

A (*Fig.* 1) is the origin, AY the meridian, AX the great circle perpendicular to the meridian. Then the co-ordinates (x_1y_1) of B are given by $x_1 = \text{AB} \sin \alpha$ and $y_1 = \text{AB} \cos \alpha$, where α is the azimuth, or true bearing of the first side AB. Similarly, if $\beta = \text{ABC} - \alpha$, $x_2 = \text{BC} \sin \beta$, and $y_2 = \text{BC} \cos \beta$, the co-ordinates of C are $(x_1 + x_2)(y_1 - y_2)$. Similarly the co-ordinates of D and further points can be found. It will be noticed that in the case of a triangulation such as is shown in *Fig.* 1 the co-ordinates of C can be found either from B or A, and those of D from B or C. It is generally advisable to compute both ways so as to provide a check on the arithmetic. It must also be noticed that once the initial meridian has been left the angles β, γ, etc., are no longer the true bearings of the sides, and must never be used as such. They are commonly known as "false bearings," and differ from the true bearings by an amount known as the convergence of the meridians. This method of calculation assumes that the perpendiculars dropped from the points B, C, etc., to the axes are parallel straight lines. In reality the perpendiculars to the Y axis are portions of great circles, and therefore not parallel to each other nor to the axis of X, hence as the points get further from the Y axis the y co-ordinates as calculated become larger than their true

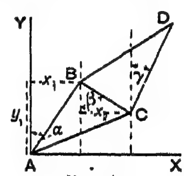

Fig. 1.

[3] See A. R. Clarke's or other book on Geodesy; or C. F. Close, *Text-book on Topographical Surveying*.

value. This error increases as the square of the distance from the meridian, and amounts to about 1 ft. per mile at a distance of 75 miles from the meridian. The errors of the x co-ordinates, and those of the y co-ordinates, due to increasing distance from the X axis, are much less serious. This method of computing, though extremely useful, must not be continued too far from the initial meridian.

§ (8) MAP PROJECTIONS.—In order to form a map the points must be plotted on a plane surface, and some orderly system of constructing the meridians and parallels must be selected for this purpose. Such an arrangement is called a map projection, although it is not, as a rule, a projection in the geometrical sense of the term. As the surface of the earth is curved it is impossible to represent it without distortion on a plane surface. For small areas, where the departure of the earth's surface from a plane is small, it does not matter much what projection is selected, and points are generally plotted by treating their (spherical) rectangular co-ordinates as plane co-ordinates. In a map covering a large area of ground the main points must be plotted either from their geographical co-ordinates, or from these reduced to plane rectangular co-ordinates, according to the projection adopted. In the case of large-scale work minor points are plotted by rectangular co-ordinates, and the consequent errors are prevented from accumulating to any appreciable extent by shifting the origin used from one principal point to another as the work proceeds. The various map projections in use are dealt with in a special article.

§ (9) METHODS OF MEASUREMENT. — The actual measurements required in the field are of two kinds:

(*a*) Length measurements, either direct by means of measuring rods, chains, tapes, etc., or indirect by the use of angular measurements. (*b*) Angle measurements. Generally horizontal and vertical angles are measured separately. The instruments most used are theodolite, compass, or plane table, for horizontal angles; theodolite or clinometer (with either a spirit-level or plumb-bob) for vertical angles; and the sextant for direct angles.

These fundamental measurements can be combined in various ways. For obtaining horizontal co-ordinates the following methods can be adopted:

(i.) *Triangulation*.—This consists of forming a network of triangles, built up one on the other, the distance between two points being first accurately measured by a base measuring apparatus. The angles of the triangles being then measured with a theodolite, the lengths of all the remaining sides can be calculated. This method is the best for providing the main framework of any extensive survey, and is the only one used for geodetic work. It should always be used where circumstances permit (see § (10)).

(ii.) *Traversing*.—Traversing consists in proceeding from point to point in straight lines. The distance between points is measured directly, and changes of direction are measured at each point by means of theodolite or compass. Traverses are used in close country, such as towns or forests, where triangulation is impossible or unduly expensive, or for railway or road location surveys where the survey of only a narrow strip of land is required. They are generally used in conjunction with a triangulation (see § (11)).

(iii.) *Detail Survey*.—Detail survey consists in the filling in of minor points of detail between the trigonometrical or traverse points already fixed. It is generally carried out by simple length and angular measurements (chain survey, etc.), or in some cases by large-scale plane-table work (see § (15)).

(iv.) *Plane-tabling*.—The plane-table consists simply of a drawing-board mounted horizontally on a portable stand. The detail is drawn straight on the board in the field. An alidade, or sight-vane, consisting of a ruler fitted with sights, enables rays to be drawn on the board in the direction of the various points. Points are fixed by interpolation or resection from known points, or by a system of graphic triangulation, or by means of directions determined graphically and distances by tacheometric means (see § (16)).

(v.) *Tacheometric or Stadia Survey*.—In this case distances are measured indirectly by the angle subtended at the instrument by a known length at the distant point. If the bearing of the point is known the co-ordinates of the point can be calculated, or its position plotted by protractor and scale (see § (20)).

(vi.) *Astronomical Observations*. — Astronomical latitudes, local time, and the direction of the true north can be obtained from observations on the sun or stars. As already explained, such observations are required for determining the position of the origin and the orientation of new surveys, and for geodetic purposes. They are also useful as a check on route traverses and rough triangulation. The determination of an azimuth is often required in many classes of survey (see § (23)).

(vii.) *Photographic Surveying*.—Photographs can be used for measuring angles if the focal length of the lens used is known. Such methods are sometimes of use in mountainous country, and the recent developments in aviation have opened up possibilities of

surveying by means of photographs taken from aircraft.

The general utility of photographic methods is, however, much debated, and for a complete topographic survey plane-table methods are generally preferable, but photographic methods may be useful in very rough country, or for location surveys in mountainous country.[1] Elaborate apparatus for plotting from photographs has been made, notably by Zeiss. A full description of the different apparatus available, together with a bibliography, is given by Max Weiss.[2]

Survey from aerial photographs suffers at present from two great disadvantages: (1) The apparent direction of gravity in an aeroplane depends on the acceleration of the aeroplane, consequently the direction of the true vertical is not known. This difficulty can be overcome if sufficient points, whose position and height are known, can be accurately identified in each photograph, but the result is that a stronger and more expensive trigonometrical control is needed than would be required for ordinary methods. (2) The difficulty in obtaining an adequate knowledge of the relief of the ground. In any case it is only the tops of walls, houses, etc., that can be fixed accurately, whereas the ground plan is usually required by surveyors. The overhang of trees and buildings creates further difficulty. These disadvantages make the method of little use in closely inhabited country. On the other hand, aerial photography proved of great use during the war to fill in fresh detail in inaccessible country, and is also of use in the survey of flat country that cannot easily be walked over, and for the rapid survey of high-water mark on the coasts or in flooded areas.[3]

The vertical co-ordinates are found in the following ways:

(*a*) *Levelling.*—Readings are taken on a vertical scale by means of a horizontal line of sight. The difference of two such readings from the same position of the instrument gives the difference of height of the two points on which the scales are supported. By a succession of such readings the heights of successive points are obtained. This is the most accurate method (see § (29)).

(*b*) *Trigonometrical Determination of Heights.*—If the distance of a point is known and the vertical angle to it measured, the height of the point above, or below, the instrument can be calculated. For distant points allowance must be made for the curvature of the earth and for atmospheric refraction. The method suffers from the uncertainty of the allowance for refraction, and the errors from this cause increase rapidly with the distance.[4]

(*c*) *Barometric Methods.*—Measurement of the atmospheric pressure by means of an aneroid, or otherwise, is the quickest method of determining heights, but as the pressure varies according to the "weather" as well as the height, this method gives only rough results in most cases.

The various methods set out above and the instruments used will now be considered in more detail.

II. Triangulation

§ (10) Triangulation.—If the length of one side, and the three angles, of a triangle are known, the lengths of the other sides can be calculated, from whence it follows that if the angles in any figure built up of triangles are measured, together with the length of any one side, the lengths of all the other sides can be calculated and the apices of the triangles fixed. The measured side is called the base, and its method of measurement is described later. The figure may consist of a chain of triangles, of quadrilaterals, of polygons, or of a network, as shown at (*a*), (*b*), (*c*), and (*d*) of *Fig.* 2.

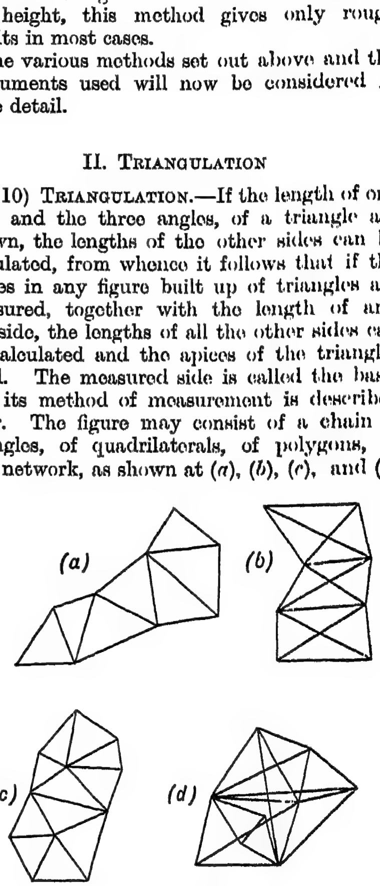

Fig. 2.

Although it is sufficient to measure two of the three angles of each triangle it is better to measure all three, as this gives a measure of the accuracy and prevents mistakes. The International Geodetic Association classes triangulation as follows: First order has a triangular error not exceeding 1″, second order not exceeding 5″, third order

[1] See F. Manek, *Österreichischer Ingenieur- und Architekten-Verein, Zeitschrift*, lxxii. 73.

[4] See article on "Trigonometrical Heights and Terrestrial Atmospheric Refraction," Vol. III.

not exceeding 15″, fourth order exceeding 15″. In a first-class extensive survey there are generally three classes of triangulation. The "primary" should, if possible, be of the first order of accuracy, or should closely approach it. The sides of the triangles would average 30 to 40 miles (up to 100 miles have been observed). All angles are measured, and a 10- or 12-in. micrometer theodolite is used. This forms a backbone, or main framework for the survey. The "secondary" triangulation is carried out with 6- or 8-in. instruments, with fewer observations, and the lengths of the sides are shorter. Errors are prevented from accumulating by adjusting the results to those of the primary work. Finally the whole country is covered by a "tertiary" network, based on the secondary work. The length of the sides depends on the scale of the map required, and for large-scale work would average about 1½ miles.

When time and funds permit, it is always advisable to provide a framework of first order triangulation. This will then serve for any survey that may be required in the future; and if accurate large-scale surveys are started in various parts of the country this framework ensures that they will join up correctly when they meet. If it is impossible to carry out such work, the main framework should be of at least sufficient accuracy to ensure that no error is introduced which will be plottable on the scale of the map which it is to control.

With any extended system of triangulation it is always advisable to measure one or more check bases, at considerable distances from the original. Bases can now be measured so easily that modern practice tends to multiply the number measured.

The errors in primary work are always adjusted by the method of least squares. The accuracy depends not only on the accuracy of measurement, but also on the "strength" of the figure. In a simple chain of triangles ((*a*), *Fig.* 2) the triangles are all independent, and the only adjustment made is by distributing the triangular error between the three angles. In other words, there are three unknown errors, and only one conditional equation that must be fulfilled by the correct angles. In the case of a chain of quadrilaterals ((*b*), *Fig.* 2), while each quadrilateral is independent, eight angles are measured, but there are four conditional equations connecting them, hence the errors can be distributed better and the figure is "stronger." The strength also depends on the figure being well conditioned; *e.g.* an equilateral triangle is stronger than one containing an acute angle. More complicated figures are still stronger, but as their strength increases so does the labour in adjusting them. Check bases provide a further correction, which must be applied throughout the chain connecting each pair of bases, it being usually considered that the measured lengths of the bases are errorless compared with those calculated through the triangulation. Similarly a chain closing on itself, or on a previously adjusted chain, so as to form a closed circuit, provides a further condition. Modern practice tends to adopt chains of quadrilaterals, forming a grid or network, with occasional more complicated figures as may be necessitated by base extensions or topographical conditions.

In first order work the signals observed to are generally lamps or heliostats, work on lamps at night giving the best results. If opaque signals are used, care must be taken to avoid a construction that presents variations in phase according to the direction from which the light falls upon it. All stations must be carefully marked and described so that they can be found again in later years. It is desirable to have concrete or brick pillars to support the instrument and the lamps. In flat or wooded country it may be necessary to erect towers to support the instrument so as to get a sufficiently clear sight.

III. Traverses

§ (11) General.—A traverse consists of a series of straight lines on the earth's surface, the lengths and bearings of which are measured. Each straight section is called a leg. The bearings of each leg may be obtained independently by compass, or the bearing of the first may be measured or assumed and the bearing of each successive leg determined by measuring the angle made with the preceding leg. Traverses may be made in many ways, and with all degrees of accuracy. The distances may be measured by pacing, by time, by counting the revolutions of a wheel run along the ground, by chain, by steel or invar tape, or by tacheometric methods, and the angles by prismatic compass, by theodolite, or by direct plotting on a plane-table. Accurate traverses may be used for the secondary framework of an extensive survey where the conditions are such as to make triangulation difficult or impossible; such conditions obtain in dense forest or flat grass country where high towers of some sort would have to be built for the stations of a triangulation, causing great expense. Modern developments in the use of steel or invar tapes for rapid and accurate measurement of length have greatly increased the accuracy, and hence the application of this type of traverse (see also § (41)).

Traverses are most widely used for roughly mapping travellers' routes, and for detail work in towns and close country.

Traverses are also used where a large-scale map of a narrow strip of country is required, such as a railway survey, and also for mining work where triangulation is impossible.

§ (12) Use of Tapes.—For town traverse work the tapes are generally stretched along the ground, the tension being applied by a spring balance, and the slope measured by the theodolite at the same time as the horizontal angles. In rough or jungle country it is convenient to use long tapes, up to 5 or 10 chains in length. In such cases it is generally best to let the tape hang free clear of the ground, supported at intervals of every chain, or some other convenient distance. For traverse purposes these intermediate supports can be wire nails driven into the sides of rods, the rods being held vertically by assistants; the supports must be aligned vertically and horizontally.

In using a spring balance for applying the tension it must be remembered that the tension indicated by the dial is that applied to the *hook* when the balance is in a vertical position with the hook downwards, *i.e.* it is the tension of the spring *minus* the weight of the drawbar and hook; the tension indicated is therefore too low, when the balance is held in any other position, by an amount $w(1-\cos a)$, where w is the weight of the drawbar and hook attached to the spring, and a the angle made by the balance with the vertical, reckoned as 0 when the hook is downwards and 180° when the hook is upwards.

In order to provide a check on the measurements it is useful to have the tape graduated on the back and front in two different units, *e.g.* feet and links, or feet and meters.

§ (13) Measurement of Angles. — The method of measuring the angles with a theodolite is similar to that employed in triangulation, but the following special considerations apply. As the bearing of any leg is burdened with the accumulated error of all the angles measured up to the point considered, the accuracy becomes of special importance irrespective of the length of the leg sighted. It is therefore of great importance, especially when using short legs, that the traverse points should be very finely marked, that both theodolite and signal should be carefully centred, and that the signal should be such that it can be accurately bisected. The longer the legs the less important this becomes.

§ (14) Computing and Plotting.—Traverses can obviously be plotted direct with a protractor and scale, but it is almost always better to calculate the co-ordinates of the points. Such co-ordinates, or their differences, are frequently known as "latitudes and departures" or "Northings, Eastings," etc.

Traverses should always be run between points already fixed, or be closed on the starting-point; this enables the total error to be determined. The errors accumulated depend on the accuracy of both the length and angular measurements, and the problem of distributing the errors found in the best manner does not lend itself to any simple solution. There are two main cases, (1) where the bearings are measured by compass, in which case the error in bearing is not accumulative, and (2) where the angles between successive legs are measured, in which case the error in bearing increases as the square root of the number of angles (assuming that all angles are read with equal accuracy). In distributing the errors it is usual to correct the angles or bearings independently of the lengths. In any closed traverse the correct sum of the angles can be calculated and the error divided equally among the measured angles. The same applies when traversing between trigonometrical points. These corrected angles are used in the calculations, and the remaining errors are distributed by corrections applied to the co-ordinates. The simplest method is to divide the total error in latitude equally among the stations, and similarly with departures. A better way (on the assumption, generally correct with careful theodolite traverses, that the length errors are large compared with the angular errors) is to use the following rule: "As the arithmetical sum of all the latitudes is to any one latitude, so is the whole error in latitude to the correction to the corresponding latitude, and so with the departures." [1]

The angular error can often be checked at intervals by observing angles to points already fixed, or by astronomical azimuths. Length errors can only be checked by closing on fixed points, or, in the case of rough exploration surveys over long distances, by astronomical observations of latitude and longitude.

IV. Detail Surveying

§ (15) General Methods.—The detail on large-scale surveys may be inserted by stadia methods (*q.v.*), by plane-table work (*q.v.*), or by chain survey. In small-scale work the plane-table is generally used. The surveyor's chain consists of links of iron or steel wire connected by rings, and with a brass handle at each end. In countries using English measures the chain is generally 66 ft. long, divided into 100 links, every tenth link being marked by a brass tab. As ten square chains are one acre, this forms a convenient decimal system for the measurement of areas; 100 ft.

[1] See J. B. Johnson, *Theory and Practice of Surveying*, 17th ed. p. 235.

and 20 metre chains are also used. The area to be surveyed can be split up into triangles (generally starting from a triangle of the tertiary triangulation) the sides of which are measured. The position of detail points are fixed by the distance along the line chained and the distance from the nearest point on the line measured (at right angles) by means of a graduated rod or tape. Such distances are called "offsets." Offsets should be kept short, or the error in estimating the right angle will become too great. Cross staves or optical squares can be used to give the right angle if long offsets are necessary. The simplest form of optical square consists of a pentagonal prism with reflection at two faces including an angle of 45°. It is more accurate, and now more usual, to use a graduated steel tape instead of a chain. Allowance for slope is made by estimation, or by measuring the slope by clinometer and calculating the correction. The field work is booked in a field book, all distances being booked as total lengths from the start of each chained line. Although the chaining of the three sides of a triangle, or the four sides and one diagonal of a quadrilateral is sufficient to determine it, it is advisable to chain also a tie line, *i.e.* a line from the apex of the triangle to a known point on the base, or the second diagonal of a quadrilateral. This gives a check, and tests the accuracy of the work when plotted.

V. Plane-tabling and Plane-tables

§ (16) Plane-tabling.—The plane-table consists essentially of a drawing-board mounted horizontally on a portable tripod, and capable of being adjusted in azimuth. Accessories used with it are a ruler provided with sights (either open or telescopic), a compass, and a clinometer. The sighted ruler is called the "alidade." The plane-table is used for topographic survey, the detail being drawn in direct on the paper, and as a rule on the scale required for the finished map. Such scale may be anything from about 1/250,000 upwards. It is not advisable to work to a larger scale than that of the final map as this entails a larger number of field sheets, limits unnecessarily the number of trigonometrical points that can be plotted on the sheet, and leads to an unnecessary amount of detail being plotted, and hence to a waste of time. The only advantage is that a lower standard of draughtsmanship can be used. If a larger scale map is likely to be required in the near future it should, however, be considered whether the larger scale should not be adopted at once for the field work.

The general principle of the work is as follows. A certain number of points are fixed first by triangulation, and carefully plotted to scale on the field sheet. The distance between such points depends on the scale, a convenient rule being that they should be about 4 in. apart on the field sheet. If the plane-table be now set up and levelled at any fixed point A on the ground, the sight rule laid along the line AB (where B is another fixed point visible from A), and the table turned till the distant station B is intersected by the sights, the table is said to be oriented, and if the sight rule be laid along the line joining A to any other fixed point, that point should be intersected by the sights. Similarly the line giving the direction of any other point from A can be drawn in; two such lines to any point from two different settings up of the table fix its position, and any subsequent lines serve as a check. Stations so fixed and checked are termed intersected points, and can be used in fixing further points. If the distance of any point be known, or estimated, this distance can be laid off along the line and the point fixed. Detail in the neighbourhood of any fixed and occupied point can thus be drawn in. The accuracy of measurement or estimation required depends on the scale, as nothing is gained by an accuracy of measurement greater than the accuracy of plotting. It is always desirable, when the table is first oriented, to mark the magnetic north by means of the compass, as the plane-table can then always be oriented approximately by compass.

If the table be set up at any unknown point from which three fixed points A, B, and C can be seen, the position can be determined by "interpolation" or "resection."[1] There are various ways of doing this, but the simplest is as follows. The table is approximately oriented by compass, and rays are drawn from the three points; if the orientation is correct these rays will meet in a point, which is the required position. If (as is probable) they do not meet they will form a small triangle, known as the triangle of error, and the true position can be determined by the following rules: (1) If the triangle of error lies within the triangle formed by the three points, the position is within the triangle of error; (2) If the triangle of error falls outside the triangle formed by the three points, the position is either to the left of all the rays when facing the fixed points, or to the right of all; (3) The distance of the point from any ray is proportional to the length of the ray. From these rules the position of the point is estimated and marked, the sight rule is placed along the line joining this position to that of the most distant of the fixed points, and directed on

[1] In America the term resection is also applied where one ray has been drawn to the point from a previously occupied point, and the fixing is completed by rays drawn at the unknown point from fixed points.

the point by revolving the table, and the orientation is then checked on the other points, or on any further points visible. If there is still an error the process must be repeated. This method fails if the position of the station lies on a circle passing through the points A, B, and C, and is inaccurate if it lie near such a position.

In small-scale work the stations at which the table is set up are fixed by intersection or resection, and the detail sketched in round them. Fixings should always be made from trigonometrical points if possible, and if not, from points that have been carefully intersected or resected and checked. By this means errors are prevented from accumulating.

(i.) *A Plane-table Traverse.*—The plane-table is not suitable for use in forest country, where sights to distant objects can seldom be obtained for fixing the positions, but it may be necessary, even in generally open country, to follow a stream or path where ordinary fixings cannot be made; in such a case it may be necessary to carry out a plane-table traverse. The plane-table is set up and oriented at the start of the traverse, and a ray drawn in the direction of the first leg (all legs should be as long as possible); the distance to the first station is measured and its position marked. The table is then set up at this station and oriented by the back ray, and the direction of the second leg drawn, and so on. As soon as a position is reached which can be fixed by ordinary methods the traverse should be adjusted as follows: if 1, 2, 3, . . . 6 are the stations of the traverse and the true position of 6 be found to be f, draw lines $2b$, $3c$, . . . through 2, 3, . . . parallel to $6f$ so that their lengths bear the same proportion to $6f$ as the lengths 1-2, 1-3, . . . bear to 1-6, then b, c, d, . . . are the adjusted positions of the traverse points. If the legs are necessarily very short and the traverse long, errors in direction may accumulate rapidly, and it may be better to make a compass traverse and plot it afterwards (see "Traverses," *ante* § (11)).

(ii.) *Graphic Triangulation.*—A graphic triangulation can be carried out if necessary, but this should be avoided if possible except for such special purposes as a preliminary reconnaissance for theodolite triangulation, etc. For such purposes a telescopic alidade should be used. Special care should be taken to get well conditioned triangles, and if possible the graphic triangulation should be tied in to a theodolite triangulation and adjusted to it.

The above method of using the plane-table is the usual British[1] practice.

[1] C. F. Close, *Text-book of Topographical and Geographical Surveying* (2nd ed., 1913); *Report on the Topographical Survey of the Orange Free State*, 1905–1911, published by the War Office, 1913.

(iii.) *American and Continental Practice.*—This has been to use the plane-table for larger scale work, and to provide it with more elaborate adjustments for levelling and orienting. Telescopic alidades are used, and detail fixed by means of stadia readings, taken either from a separate instrument or by means of stadia hairs in the alidade telescope. This method[2] gives the position and height of all points at which the stadia rod is held up to a distance of about ¼ mile from each station occupied by the plane-table.

§ (17) PLANE-TABLES AND ACCESSORIES.—The British Army pattern of plane-table is the simplest form and consists of a drawing-board 18 × 24 in. attachable to a simple tripod by a screw. The levelling is done entirely by suitably placing the legs. When

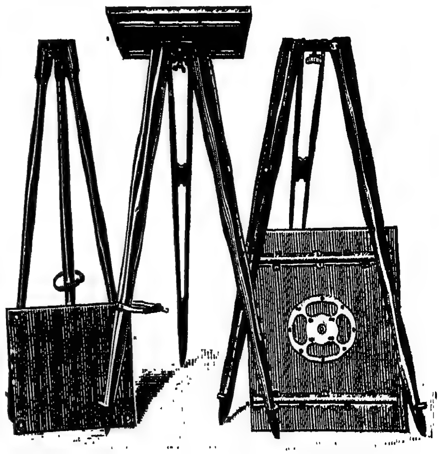

FIG. 3.

the screw holding the top is slacked off, the top can be turned horizontally. *Fig.* 3 shows three simple patterns of plane-tables: the centre one has a "Johnson" ball-and-socket levelling head. In this case the upper clamping screw clamps the top so that it cannot tilt but can rotate in azimuth until the lower screw is tightened. Smaller patterns and stands with folding legs are also used, but folding legs, though more portable, are apt to be less rigid. It is convenient on steep ground to have one leg whose length can be adjusted. The paper is usually mounted on linen, and then damped and stretched over the board, the edges turned over and glued to the back. When dry this forms a good smooth working surface which does not cockle, but suffers from the disadvantage that the

[2] J. B. Johnson, *Theory and Practice of Surveying* (17th ed., 1914); *Coast and Geodetic Survey Report*, 1905, Appendix 7.

paper distorts considerably on being removed, and it is impossible to remount the paper when once it has been taken from the board. As a result the trigonometrical points can only be plotted after the paper is mounted, and if the field sheet has to be sent for further points to be plotted, or for revision or amplification, the whole plane-table top must be sent, and no such work can usefully be done when the paper has once been dismounted. Even if the paper is kept mounted a certain amount of distortion occurs, as the table top itself expands and contracts with varying moisture, and does so unevenly, expanding more across than along the grain of the wood. A method tried with some success in India consists in pasting the field sheet (preferably of Bristol board) firmly along one long edge of the plane-table by means of a strip of cloth. The other three sides are cut so as to leave a ½-in. margin of plane-table top. Strips of cloth are then pasted along the upper surface of the field sheet and the under surface of the plane-table. The cloth is pulled tight but the paper is not wetted. If the wood now shrinks the cloth will get slack but the sheet will not cockle.

In any case of paper, Bristol board, or paper mounted on wood, more or less expansion, etc., will take place; and although uniform expansion or contraction can be remedied by photography for final reproduction, it complicates the comparison of edges of adjacent sheets and the plotting of trigonometrical points, and if the expansion is not uniform it necessitates re-drawing for the final map. A method [1] which appears to overcome all these difficulties is to mount the paper on linen, and then paste or glue this down to an aluminium sheet. The aluminium is grained to take the glue and is the same size as the top of the table; the linen extends about 3 in. over the sides and ends of the aluminium sheet; these extensions provide overhanging flaps which are stiffened by aluminium strips. The flaps are turned under the table top, and spring hooks engage in holes in the strips and keep the whole firmly attached to the board (see *Fig.* 4). The plane-table top itself need only be a framework, and the whole arrangement is lighter than the ordinary pattern. The field sheets form a permanent record which can be attached to or detached from the plane-table as often as may be required.

American surveyors usually clip the paper to the board, or clamp it down by countersunk screws; the use of celluloid sheets with such clamping screws is satisfactory, but even this is liable to cockle.

For large-scale work, particularly when a telescopic alidade is used, it is desirable to have arrangements for more accurate levelling, and both ball and socket heads and levelling screws are used for this purpose.

FIG. 4.

A slow-motion traversing screw is also desirable. These attachments add considerably to the weight of the outfit. *Fig.* 5 illustrates such an outfit.

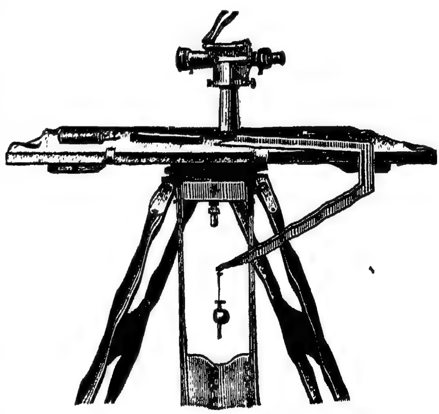

FIG. 5.

§ (18) ALIDADE.—The alidade or sight-rule should be about as long as the short side of the table. The simplest form consists of a wood rule with folding sights, the back sight having a vertical slit and the fore sight carrying a stretched vertical thread. The precise

[1] H. St. J. L. Winterbotham, *Royal Engineers' Journal*, 1919, xxx. 233.

parallelism of the sight line and the edge of the rule is of no importance provided the same edge of the rule is always used. It is a great convenience, and with telescopic alidades almost essential, to have the actual edge used for ruling on an arm moving parallel to the rule; this makes it unnecessary to pivot the alidade on the point, the arm being moved up as required after the alignment has been made. For ordinary small-scale topographic work based on an adequate triangulation a simple sight-rule is the best.

The telescope, when used, should be similar to that on small theodolites, and be provided with stadia hairs, and with a vertical arc

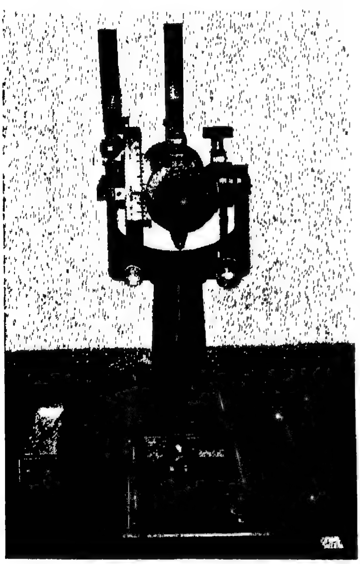

FIG. 6.

and spirit-level for reading angles of elevation and depression. No iron or steel should enter into any part of the alidade or plane-table. *Fig.* 6 shows a telescopic alidade with parallel motion and "Beaman Arc" (see also § (21), (v.)).

§ (19) ACCESSORIES.—The most suitable type of compass is a simple trough compass, 4 to 6 in. long, preferably fitted with a lid to protect the glass, and with a catch which lifts the needle from its pivot when the lid is closed (see *Fig.* 6).

For small-scale work no plumb-bob or special centring device is needed; a foot or two in the position of setting up will make no difference, but in large-scale work the table should be set up so that the plot of the point is vertically over the station mark. A plumbing bar is useful for this purpose. The illustration (*Fig.* 5) is self-explanatory.

VI. TACHEOMETRIC OR STADIA SURVEYS

§ (20) GENERAL METHODS. — Tacheometry means literally "quick surveying," and the general principle is illustrated in *Fig.* 7.

O is the observer, AB a rod of known length, C being the mid-point of AB, and OC perpendicular to AB. Then if α is the angle AOB,

$$OC = \frac{AB}{2}\cot\frac{\alpha}{2}.$$

If the rod be not perpendicular to OC, but takes a position A′B′, making an angle β with AB, then the formula becomes

$$OC = \frac{AB}{2}\cot\frac{\alpha}{2}\cos\beta.$$

If OC is inclined to the horizontal by an angle γ, then the horizontal distance of C from O is OC $\cos\gamma$, and the height of C above O is OC $\sin\gamma$. If the direction of OC is known, then the position of C with respect to O can be determined at once from measurements taken at O. This method is in many cases more rapid than chaining and levelling, and especially useful where it is difficult to measure the distance OC directly.

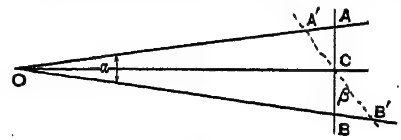

FIG. 7.

The practical methods of applying this fall into two cases: (1) where α is a fixed angle and AB is a graduated rod, the intercept AB being observed from O; this is generally called stadia surveying; (2) where AB is a known length and the angle α is measured; this is generally called the subtense method, though this term is used differently by different writers. In subtense work the angle α may either be measured by the arc of a theodolite, or by a micrometer eyepiece in the telescope.

§ (21) STADIA WORK.—The angle α is determined by two cross hairs in the focus of the telescope, and the portion of the graduated staff (stadia rod) intercepted by these two cross hairs is read off. The stadia rod is either an ordinary levelling rod, or a similar rod with rather larger divisions for use at long ranges. Stadia methods are chiefly of use in filling in the detail in large-scale topographic work.

(i.) *General Methods.*—In *Fig.* 8 O is the object-glass of an ordinary telescope of focal length f, S is the rod, the image of AB (length l) being formed at ab where a and b are the stadia hairs of the telescope at a fixed distance p apart. V is the vertical axis of the telescope.

c is the distance VO, e the distance FS, where F is the first focal point of the object-glass. A ray of light from A which passes through F will meet the object-glass in a' and be refracted parallel to the optical axis to the cross hair a, similarly with a ray from B. The figure shows at once that $e/l=f/p$, and $R=e+f+c=(l/p)f+f+c$, irrespective of the distance the cross hairs ab have been racked out in order to focus the staff. Here p, f, and c are all constants, so we can write simply $R=kl+m$, where k and m are constants. The

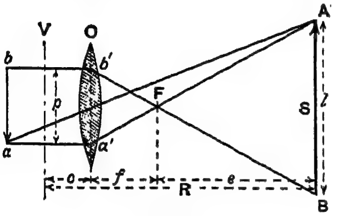

FIG. 8.

cross hairs are usually placed so that $k=100$, but sometimes $k=66$ (in which case l in feet gives e in chains), or $k=200$ (for long-distance work). The value of $m=f+c$ can be obtained with sufficient accuracy by measuring the distance (f) from the centre of the object-glass to the diaphragm when the telescope is focussed on a distant object, and from the centre of the object-glass to the vertical axis (c).

It is usual in stadia work to hold the rod vertical, as being more convenient than holding it horizontal and perpendicular to the line of sight, or perpendicular to the line of sight in a vertical plane. This results in a rather more complicated formula. In *Fig.* 9

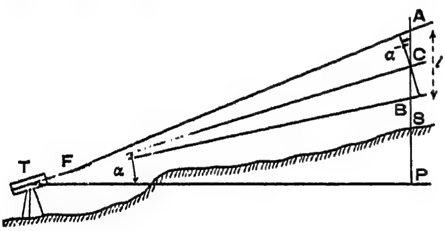

FIG. 9.

T is the instrument, S the foot of the rod, C the mid-point between A and B (the points read on the staff), P the projection of S on the horizontal plane through T; then the distance TC is $kl\cos\alpha+m$, the horizontal distance TP is $kl\cos^2\alpha+m\cos\alpha$, and the difference in height PC is $kl\cos\alpha\sin\alpha+m\sin\alpha$. If the difference in height of the ground at S and T is required, the height of the instrument must be added to PC and the distance CS subtracted.

When the stadia method is used for plotting detail and fixing points which will not be used for fixing further points by calculation, there is no object in measuring the distance to a greater degree of accuracy than it is possible to plot. A point cannot be plotted with a greater accuracy than about $\frac{1}{100}$ in., consequently on a scale of $\frac{1}{2500}$ an error up to 2 feet in the length is of no importance, and with smaller scales still larger errors have no effect. For such purposes, therefore, the constant m can be neglected. In the same way the reduction to the horizontal can always be neglected when the slope is less than 2° and generally up to 6°. If stadia traverses are being run, and the co-ordinates of the stations calculated, then greater accuracy is required, and m should be allowed for. Tables of $\cos^2\alpha$ and $\cos\alpha\sin\alpha$ are given in most text-books dealing with stadia surveying.

It is always desirable to check the interval between the stadia hairs, and to check whether they are equidistant from the centre cross hair, and for accurate work this should always be done. However accurately the makers have spaced the cross hairs, the value of k will vary owing to atmospheric refraction. The rays of light from the staff to the telescope are not straight lines, but are almost invariably concave downwards; and the amount of this bending not only varies with the state of the atmosphere, but also depends on the height of the ray above the ground, consequently both readings of the staff will be too low, and the lower reading will have a greater error than the upper. The result is that the value of k depends on the atmospheric conditions, so it is desirable to determine k for the average conditions actually met with. The determination can be made by setting up the rod at known distances from the instrument, when each reading will give a value of k if the value of m has already been determined by measurement. The conditions should be as nearly as possible those that will be met with in the work in hand, and specially favourable conditions should not be chosen; the mean value of k found should be adopted in calculating the work. An incorrect value of k will affect the scale of the resulting map, so if traverses are being run between trigonometrical points, a comparison of the distance between two such points as determined by the traverse with that determined by the triangulation will give a value for k which is a good average value for the conditions of the work in question. If the value of k to be used is not a round number it is best to construct a table connecting the stadia readings with distance, and if this be done the correction m can be allowed for in the table. Some makers provide instruments with adjustable stadia hairs, but these are not to be recommended as they are more

liable to accidental change in the value of k, and the saving in labour in reducing the results is very small.

(ii.) *Anallatic Telescope.*—With a view to obviating the necessity for the constant m Porro proposed in 1823 the use of a second lens (termed the anallatic lens) arranged as in *Fig.* 10, where C is the second (convex)

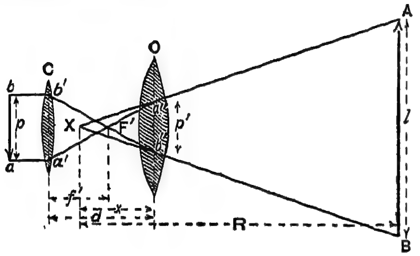

FIG. 10.

lens, whose first focal point is at F′. A ray of light from A, striking O at a'' and then passing through F′, will be refracted at a' to a, aa' being parallel to the axis. The distance d is fixed, and focussing is carried out by moving the cross hairs ab. This being the case $a''b''=p'$ is constant, and if the lines Aa'', Bb'' produced meet in X it is seen from the figure that $R/l=x/p'$=constant, and that $R=lk$. Also $p'=(d-f'/f')p$, and as X is the virtual image of F′,

$$\frac{1}{d-f'}-\frac{1}{x}=\frac{1}{f'},\quad \text{or } x=\frac{f(d-f')}{f+f'-d},$$

hence

$$R=\frac{f(d-f')}{f+f'-d}\cdot\frac{l}{p'}=\frac{ff'}{f+f'-d}\cdot\frac{l}{p}.$$

If the values of f, f', and d be so chosen that X falls on the vertical axis of the instrument, the constant m of the original formula is eliminated. The formula also shows that if the cross hairs are not quite correctly spaced, a small adjustment in the distance apart of the two lenses will enable the constant to be corrected; while this adjustment will displace the point X from the vertical axis, the error introduced will be so small as to be negligible.[1]

This construction involves not only an extra lens, but either a more bulky telescope or a falling off in its optical qualities, and it is generally considered that these disadvantages are not compensated for by the fact that no additive constant is required. It has already been pointed out that for accurate work it is desirable to use tables connecting the distance with the stadia readings, and if this be done the constant entails no inconvenience, while for rough work it can be ignored.

(iii.) *Stadia Work with Internal Focussing Telescope.*—A telescope with a negative internal focussing lens has many advantages (see § (30), (i.)), and it must be considered how far this is suitable for stadia work. Such a telescope is illustrated diagrammatically in *Fig.* 11. O and N are the object-glass and −ve lens, with their first focal points at F and F′, and focal lengths f and f'. In the absence of the lens N, an image ab of the staff would be formed at I, distant f_2 from O, where $1/L+1/f_2=1/f$, and the size of the image p would be such that $L=(f/p)l+f$. If the lens N be now inserted, the ray which previously passed along AF$a'''a$ will be refracted by N at a'' towards a', and F′$a''a'$ will be a straight line; also a ray from A

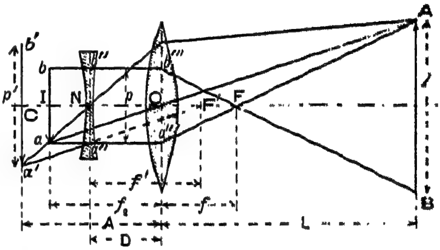

FIG. 11.

passing through the centre of N will not be refracted by N but will pass through a and a', and an image will be formed $a'Cb'$.

Then, from the figure,

$$\frac{p'}{p}=\frac{a'b'}{a''b''}=\frac{CF'}{NF'}=\frac{f'+A-D}{f'},$$

where A is the distance of the cross hairs from the object-glass, hence

$$L=\frac{f(f'+A-D)}{f'p'}l+f.$$

Here A is a constant, and D increases as L decreases. Call D_∞ the value of D when L is very large, so that $D=D_\infty+d$, then

$$L=\frac{f(f'+A-D_\infty)}{f'p'}l-\frac{fld}{f'p'}+f.$$

As D_∞ is constant put

$$\frac{f(f'+A-D_\infty)}{f'p'}=k,$$

whence

$$L=kl-\frac{kd}{f'+A-D_\infty}\cdot l+f.$$

This shows that L varies with d as well as with l, and that no simple accurate formula of the form $R=kl+m$ holds. It is simplest

[1] J. Porro, *La Tachéométrie*, Paris, 1858; see also *Zeits. Instrumentenk.*, 1882, pp. 117 and 157, and 1885, p. 413; and A. E. Young, *Inst. Civ. Eng. Proc.* cxxxix. Pt. 1.

to consider k as a constant and ascertain how m varies.

We have
$$\frac{A-D}{f_2-D}=\frac{p'}{p}=\frac{f'+A-D}{f'},$$

hence
$$f_2=\frac{-D^2+DA+f'A}{f'+A-D}.$$

Put $D_\infty=nA$, $(n<1)$, then

$$f=\frac{A^2n(1-n)+f'A}{f'+A(1-n)},\quad f'=\frac{A(1-n)(f-nA)}{A-f},$$

$$f'+A-D_\infty=\frac{A^2(1-n)^2}{A-f}.$$

$$f_2=\frac{-d^2(A-f)+Ad(1-2n)(A-f)+A^2f(1-n)^2}{A^2(1-n)^2-d(A-f)},$$

$$L=f.\frac{-d^2(A-f)+Ad(1-2n)(A-f)+A^2(1-n)^2f}{-d^2(A-f)+d\{A^2(1-2n)+f(2nA-f)\}},$$

$$kl=\frac{(L-f)A^2(1-n)^2}{A^2(1-n)^2-d(A-f)}$$
$$=\frac{f^2A^2(1-n)^2}{-d^2(A-f)+d\{A^2(1-2n)+f(2nA-f)\}}.$$

The error in assuming that $L=kl$ is E, where $E=L-kl$, hence
$$E=\frac{f\{A(1-2n)-d\}}{A(1-2n)+f-d}.$$

If we put $n=\frac{1}{2}$ as indicated in British Patent 25622 of 1910, then E reduces to $-df/(f-d)$, which is zero when the telescope is at stellar focus. The apex of the tacheometric angle (point X of *Fig.* 10), from which the distance given by $L=kl$ is measured, is therefore in the object-glass for long distances, and moves slowly backwards as the range diminishes. Taking a telescope with $A=1$ ft., $n=\frac{1}{2}$, $f=0{\cdot}9$ ft., then $f'=2$ ft., and E does not reach 0·1 ft. until L is reduced to about 25 ft., hence with such a telescope the error caused by taking $R=kl$ (R is measured from the vertical axis) will be about 6 in. at long ranges and reducing to about 5 in. at 25 ft. For detail work this is quite negligible; even for accurate traverse work it is generally negligible, as the errors due to reading the staff, and refraction errors, will be greater than this correction unless the lengths of the sights average less than, say, 100 ft. In such a case the correction to be applied is best obtained by direct trial.

If n be increased the apex of the tacheometric angle is thrown back, and the error in assuming that the telescope is anallatic is still further reduced, but for this a rather short-focus negative lens is necessary, and the optical qualities of the telescope suffer. (See the *Transactions of the Optical Society*, xxii. 20.)

(iv.) *Accuracy of Stadia Work.*—With suitable instruments and rods an accuracy of from 1/200 to 1/500 is obtained in individual sights. This error is not systematic, and, therefore, a traverse of, say, 16 legs should have an error of from 1/800 to 1/2000. About $\frac{1}{4}$ mile is the limiting length of sight for ordinary work, but up to $\frac{1}{2}$ mile can be used. An ordinary telescope, such as is used on a 5-in. theodolite, will read ordinary levelling rods up to about 400 ft.; for longer distances the $\frac{1}{10}$-ft. divisions only can be read, and for over 1000 ft. the rods should be graduated in yards or metres and tenths, or in links. The error due to refraction increases as the square of the distance, consequently long sights should not be used when the line of sight is close to the ground; such conditions are favourable for rapid and accurate work with the chain or graduated tape, but unfavourable for stadia work. On the other hand, uneven, steep, or broken ground is more favourable to stadia work, which, under such conditions, will give quicker and more accurate results than chaining.

If the stadia rod be held horizontally the refraction errors are eliminated, so far as they affect the horizontal distances, but it is necessary to provide a stand to support the rod, and to fit it with a sight to ensure its being held perpendicular to the line of sight. This is generally not considered worth while.

(v.) *Special Instruments for Stadia Work.*—Various special instruments have been made for stadia work, but they have little advantage over an ordinary theodolite, provided the latter has a suitable telescope. Greater magnification and resolution are required to read a graduated staff then to bisect a suitable target with equal accuracy.

An adjunct to enable the reduction to the horizontal etc., to be made rapidly, designed by Mr. W. M. Beaman, U.S. Geological Survey, is useful when a telescopic alidade is used for stadia working with a plane-table (see § (18)). In *Fig.* 9, if the angle of elevation α is such that $CP=nl$, and ignoring the additive constant m, we have $nl=kl\cos\alpha\sin\alpha=\frac{1}{2}kl\sin 2\alpha$, or if $k=100$, $\sin 2\alpha=\cdot 02n$. The values of α corresponding to $n=1, 2, 3\ldots$ are marked on a supplementary scale (known as the V scale) on the vertical arc. In use the telescope is set so that the index corresponds with a mark (n) on the V scale, and a full stadia interval can be read on the rod. If the centre cross hair then read $c(=CS)$, and the difference between the stadia readings be l, we have the height of S above the instrument is PS, and $PS=PC-SC=nl-c$. A second (or H) scale is graduated on the vertical arc so that any reading m on this scale indicates that the horizontal distance is m per cent less than the distance given by kl. From *Fig.* 9, $TP=kl\cos^2\alpha=kl(1-m/100)$, hence $\sin^2\alpha=m/k$. In practice the V scale is set exactly to a mark, in which case the H scale will generally not be on a mark, but by interpolation the percentage to be deducted on account of the slope can be estimated with sufficient accuracy. The alidade shown in *Fig.* 6 is fitted with a "Beaman" arc.

§ (22) SUBTENSE METHODS.—A "Subtense" bar, 10 or 20 ft. long, has been used with good results with an ordinary theodolite. The 20-ft. bar has discs 12 in. in diameter at its ends,

and is supported horizontally on a stand. A sight attached to the bar enables it to be set perpendicular to the line of sight. The angle is observed by the repetition method on the horizontal arc of the theodolite, some ten repetitions being taken. A 20-ft. bar can be used up to three miles with reasonable accuracy. The angle can also be measured very conveniently by an eyepiece micrometer, a number of readings can be taken very rapidly, and the mean of, say, 10 should give a good result. A table should be prepared giving the distance in terms of the micrometer reading, and this table should be prepared from the results of actual trial. If D is the distance from the vertical axis of the instrument to the bar, L the length of the bar, M the micrometer reading, and f the focal length of the object-glass, and c the distance of the object-glass in front of the vertical axis, we have $D = A/M + B$, where A and B are constants, as in stadia working. $B = f + c$ and A depends on the graduation of the micrometer and on the focal length of the object-glass. This method is neither so convenient nor so rapid as stadia working, but as a suitable target can be bisected with greater accuracy than a graduated staff can be read, it may be more accurate, and it can be used for longer distances.

Another method, sometimes used, is to hold the rod vertical and read the angles of elevation or depression to the two targets. In this case (see *Fig.* 12), if the angles AOP, BOP are θ and ϕ respectively, $OP = AB/(\tan\theta - \tan\phi)$

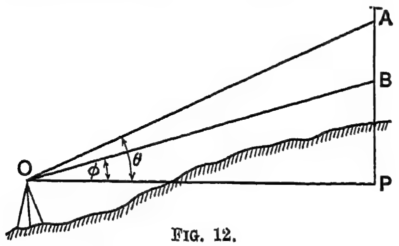

FIG. 12.

and $BP = OP \tan\phi$. If a suitably graduated horizontal scale be fitted on the theodolite at a fixed distance below the horizontal axis, the values of $\tan\theta$ and $\tan\phi$ can be read directly by means of a microscope attached to the telescope and perpendicular to it, the divisions of the scale are uniform, and the fractions of a division can be read on a micrometer which moves the scale longitudinally. An alternative arrangement is to elevate the telescope by a screw acting directly on an arm attached to the telescope so that the travel of the screw is proportional to the tangent of the angle of elevation. Various other arrangements have been made for giving more or less direct readings of the distance and height of the rod, but they are little used; their advantages for the special work are small, and they reduce the convenience of the instrument for use as an ordinary theodolite.

A variation of the subtense method is sometimes useful for executing traverses where triangulation or tape traverses are impossible. In this case signals are put up by an advanced party, and the angle subtended by these is measured as in the case of ordinary subtense work. The signals must be carefully plumbed, or else arranged so that their intersection with the ground can be observed. The distance between the signals should subtend some eight to twelve minutes, and they should be placed in a line perpendicular to the line of sight. A third signal for the actual traverse station is sometimes desirable in addition. When the observer reaches the position he must measure the distance between the signals with a tape.

VII. Astronomical Determination

§ (23) General.[1]—Astronomical determinations are used in survey work for determining latitude, local time (hence, if Greenwich time be known, longitude), and azimuth, or true north. For survey work on land the instrument usually employed is the transit theodolite. Where possible observations are made on stars, but the sun can be used. It must be remembered that latitudes, etc., thus obtained are *astronomical* latitudes and differ from the geographical values by an amount depending on the deviation of the plumb-line. Astronomical observations of position give, therefore, no check on traverse work, etc., unless the error of the traverse is likely to be greater than that due to the deviation of the plumb-line, as well as those due to the astronomical observations themselves.

§ (24) Latitude.—The usual method of determining latitude for survey purposes is by "circum-meridian altitudes." The altitude of a star when crossing the meridian, together with the known declination of the star, gives the latitude. Single observations with a theodolite suffer from errors of collimation, etc. (see article on "Theodolite"), and are of little value; hence pairs should always be taken. The usual field practice is to start observing eight to ten minutes before the star reaches the meridian, and to take as many observations as possible before transit, and an equal number afterwards. The observed altitude and time of each observation are booked, and the "face" of the telescope is changed after the first, third, fifth, etc., observation. The interval in time between each observation, and the moment of transit, being known, a correction can be

[1] For astronomical determinations for geodetic purposes see article on "Gravity Survey," Vol. III.

applied to the observed altitude to "reduce" it to the true meridian altitude. A correction must also be made for atmospheric refraction.[1] This correction is always rather uncertain, but can be largely eliminated by observing one star that transits to the north, and another that transits to an approximately equal altitude to the south; the mean of the pair will be largely free from refraction errors. As refraction is more variable for low than high altitudes, it is inadvisable to observe stars at a less altitude than 40°. Using a 6-in. micrometer theodolite, and taking the mean of several pairs of north and south stars, there should be no difficulty in obtaining a probable error of $\frac{1}{4}$ to $\frac{1}{3}$ second in the latitude.

§ (25) Observations for Time.—Local time is obtained directly from the moment any astronomical body, whose right ascension is known, crosses the meridian, and this is the method employed in fixed observatories and for geodetic purposes in the field; it is not, however, generally possible for survey purposes. If the latitude be known, and the altitude of a star be observed when it is some distance from the meridian, the local time of the observation can be calculated. The star is moving most rapidly in altitude when on the prime vertical (*i.e.* due east or west of the observer), and this is the most favourable position for observation. The latitude need not be known with any great accuracy provided the star be observed near the prime vertical. Observations should be paired, as in the case of latitude observations, both for change of face of the theodolite and for east and west stars. With a 6-in. theodolite there should be no difficulty in getting a probable error of $\frac{1}{4}$ to $\frac{1}{3}$ second in the result.

Other methods for determining latitude and time are:

§ (26) Equal Altitude Method.—This has come into favour recently. The simplest form of the method is to observe the moment a star reaches a given altitude before crossing the meridian, and the moment it reaches the same altitude after crossing. Half-way between these two times the star must be on the meridian, hence the time of transit is known and hence local time. This method is very simple and is independent of any knowledge of latitude and of such instrumental errors as graduation or collimation errors, and is largely free from refraction errors. The disadvantage is that the pair of observations must be taken at a considerable interval of time. If the sun is used a correction must be made for the change in declination in the interval. If a succession of observations is made on different stars, noting the time each reaches the fixed altitude, each observation gives an equation connecting time (hence chronometer error) with altitude, latitude, and declination. The declination is known in each case, and the altitude and latitude are the same in every case, so three such observations give values for time, latitude, and the exact altitude observed. Further observations give a check. Gauss' original solution entailed working out by least squares those corrections to the assumed chronometer error and latitude that make the observations best fit the condition that all the altitudes are equal. MM. Claude and Driencourt have found an extremely simple and accurate graphical solution, which enables the results to be obtained with great speed. The preparation of a programme from the data given in the *Nautical Almanac* entails considerable work, as a suitable number of stars reaching the desired altitude sufficiently close together must be found and their azimuths calculated. This work can, however, be done once for all for any range of latitude, and Messrs. Ball and Knox Shaw have tabulated sidereal times and azimuths of some 17,000 star passages for an elevation of 60°, including only *Nautical Almanac* stars of fourth magnitude and upwards and latitudes from 55° S. to 55° N., based on the star places given in the *Nautical Almanac* for 1918. The tables will in time go out of date owing to change in declination, but they should serve for topographical survey work for some fifteen years. The advantage of the method lies in the fact that an exact knowledge of the altitude is not necessary, hence changes of face are not required with the theodolite, nor determinations of the index error with a sextant. The method can be used with an ordinary theodolite or sextant, but is simplest with the prismatic astrolabe (see article on "Gravity Survey," Vol. III.).

§ (27) Talcott's Method (see article on "Gravity Survey," Vol. III.).—Talcott's method is another excellent method for determining latitude, and can be used with a theodolite provided it be fitted with stops to enable it to be turned exactly 180° in azimuth, and with a micrometer eyepiece.[2] With such an instrument the probable error of a single pair of observations should be about 0·7 second.

§ (28) Determination of Azimuth.—The azimuth of a heavenly body is the angle between the meridian plane of the observer and the vertical plane passing through the body; thus in astronomical work the azimuth is always measured the shortest way from the elevated pole. In triangulation work[3] the azimuth of a terrestrial object is always

[1] See article on "Field Astronomy and Atmospheric Refraction," Vol. III.

[2] See "Description, Adjustments, and Methods of Use, of the 6-Inch Micrometer Theodolite, 1912 Pattern, etc.," *Bulletin 34 of the Canadian Topographic Survey*.

[3] See C. F. Close, *Text-book of Topographical and Geographical Surveying*.

reckoned from the south by the west. If the latitude be known, and also the declination of a heavenly body and its elevation at any moment, its azimuth at that moment can be calculated. To determine the azimuth of a terrestrial object, *i.e.* to determine the direction of the meridian, some reference object (R.O.) is required; this must be a lamp by night, and in any case must be at such a distance that it can be observed to with the telescope at stellar focus. In observing on a star the R.O. is first intersected, and the horizontal circle read, the bottom plate being kept clamped, the telescope is swung on the star, and the horizontal hair set slightly in advance of the star, while the vertical hair is kept on the star by the slow-motion screw. At the moment the star passes the intersection of the cross hairs the slow motion screw is stopped and both vertical and horizontal circles read. It is desirable also to read both the micrometer arm, and the striding, levels. Face is then changed and the star and R.O. again intersected. This completes one set of observations on one star. Observations should always be paired as in other astronomical work. It is also desirable that the star should not be moving rapidly in azimuth, or a small error in the observed altitude will produce a large error in the result. The best time for observing is when the body is in the prime vertical or when a circum-polar star is at elongation.

If local time be known, the azimuth of the star can be calculated if the instant of observation be observed instead of the altitude. The observation in this case is somewhat easier.

In all cases of astronomical observations for azimuth the levelling of the instrument is of great importance, and it is very desirable that the striding level should be used and any dislevelment of the horizontal axis allowed for.

VIII. Levelling and Levelling Instruments

§ (29) Levelling.—Levelling is the art of determining the heights of points on the earth's surface, and the term is generally restricted to the method by which the difference in height between neighbouring points is directly determined by reading with a horizontal line of sight on graduated staves held vertically at the points. If a graduated staff be held vertically at a point A, and read by means of a horizontal line of sight from a point P, the reading gives the difference of height between points A and P. If the staff be now held on any other point B, and again read by a horizontal sight from P, the height of B over A is given by $a - b$, where a and b are the readings on the staves at A and B respectively. The reading a is generally called the "back sight," and the reading b the "fore sight." It is obvious that the points A and B must be comparatively close together, and that the difference in height obtained is with reference to the horizontal plane through P. As the surface of the earth approximates to a sphere rather than to a plane, the reading a is subject to a small correction due to the earth's curvature, and similarly with b. If the distances from P to A and B are equal these corrections will also be equal in magnitude and sign, and consequently the difference $a - b$ will also give the correct difference in height when referred to a spherical level surface. The error introduced by the assumption that the earth is a sphere is quite negligible in levelling operations. If the points whose difference in height is required are so situated that the staves held on them cannot both be read from one position, a series of intermediate points is used, and their heights determined successively.

§ (30) Levelling Instrument.—The levelling instrument consists essentially of some form of sighting apparatus, the line of sight of which can be set in a horizontal plane. The simplest form consists of a water-level. This is illustrated in *Fig.* 13, and consists of

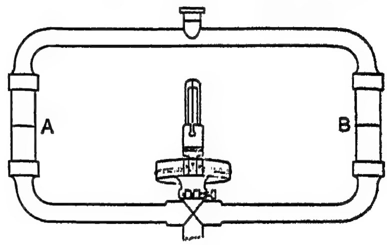

Fig. 13.

two vertical glass tubes A and B connected by horizontal tubes, and mounted on a stand. The tubes are partially filled with coloured water so that the surface of the water is visible in the glass tubes. A line of sight taken across the water surfaces is necessarily level. The instrument is very simple and cannot get out of adjustment. On the other hand, it is impossible to take long or accurate sights.

(i.) *The Ordinary Levelling Instrument.*—This consists of a sighting telescope with a spirit-level attached so that the collimation line can be set horizontal. The important points are that the line of sight of the telescope shall be horizontal when the bubble is in some known position in its tube, and that the telescope can be turned in any direction without altering its height.

The telescope is generally of the astronomical type giving an inverted image, and using an eyepiece of the Ramsden type.

Cross hairs are provided at the focus of the object-glass to define a definite line of sight or collimation line. In order that the line thus determined may not vary as the distance between the object-glass and the cross hairs is altered in the process of focussing, it is necessary that the cross hairs should be accurately on the optical axis of the object glass, and that the mechanical guiding of the moving portion should be true.

Telescopes with an internal focussing lens have been introduced lately. These have the cross hairs rigidly fixed in the tube carrying the object-glass, while the focussing is carried out by means of a negative lens moving between the two. In *Fig.* 14, A is the object

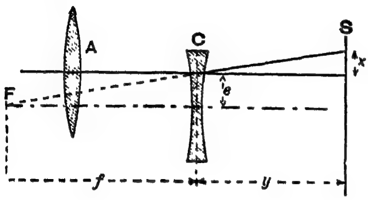

FIG. 14.

glass, C the negative lens, and S the diaphragm carrying the cross hairs. The focal length of C is f, and its axis is supposed parallel to that of A but distant e from it. A ray passing along the axis of A will then be deflected by C and meet the diaphragm at a distance x above the axis. It is seen at once from the figure that $x = ye/f$, where y is the distance between C and S; as in practice f is three or four times y, a given eccentricity in C produces only one-third to one-fourth the change in collimation that would be produced by an equal movement in A or S. Not only is the effect of variable eccentricity reduced by this means, but it is easier mechanically to provide true guides for an internal lens than for the object-glass or diaphragm and eyepiece. A further advantage of this arrangement is that when a glass diaphragm is used, the telescope can be made air-tight, and consequently dust- and damp-proof. An internal positive lens could be used in the same manner, but at the expense of compactness.[1]

Although it is possible to reduce the change in collimation of an instrument to a very small amount by suitable design and good workmanship, it is impossible to eliminate it entirely. For the most accurate work it is possible and necessary so to arrange the observations that errors due to this cause will cancel out.

(ii.) *The Dumpy level* is the type most generally used, and is the simplest type. It consists of a telescope with a spirit-level attached on the top or side, the support of the spirit-level being sometimes cast in one piece with the telescope tube. The whole is mounted on a vertical axis and provided with the usual levelling screws. A clamp and slow motion in azimuth is generally provided for convenience in directing the telescope on the staff. When the instrument is in adjustment the axis of the bubble tube is parallel to that of the telescope and perpendicular to the vertical axis. In use the instrument is set up and focussed and the vertical axis set vertical by means of the levelling screws and bubble in the usual way. If the instrument is in adjustment the collimation line is then horizontal in whatever direction the telescope is turned. The adjustments can be checked and corrected as follows:

(*a*) *Coincidence of Collimation Line and Axis of Telescope.*—Drive in three pegs A, B, and C (*Fig.* 15) so that AB=BC=about 200 feet. Set up the instrument half-way between A and B and ascertain the difference in level between A and B. If the instrument is equidistant from A and B any errors in adjustment will affect the two readings equally, so that the true difference in level will be found. Similarly, find the true difference in level between B and C. Then set up at c as close to A as it is possible to focus the staff, read the staff on pegs A, B, and C.

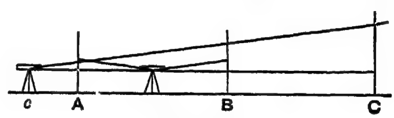

FIG. 15.

From the known correct differences of level compute the correct readings on B and C corresponding to the new reading on A. If the cross hairs are on the telescope axis the error at C will be twice that at B, or more correctly in the ratio cC/cB. If the cross hairs are adjustable any error found can be corrected. If the instrument has been well made and adjusted by the maker no correction should be necessary. As the screws for adjusting the cross hairs (if provided at all) are necessarily small, the less they are used the better, as if they become loose or worn the instrument cannot hold its adjustment.

(*b*) *Parallelism of Bubble Axis and Collimation Line.*—With the instrument at point c (as in above), set the cross hairs at the correct reading on staff at B and then bring the bubble to the centre of its run by means of its adjusting screws. Check the reading on the staff at A, and if this has not altered the adjustment is correct. If a considerable alteration has been made to the bubble screws the reading on A will have been altered, and

[1] See *Zeits. Instrumentenk.*, 1909, p. 320.

the operation must be repeated until the adjustment is correct.

(c) *Bubble Axis Perpendicular to the Vertical Axis.*—Place the telescope parallel to two of the levelling screws of the instrument, and bring the bubble to the centre of its run, then turn the telescope through 180° so as to reverse it end for end. If the bubble is still in the centre of its run the adjustment is correct; if not, correct half the error by the foot screws and half by the screws under the telescope supports, if such be provided. If no arrangement is made for this adjustment the bubble axis must be made perpendicular to the vertical axis, and the collimation line made parallel to the bubble axis by means of test (*b*) and moving the cross hairs. If this introduces any serious error in test (*a*), which is unlikely, the necessary adjustment can only be made by an instrument-maker. With modern methods of manufacture, and with a machined telescope tube, there is no difficulty in making the axis of the telescope perpendicular to the vertical axis with sufficient accuracy for ordinary purposes and without any special adjustment for the purpose. The cross hairs can then be fixed in their correct positions, and the only adjustment that should ever be required to be made by the user is to make the bubble axis perpendicular to the vertical axis.

It should be noted that for ordinary levelling an error of a few seconds of arc in the adjustment is of no importance. For precise levelling it is necessary for a variety of reasons to make the fore and back sights of equal length; and if this be done any adjustment errors cancel out, provided that there is no change of adjustment between the two readings; as in this case it is not necessary to refocus between the readings, the exact collimation is also not necessary. It is seen, therefore, that for precise work also an extremely good adjustment of the instrument is not required.

(iii.) "*Y*" *Levels.*—In this type of level the telescope is provided with two cylindrical collars; the two collars should form parts of the same cylinder, with the same axis as the telescope. The collars rest in Y's, and the bubble tube is attached to the telescope. The telescope can be rotated in the Y's and also reversed end for end after opening the clips which hold it in position. The adjustments are carried out without the use of a staff as follows: (1) The telescope is directed on to some distant object, which is bisected by the horizontal cross hair. The telescope is then rotated in the Y's through 180°. If the object is still bisected, the collimation line is coincident with the axis of rotation of the telescope; if not, half the apparent error is corrected by the diaphragm screws. This brings the collimation line coincident with the axis of rotation. (2) The bubble is then brought to the centre of its run by means of the foot screws. It is then lifted out of the Y's and reversed end for end. If the bubble remains in the centre of its run it is in adjustment; if not, half the error is corrected by the bubble adjusting screws, and half by the foot screws. This brings the bubble axis parallel to the axis of rotation of the telescope in the Y's. (3) The vertical axis is then made vertical in the usual way (see article on "Spirit-levels," § (5)), and if the bubble is not then in the centre of its run it is brought there by means of the screw provided for raising or lowering one of the pillars supporting the Y's.

The above adjustments assume that the axis of the collars coincides with the optical axis of the object-glass. This can be tested by repeating test (1) above on a near object. If the adjustment is correct for a distant object, but not for a near one, the object-glass itself must be moved, and it is not as a rule possible to do this in the field. The adjustment (2) assumes that the collars are of equal diameter. This can be tested by means of a striding level. The striding level is placed on the collars, and the bubble brought to the centre of its run by means of the foot screws. The telescope is then reversed end for end, but the striding level is replaced in its original position. If the bubble is no longer at the centre of its run the collars are of unequal diameters.

The Y level suffers from the disadvantage of a large number of adjusting screws, any one of which is liable to work loose. If the collars become worn or damaged in any way, or if dust or dirt gets between the collars and the Y's, they cannot be used with safety for adjusting purposes, and the instrument is no better than a Dumpy level as regards ease of adjustment, and is more liable to get out of adjustment.

(iv.) *Cooke's Reversible Level.* This is on the same principle as the Y level; but instead of the telescope collars being supported on Y's they are supported in closely fitting rings from which the telescope can be withdrawn longitudinally. The bubble tube is fixed to the rings and not to the telescope direct.

§ (31) PRECISE LEVELS. Levelling instruments for precise work are designed on much the same lines. They are provided with more sensitive bubbles and more powerful telescopes, but the chief difference is that they are provided with a screw for tilting the telescope with the bubble attached, independently of the levelling screws of the instrument, and no attempt is made to set up the vertical axis truly vertical. The bubble is brought to the centre of its run *after* the telescope has been directed on the staff. A mirror or prism arrangement is provided so that the observer

can see that the bubble is set correctly at the moment the observation is taken. This arrangement is very convenient to use, and is to be recommended for all levelling work, except possibly where a large number of staff readings are made from each position of the instrument, as when running cross-sections or when contouring.

(i.) *French Pattern.*[1]—This pattern is of the Y type, and the bubble is fitted as a striding level. Two readings are taken on each staff—(1) with the telescope and bubble in their normal position, and (2) with the telescope rotated through 180° in the Y's and with the bubble reversed end for end.

(ii.) *Coast and Geodetic Survey* (*U.S.A.*) *Pattern.*—This pattern consists of a large Dumpy level with the addition of a tilting screw. The telescope tube is of invar, and the bubble tube is sunk into the telescope tube so as to be as near the telescope axis and as well protected from temperature changes as possible. The bubble is viewed by a system of mirrors and prisms. The telescope is of high power and the bubble very sensitive; in consequence the instrument is heavy. There are only two adjustments, viz. a screw for adjusting the bubble tube parallel to the collimation line, and an adjustment for the cross hairs. It is very suitable for use on level ground where long sights can be taken.[2]

(iii.) *Zeiss Pattern.*—This was designed by Dr. Wild, and has a telescope of special construction. There is no draw tube, and an object-glass is fixed at each end of a rigid tube. The object-glasses are of equal focal length, and each has a set of cross hairs engraved on it. The eyepiece can be attached at either end. The focussing is carried out by an internal lens. The bubble is attached to the telescope tube at the side, and is viewed by the special prism[3] arrangement. The telescope is capable of rotation round its axis through an angle of 180°, and carries the bubble with it. The bubble being ground to a barrel shape can be used in either position. The adjustment is carried out in a special manner. A staff is set up at a convenient distance, and four readings are taken as follows:

(1) Normal working position, bubble to left, prism box up.

(2) Bubble to right, prism box down.

The eyepiece is then placed at the other end of the telescope, which is rotated 180° in azimuth.

(3) Bubble to left, prism box down.

(4) Bubble to right, prism box up.

The bubble is brought to the centre of its run by means of the tilting screw, before each reading is taken. The mean of the four readings is correct, and if the mean is the same as reading (1) the instrument is in adjustment; if not, the telescope is tilted until it reads correct in position (1) and the bubble tube adjusted as necessary. It will be observed that in these four readings two collimation lines are used, the first in positions (1) and (2) and the second in positions (3) and (4). The mean readings (1) and (2), and also the mean of (3) and (4), are free from collimation error. There are also in effect two bubble tubes, the first used in positions (1) and (4) and the second in (2) and (3). The mean of readings (1) and (4) and the mean of (2) and (3) are each free from any error due to the bubble tube not being parallel to the collimation line, hence the mean of all four readings is free from collimation and bubble errors. The method is simple in use, and the instrument holds its adjustment remarkably well owing to the absence of any delicate adjusting screws. It is doubtful, however, whether the complication of the second object-glass is really justified. A simple Dumpy level with a tilting screw, and the bubble mounted and viewed as in this pattern, would appear to be all that is required. The instrument requires adjusting so seldom that the slightly increased labour involved in adjusting by the ordinary method will hardly

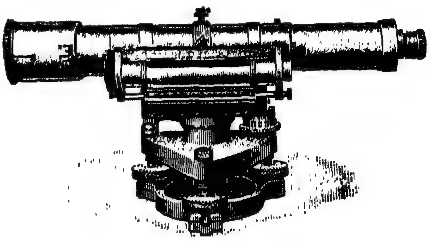

FIG. 16.

be noticed. *Fig.* 16 illustrates such an instrument.

(iv.) *Plate Micrometer.*—It is more accurate to bisect a division on the staff than to estimate the reading of the cross hair when it falls between two divisions. This can be done most readily by mounting a thick plate of glass with parallel sides in front of the object-glass. If the plate be perpendicular to the axis of the telescope it has no effect on the reading, but if it be tilted about a horizontal axis the rays of light are displaced vertically by an amount depending on the thickness and refractive index of the glass and the angle of tilt, hence by tilting the plate the staff can be apparently raised or lowered till the cross hair intersects a mark on the staff. The displacement can be

[1] See Ch. Lallemand, "Nivellement de haute précision," being the third part of "Lever des plans et nivellement" of the *Encyclopédie des Travaux Publics*.

[2] For full description see *C. and G. S. Report*, 1900, p. 521; 1903, p. 200.

[3] See "Spirit-levels," § (10).

read off on a suitably graduated drum connected with the plate. The displacement is read direct, and no calculation involving the distance of the staff is required as is the case when a mark is bisected by tilting the telescope. With a 30-power telescope, and a suitable arrangement of cross hairs, the third place of decimals of a foot can be read accurately up to a range of 100 yards and the fourth place estimated. The form of cross hair shown in *Fig.* 17 is convenient for this purpose, the > being placed over the line on the staff.

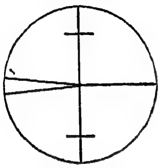

FIG. 17.

§ (32) LEVELLING STAVES.—The usual levelling staff is made of wood, with the graduations painted on. The divisions are either feet and hundredths (sometimes fiftieths), or metres and centimetres or half centimetres. The graduations are usually of the same thickness as the intervals between them, giving a checker pattern. Many different patterns have been devised with a view to ease of reading and avoiding mistakes. The most suitable staff for precise work is probably one with simple line divisions, the divisions just thick enough to be read at the longest range required. This applies especially when a plate micrometer is used, in which case divisions of $\frac{1}{50}$ foot or $\frac{1}{2}$ centimetre are most convenient. As the telescopes generally used are inverting, it is convenient to have the figuring on the staff also inverted. For ordinary work folding or telescopic staves 14 or 15 feet long are convenient, but for precise work they should be in one rigid piece, and 10 feet is long enough. "Target rods" are sometimes used, having a movable target on the face. This is adjusted by the staff holder by signal from the observer at the instrument, so that it is bisected by the cross hair, and the reading is taken by means of a fine scale and vernier on the staff. This method has proved to be neither so convenient nor so accurate as a staff read direct from the instrument, but may be useful where an occasional extra long sight is required.

Wooden staves are liable to change their length with varying humidity; a variation of 3 to 5 parts in 10,000 may be expected from this cause. This is serious in precise work in hilly country. If such staves be used their length must be checked at regular intervals either by a standard bar or otherwise. A method due to Colonel Goulier, of the Commission du nivellement général de la France, is as follows: Two bars of iron and brass respectively are run up the centre of the staff, being secured at the foot of the staff and free to slide elsewhere. They carry at their upper ends marks which are read against a scale fastened to the wood of the staff. The combination of the two rods forms a metallic thermometer, so that from the readings their true lengths and also that of the staff can be found. Since the introduction of invar one bar of this material has been substituted for the two of iron and brass. Staves graduated direct on invar have been used by the Ordnance Survey; there was considerable difficulty in obtaining these, but the Cambridge Scientific Instrument Co. finally provided some of such accuracy that the staff readings could be used direct without correction for temperature or graduation errors.

If the staff be not held vertical when the reading is taken the reading will always be too high. A common method of dealing with this is to swing the staff and estimate the lowest reading of the cross hair; this, however, decreases the precision of the reading. It is equally quick and much more accurate to hold the staff vertical with the assistance of a small circular spirit-level. In this case some means of holding the staff steady must be employed; that illustrated in *Fig.* 18 is convenient.

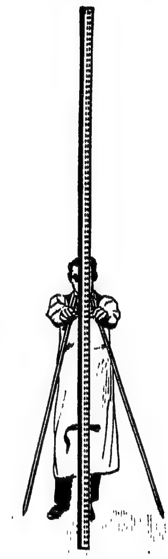

FIG. 18.

§ (33) STAFF SUPPORTS.—The stability of the support on which the staff rests is of great importance; it is obvious that if this changes its height between the forward reading to the staff from one position of the instrument and the back reading from the next position, an error will be introduced. For ordinary work it is convenient to use a small metal tripod pressed into the ground; for precise work a peg (either wood or metal) driven in is generally used, but the actual support used must depend on the nature of the ground. The error caused by the instability of the staff supports is one of the most important in long lines of precise levelling.

§ (34) BENCH MARKS.—The ordinary bench mark of the Ordnance Survey consists of a horizontal line cut in some vertical face, with the Government "broad arrow" cut below it, thus ⊼. In the new precise levelling the marks are of two kinds. The "fundamental" marks, which average 30 miles apart, are illustrated in *Fig.* 19; they are confined to sites where the reference points can be either

fixed in the living rock or in concrete founded on the rock. There are three actual reference points—one a gun-metal bolt for general use,

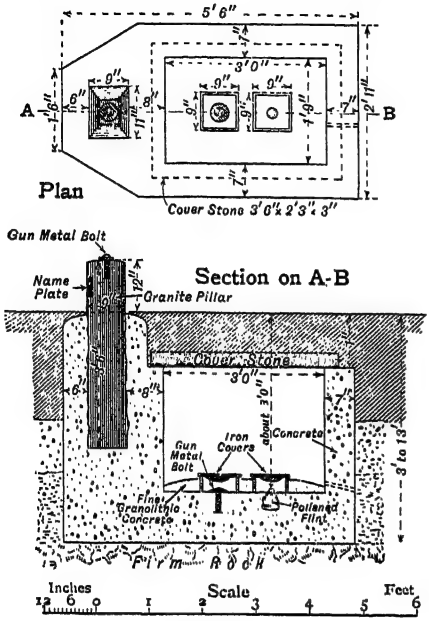

FIG. 19.

and the other two buried for the future use of the survey. The secondary marks, generally about a mile apart, are gun-metal plates as shown in *Fig.* 20, cemented into a vertical

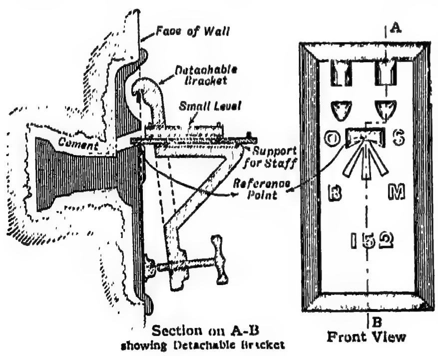

FIG. 20.

face; a detachable bracket serves to support the staff.

§ (35) ERRORS IN LEVELLING.—Some of the causes of errors have already been touched on. Errors due to lack of adjustment of the instrument are eliminated if the instrument is equidistant from the two staves, provided the adjustment does not alter between the two readings. Such change may be due to temperature effects or change of focus. The former acts slowly, provided the instrument is shielded from the direct rays of the sun; the latter does not come in if the instrument is equidistant from the staves. If there is any tendency for the staff supports to move always in the same direction a systematic error will be introduced, which in long lines may easily become the predominant error. The only way to eliminate this is to relevel the line in the reverse direction, keeping all other conditions as unaltered as possible; this is invariably done in all precise work, and a systematic difference between the two levellings has almost always been found. Another cause of error is due to atmospheric refraction; the statement in many text-books that this error cancels out when the instrument is equidistant from the two staves is only true on the assumption (generally incorrect) that the atmospheric conditions along the paths of the two rays are the same. See article on "Trigonometrical Heights and Atmospheric Refraction," Vol. III.

§ (36) DEFINITION OF HEIGHT.—The obvious definition of the height of a point is the distance of the point above the reference surface measured along the vertical through the point. This is called the "orthometric" height. As the surface of the earth approximates to a spheroid rather than to a sphere, this definition leads to the result that two points at the same height are not necessarily at the same gravitational potential, and water might flow from one point to the other, or even from a lower point to a higher. An alternative definition is based on the assumption that all points which are at the same "height" are on the same equipotential surface, and measuring the actual height of each such surface at some fixed point. For this purpose the earth is generally assumed to be a spheroid, and the fixed point is taken in latitude 45°. This is called the "dynamic" height. In practice the distinction only becomes of importance when large areas are covered with a network of precise levelling, and especially when the area covers a tract of hilly country extending north and south. The difference of height as determined by spirit-levelling does not conform to either of the above definitions. The height is first measured on a vertical staff (orthometric) and then carried horizontally to a second staff (dynamic), and so on. The result is that a circuit of levelling carried out without any error, and closing on the starting-point, will, in general, show a difference in height between the starting-point and the (same) finishing-point. The magnitude of this apparent error can be calculated on the assumption that the vertical as indicated

by the level at each setting up of the instrument is a normal to the spheroid of reference. In practice it is the normal to the geoid, and the true correction to be applied to the levelled heights to give either orthometric or dynamic heights cannot be calculated unless the deviation of the plumb-line, or the true variation in the force of gravity, be known for each station occupied. F. R. Helmert[1] has calculated the theoretical closing error of a circuit in the Tirol (*a*) assuming the usual formula, (*b*) based on the actual values of gravity measured by R. V. Steineck; the results were 7 mm. and 24 mm. respectively.[2]

IX. Contouring

§ (37) Contouring.—A contour is a line of equal height above sea-level, and contours drawn on a map at equal vertical intervals form the best method of showing the vertical relief of the ground. The vertical interval depends on the scale of the map and the steepness of the ground. On small-scale maps the contours are necessarily generalised and become "form lines." Accurate contouring must be controlled by spirit-levelling. In large-scale work the contours are established on the ground by means of a spirit- or water-level, and surveyed. The survey may be done either simultaneously with the marking of the contour, or later, and may be done by chain survey, stadia traverse, or plane-tabling, or by a combination of the above.

In contouring with a plane-table on small scales the Indian pattern clinometer is a useful instrument. It is 9 in. long, and has two vanes which are upright when in use. The rear vane has a sight-hole, and the front vane a vertical slit with a scale of degrees on one side of the slit and of natural tangents on the other. The sight-hole is brought level with the zero of the scales by means of a screw, a level on the horizontal arm indicating the position. The adjustment must be checked by comparison with the readings of a theodolite or by means of reciprocal observations. It is used standing on the plane-table, and by its means the height of the table can be found by measuring the vertical angle to any point whose height is known. The slope of the ground and hence the spacing of the contours on the map can also be found. Sights can be taken up to a distance of about 3 miles. By fixing the height of ruling points, and the slope down spurs and valleys, etc., the contours can be drawn in with sufficient accuracy for small-scale work.

X. Base-line Measurement

§ (38) General.—Before a triangulation can be computed, it is necessary to know the length of one of the sides of one of the triangles, and this must be measured directly. This measured side is called the base, and thus forms the starting-point of any system of triangulation required to determine the horizontal co-ordinates of its points. These co-ordinates are measured on the spheroid of reference, consequently the length of the base (as required for purposes of calculation) is the distance, measured along the spheroid, between the points on the spheroid vertically below the ends of the actual base. Thus if A, B (*Fig.* 21) are the terminal points of the base, ANB being the ground surface, the distance required is A′B′ (measured along the curve) where A′B′ lie on the spheroid of reference and AA′, BB′ are the verticals through A and B.

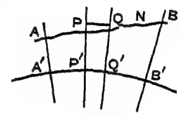

Fig. 21.

The actual line followed by the base may be either in the plane through AA′B or that through ABB′, or it may be such that if P be any point in the base and PP′ the vertical through it, ABPP′ all lie in one plane. These cases represent respectively the result of the line being laid out by a theodolite at A, or at B, or by a transit theodolite at each consecutive point P. The three lines are not strictly the same when the spheroidal shape of the earth is taken into account, but the differences are negligible for base-line measurements, which only extend for a few miles, hence any of these three methods may be used for laying down the base on the ground. The base is necessarily measured in small sections such as PQ, representing the length of a single bar or tape. As these are short compared with the radius of curvature of the spheroid, the straight line distance PQ can be taken as equal to the arc, provided the length of PQ is horizontal. If PQ be not horizontal it must be multiplied by cos i, where i is the inclination of PQ to the horizontal. Unless the base is being measured at sea-level, a further reduction must be made. If R is the radius of curvature of the spheroid at P′ and h the height of P above P′, we get

$$\mathrm{P'Q'} = \frac{\mathrm{R}}{\mathrm{R}+h} \cdot \mathrm{PQ} \cos i,$$

whence L, the length of the base, is given by

$$\mathrm{L} = \Sigma(\mathrm{P'Q'}) = \Sigma(\mathrm{PQ} \cos i) - \Sigma\left(\mathrm{PQ} \cdot \frac{h}{\mathrm{R}}\right),$$

or if i is small, as it is when rods are used,

$$\mathrm{L} = \Sigma(\mathrm{PQ}) - \tfrac{1}{2}\Sigma(\mathrm{PQ} \cdot i^2) - \Sigma\left(\mathrm{PQ} \cdot \frac{h}{\mathrm{R}}\right).$$

These two corrections are known as the reduction to horizontal and reduction to sea-level respectively. It is not necessary in practice to correct each length PQ separately for reduction to sea-level, and the whole correction can be put in the form $L(H_m/R_0)$ where H_m is the mean height of the base above sea-level, and R_0 the mean radius of curvature of the spheroid from A′ to B′.

§ (39) Historical.—The earlier bases were frequently measured by means of deal rods shod with metal at their ends. Such rods do not vary greatly in length with change of temperature, but alter their length considerably with varying moisture. This variation can be largely reduced by boiling the rods in paraffin wax. Wooden rods were used in the classic measurements undertaken by the French in Lapland and Peru in 1735–45. They have been used successfully in Germany,[1] and more recently in Egypt,[2] where a probable error of about five parts in a million was obtained by this method.

The earliest base in this country (Hounslow Heath,[3] 1784) was measured with deal rods with bell-metal ends, and with glass rods. In the case of the deal rods it was noticed during the work that their length was much affected by changes in the humidity of the atmosphere. No attempt appears to have been made to avoid this by varnishing or otherwise treating the rods. The temperature of the glass rods was found by two thermometers in contact with each rod, and the expansion due to temperature was allowed for. The discrepancy between the two measurements was 1·8 ft. in 27,400 ft., or 66μ (μ in this section represents one-millionth of the total length). In 1791 this base was remeasured with a steel chain, made by Ramsden, of 100 ft. length (40 links of 2·5 ft. each); the discrepancy of the result compared with the glass-rod measurement was 0·23 ft., or 8μ. The Ramsden chain was used for four other bases in England, and is now deposited in the Science Museum at South Kensington.

During the nineteenth century accurate bases were almost invariably measured with metal bars, a probable error of 1 to 2μ being obtained. In 1885 E. Jäderin [4] suggested the use of metal tapes or wires suspended free in catenary for base measurements, and the introduction of "Invar," due to the researches of Ch. Ed. Guillaume, of the International Bureau of Weights and Measures, has enabled Jäderin's apparatus to be so improved that it now forms a method of base-line measurement which is not only fully as accurate but much quicker and cheaper than the older methods.

The measurement of the Salisbury Plain base (length 6·9 miles) in 1849 with Colby's apparatus took a large party nearly six months in the field, while the Lossiemouth base of 4·5 miles was measured in 1909, using invar tapes, by a much smaller party in about a month, and with a higher degree of accuracy.

§ (40) Base Measurement in the Nineteenth Century.—The great trouble in all base line measurements has been the change in length of the apparatus due to humidity (in the case of wood bars) or temperature. A metal rod needs time to take up the temperature of its surroundings, and in the field the conditions are such that the true mean temperature of the rods cannot be obtained satisfactorily by the use of thermometers in contact with them. To overcome this difficulty Borda [5] introduced the principle of the bimetallic thermometer. His apparatus consisted of two strips of metal in contact. The lower strip of platinum (either 2 toises or 4 metres long) rested on a stout beam of wood; lying immediately on it, and fastened to it at one end, was a strip of copper about 6 inches shorter. A scale on the free end of the copper, read by a vernier on the platinum, indicated the relative expansions of the two bars, whence the temperature, and therefore the true length of the platinum strip, could be inferred.

Another apparatus designed to the same end was Colby's [6] compensated bar apparatus, which consisted of two 10-ft. bars, one of iron and one of brass, firmly connected at their centres. At either end was a metal tongue about 6 inches long pivoted to both bars so that, while free from shake, they did not impede the free expansion of the bars. At the outer end of each tongue was a small dot, and the distance between the dots determines the length. If aa' and bb' (*Fig.* 22) are the bars,

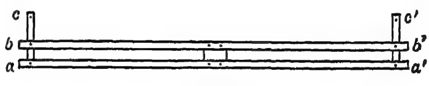

Fig. 22.

having a temperature coefficient of α and β respectively, and if abc, $a'b'c'$ are the tongues, the lengths ab, bc, etc., are so chosen that $ac/bc = \alpha/\beta$; if, therefore, owing to a change of temperature, a moves a distance ad, b will move βd, and c will not move. If the expansion can be considered as proportional to the change of temperature, and if both bars are at the same mean temperature, the distance

cc' will remain constant. This apparatus was used for the two chief bases of the Ordnance Survey of the United Kingdom, for ten bases in India, and also in South Africa. It has not been used since 1870, as it was found that the temperatures of the two bars did not remain equal, and it was found necessary in India to use thermometers, and not to rely entirely on the automatic compensation.[1] The probable error of measurement with this apparatus was about $1{\cdot}5\mu$.

In most of the earlier bases the rods were used as end measures, and were laid touching end to end. Borda introduced a graduated slider moving in a groove at the free and uncovered end of the platinum strip, for the purpose of measuring the small gap left between successive bars. This was improved later by the addition of a spring and contact screw. Struve,[2] for the Russian bases, used a wrought-iron bar (whose temperature was determined by two thermometers) fitted with a contact lever (*Fig.* 23) for measuring the small interval between the bars, the lever being held in contact by a spring. Bessel[3] used bimetallic bars of iron and zinc. The upper (zinc) terminated in horizontal knife-edges, while at the free end a small piece with two vertical knife-edges was attached to the iron bar (*Fig.* 24). The distance between the knife-edges was measured by a glass wedge, and gave the temperature correction, and the distance between successive bars was measured in the same way. The bases measured with this apparatus had an error of about 2μ.

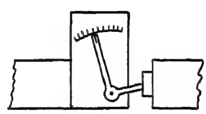

FIG. 23.

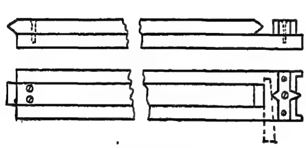

FIG. 24.

Bache in 1845 designed an apparatus which was used by the Coast Survey of the United States, and which combines several of the above-mentioned arrangements. *aa'*, *bb'* of *Fig.* 25 are iron and brass rods respectively, forming a Borda bimetallic thermometer. They are separated by rollers so that they can expand freely. The cross-sections of the bars are so arranged that, while they have equal absorbing surfaces, their masses are inversely proportional to their specific heats, allowance being made for their difference of conducting power. Lever C is a compensation lever so arranged (as in Colby's apparatus) that the position of the upper knife-edge remains constant irrespective of the expansion of the bars. A collar on a sliding rod *d* is pressed back against the knife-edge by a spring, and the sliding rod terminates in an agate plate for contact with the next bar. A scale and vernier attached to the free ends of *a* and *b* enable the relative expansion of the bars to be measured if desired. At the other end, where the bars are fixed together, is another sliding rod *e* terminating in a blunt knife-edge for making contact with *d*; the inner end of *e* abuts on a contact lever *f* pivoted below, which in its turn comes in contact with the short tail of the lever *g*, mounted on trunnions, but not balanced, and carrying a spirit-level. For a certain position of the rod *e* the bubble becomes central, and this position determines the standard length of the bar. This arrangement is very delicate, and ensures that the pressure of contact is always the same.

All the bars so far considered (except Colby's) are end measures. Colby set the bars so that the dots of two successive bars were exactly 6 inches apart, by means of two microscopes. The two microscopes were connected by two bars of brass and iron respectively in such a manner that the focal points of the microscopes were exactly 6 inches apart, the temperature compensation being on the same principle as that of the bars. A third microscope passed through the centre of the bars, and was constructed to focus a point at ground-level. The microscopes were provided with levelling screws, and screws for giving motion in longitudinal and transverse directions. The whole compensated microscope set rested on a bracket attached to one end of the case enclosing the bars. The measurement of the 6-inch intervals was effected by bringing one of the outer microscopes to intersect the dot on the bar last placed, and then moving the next bar up by its slow-motion screws so that its dot was

bisected by the other microscope. The end of each section of six bar lengths was transferred to the ground by the centre microscope, a suitable reference point being adjustably mounted on a heavy cast-iron plate resting on the ground. The Salisbury Plain base, which was measured in 1794 with the Ramsden chain, was remeasured in 1849 with the Colby apparatus, and a discrepancy of 1·03 ft., or 28μ, was found between the two measurements. Some of the original Colby apparatus is now in the Science Museum at South Kensington.

Boscovitch in Italy in 1751 used bars with the length defined by line marks on the bars, measuring the distances between successive bars by dividers and scale, and other early work was done with marks on the sides of the bars.

All the above-described methods used a succession of bars, either actually or nearly touching. J. Porro and others used a single bar to measure the distance between successive microscopes mounted on tripods, and carefully aligned and levelled. Porro used a bimetallic bar for temperature correction. His apparatus was improved by Ibañez [1] and used in Spain and Switzerland.

In 1871 R. S. Woodward,[2] of the Coast and Geodetic Survey, overcame the temperature difficulty by using a single iron bar carried in a V-shaped trough filled with melting ice. An error of $0{\cdot}25\mu$ is claimed for this apparatus, and it is probably the most accurate method that has been adopted. It is slow and expensive to use, and its greatest utility is perhaps for laying down a field standard for standardising wires or tapes.

Any method, such as those described above, which involves the use of metal measuring bars in the field entails the provision of heavy trestles for their support. These trestles must be carefully aligned and levelled, and in order to do this the ground must be fairly level and smooth, and in many cases much clearing and preparation of the ground are required. Such methods are therefore necessarily slow and expensive.

For further particulars of the older methods see A. Westphal, *Zeits. Instrumentenk.*, 1885, v. 257, 333, 373, 420, and 1888, viii. 189, 225, and 337. For fuller details reference must be made to the original accounts mentioned, or to the official reports of the surveys concerned.

§ (41) Modern Base Measurements. (i.) *In America.*—The American "Duplex" bar apparatus has been used with success in modern work. It consists [3] of two measuring tubes 5 metres long, each containing two hollow cylindrical bars, one of steel and one of brass. The outer tube is mounted on two wooden tripods, with fine adjustments for levelling and aligning. The measuring bars project at both ends from the outer tube, and are brought into end contact, steel to steel and brass to brass, by means of screws which move them bodily in the outer tube. The contacts are agate knife-edges. The process results in two simultaneous, but independent, measurements, one with the steel bar and one with the brass bar. If, owing to temperature, one bar gain too much on the other, it can be set back a known amount by means of a vernier on the steel bar read against a scale on the brass. Thermometer readings give the temperatures of the bars. The difference between the total lengths of the base as obtained from the brass and steel, uncorrected for temperature, gives the mean temperature of the bars, and thus the temperature correction to be applied. The thermometers give the corrections to be applied to each individual bar length, which provides a check. The bars are actually tubes of comparatively thin metal, the thicknesses being calculated to compensate for relative specific heats and conductivities; they are both nickel-plated, and enclosed in a double tubular covering; the result is that they maintain very closely the same temperature.

(ii.) *Tapes.*—If wires or tapes be used for the actual field measurements, they can be much longer than the bars, consequently there are fewer points requiring accurate alignment, and fewer measurements or settings at the end of each unit length; this tends to both speed and accuracy. At the measurement of the Holton Heath base [4] a comparison of various methods was made and the practical use of tapes tested in the field. Steel tapes graduated every 20 metres over a length of 100 m. were employed, the total length being about 101 m.; the cross-section was 6·34 by 0·47 mm., and the weight 22·3 grams per metre. The tape was strained to a constant tension of 25 lbs. 9 oz. by means of a spring balance. The tensioning apparatus consisted of a lever of steel tubing, with a wooden extension as handle, hinged by a universal joint to a platform on which the operator stood. The tube was threaded, and a wheel nut carried a gimbal-jointed support, to which was attached the spring balance. The balance was used at one end only. The tape was supported every 20 m. on wire nails driven into posts. At the end of every 100 m. length a properly ranged marking-post was cut off, or driven down, to the proper height, and capped by a plate of zinc. The supporting

nails were carefully adjusted as to height by a telescope, so that they lay in a line joining the two marking-posts. The tape being placed in position, the rear mark was brought to coincide with a mark on the zinc top of the marking-post, and the strain taken at the front end by the spring balance; the tape was then lifted clear of the nails, and dropped on to them so as to avoid friction and any lack of alignment in the tape itself. When all was correct, a scratch corresponding with the forward end of the tape was made on the zinc of the forward marking-post with a fine bradawl, the thermometers were read, and the tape moved forward to the next section. If temperature effects, or inaccurate spacing of the marking-posts, caused the tape ends to get too near the edges of the zinc plates, the tape was set forward or back an even number of centimetres by means of a scale. The tapes were standardised in the field on a special 100 m. comparator by means of the 5 m. iced bar. A special section of the base 1 km. long was measured by the iced bar, by 5 m. contact rods, and by the 100 m. tape. The tape measurements were taken both by day and by night. Two or more measurements went to a set; the sets taken at night varied $\pm$ 3 mm. from the mean, those by day up to 10 mm. The mean of the night sets (21 measurements) differed from the iced bar measurement by only 0·2 mm. The greater accuracy at night is due to the better temperature conditions. The rate of working with the iced bar was 100 m. an hour, and the probable error of one such measurement of 100 m. was about $\pm$ 0·034 mm. The probable error of the 1 km. section (mean of 4 measurements with the iced bar) was $\pm$0·26 mm. The rate of working with the tapes at night was about 2 km. per hour. The probable errors given are those of measurement only, and do not include the error of the iced bar itself. The final results for the kilometer section were:

Mean of 6 measurements with steel rods	1000 m. – 4·9 mm.
Mean of 21 measurements with steel tapes	1000 m. – 3·6 mm.
Mean of 4 measurements with iced bar	1000 m. – 3·4 mm.

These results showed the possibility of using steel tapes for work of first-class accuracy.

In 1900 the Coast and Geodetic Survey [1] considered that, in view of the speed with which base measurements could be made with tapes, it would be advantageous to measure frequent check bases. An accuracy of 2 μ was laid down, and no time was to be spent in trying for more accurate results than this. Fifty and 100 m. tapes were used, supported every 25 m.—2 × 4 in. stakes for intermediate supports, and 4 × 4 in. stakes for the marking-posts, topped with copper instead of zinc. A kilometer of each base was measured with the duplex bar apparatus, and tapes and bars were standardised against the iced bar at the beginning and end of the season. The methods for using the tapes were generally the same as those employed at the Holton Heath base. In the result, 9 bases with a total length of 69 km. were measured by one field party between July 16 and January 18; including the standardisation work, the worst probable error obtained was 1·4 μ and the average 0·8 μ. Later on invar tapes were used,[2] which enabled work to be done in the daytime with less danger of temperature errors and greater ease and accuracy, as compared with steel tapes by night. In 1907 a party of from seven to thirteen men prepared and measured 3 bases, and measured 3 more (prepared by another party), in all 6 bases with a total length of 100 km., in four months. The worst probable error was 0·46 μ and the average 0·36 μ. Both steel and invar tapes were used, the latter proving 7 per cent faster and 70 per cent more accurate.

(iii.) *Tapes or Wires in Catenary.*—When tapes are used as above described, with the tapes supported at short intervals, and always supported in the same way both when being standardised and when in use, and when only small inclinations are used, no allowance need be made for sag, etc. The method, however, while much quicker than the use of bars, and not necessitating quite such a smooth stretch of ground, still requires a fairly smooth and level site for the base. The latest base apparatus, a development of Jäderin's,[3] uses the tapes hanging free in catenary throughout their length. By this method fewer supports are necessary, and bases can be accurately measured over more uneven ground and on steeper slopes.

The method and apparatus used have been described in detail by Benoit and Guillaume.[4] The tapes are not graduated throughout their length, but carry small scales at either end, reading + or − from the zero graduation. The scales are a few inches long and are graduated in millimetres, or some similar divisions such as $\frac{1}{25}$ in. The nominal length of the tape is the straight line distance between the zero graduations when they are at the same level, with the tape hanging free at standard tension. There is some difference of opinion

as to the relative merits of tapes or wires. If tapes are used, the scales can be marked direct on the tapes themselves, and it is easy to ensure that there is no twist in the tape. With wires the scale has to be attached to the wire, and a twist is not so easily detected. On the other hand, wires are probably less affected by wind. The tension is applied to the tape by means of a cord or wire, passing over a pulley, with a weight attached. The measurement is carried out as follows: A number of trestles are aligned along the base and spaced at intervals of one tape-length. The trestles have heads somewhat as shown in *Fig.* 26, the heads being movable horizontally on the trestles for accurate alignment. The tape is then placed alongside the trestles, just not touching the tops, and strained by means of the straining trestles to the standard tension. Simultaneous readings are taken by observers at the two ends, the scale on the tape being read against the mark on the trestle. Eight or ten such readings are taken, the tape being moved slightly in a longitudinal direction between each reading. The tape is then moved to the next span and the process repeated. After every six spans or so the observers change ends, in order to eliminate personal errors. Each section of a convenient number of spans is measured two or more times, the direction of measurement being changed between each. It is preferable to use more than one tape. At the end of each day's work the point on the ground directly under the terminal trestle head is marked on the ground, and checked before recommencing work to ensure that the trestle has not shifted. The difference in height between the trestle heads must be ascertained by levelling, or by observing the slope between them. This is required both for the ordinary reduction to the horizontal and to allow for the change in shape of the catenary when the ends of the tape are no longer at the same level. The temperature of the tapes must also be noted; but as the coefficient of expansion of invar is so small (about 5×10^{-7} per 1° C., or less), no great accuracy is necessary. The temperature can be observed either by means of a swing thermometer or by thermometers attached to the tape beyond the terminal marks; the former is probably the preferable method, at any rate in temperate climates.

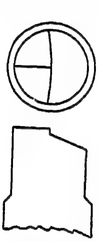

FIG. 26.

The apparatus as originally designed had weights and pulleys at both ends for applying the tension; but if the tape is on any appreciable slope the tension for equilibrium is not the same at the two ends, and the tape will run downhill, or, if it does not, the excess tension at the lower end must be absorbed by friction, and in such a case an uncertainty as to the true tension at once arises. A preferable method is to attach one end direct to the straining trestle by means of a screw, and to move the tape by its means between the readings, half the readings being taken after a screwing-up motion and half after a screwing-out motion; if a fine wire or steel tape be used for connecting the weight, there is practically nothing lost by friction (which is not necessarily the case when a cord is used), and the mean tension applied at the weighted end is the standard tension as determined by the weight.

No elaborate apparatus is required. The straining trestles for the tapes consist of one long leg carrying the pulley, which is placed in the alignment of the base, and two shorter legs supporting it, one on each side. If the long leg be continued beyond the point of attachment of the supporting legs, so as to form a handle, it can be placed in its correct position without much difficulty. In the simplest form the pulley is mounted in a slot in the leg, but some users prefer having it mounted in a frame, the frame being pivoted so that the pulley automatically places itself in the plane of the tape, being capable of movement up or down, and sideways, relative to the trestle, by means of screws. In any case it is essential that the pulley should be true on its axis, and as frictionless as possible.

The trestles for marking the ends of the tape lengths are easily aligned by a theodolite. The difference of height between successive trestles is best determined by an ordinary telescopic level, using a special short levelling staff resting on the trestle heads. It is sufficient in the field to read the scales on the tapes with the aid of a reading-glass; microscopes are not necessary.

Great care must be taken in handling the tapes or wires. It must be remembered that the whole accuracy depends on the constancy of their lengths; they must therefore on no account be strained beyond their elastic limit, or bent or kinked. To ensure this, great care is necessary in winding and unwinding the tapes on the drums used for storage or transport, and they should never be dragged along the ground. The following points must be kept in mind in the design and use of the drums: (1) The diameter of the drum must be such that no sharp bend is given to the tape or wire; a diameter of about ½ metre is suitable. (2) In the case of a wire, which has a stiff scale attached, the end must be attached to a projecting hook on the drum of such length that the scale forms a tangent to the drum, touching the drum well beyond the

scale, so that the wire is not bent at the point of its attachment to the scale. (3) Wires should be wound helically on the drum without overriding. (4) Tapes should be wound on a narrow drum with cheeks, the distance between the cheeks being only slightly greater than the width of the tape to avoid any possibility of the tape catching in itself when being unwound. (5) The tape or wire must not be wound so tightly that any expansion of the drum with temperature can possibly strain the wire beyond its elastic limit. There is no difficulty in the case of a tape, but if a wire is not rolled tightly the turns may override, and it is safer to insert a spring between one end of the wire and its hook on the drum, and thus ensure a sufficient but not excessive tension. Provision must be made for mounting the drum, either on the straining trestle or in its carrying box, so that it can be easily turned for winding and unwinding.

It is desirable to keep one or more tapes as standards, and to use one or more working tapes for the actual base measurement. A pair of marks similar to those on the trestles should be set up one tape-length apart on firm-fixed pedestals somewhere near the base, for use as a comparator for comparing the working tapes with the field standards, and such comparison should always be made before and after the base measurement, even if intermediate comparisons are not made. By this means any variation in the length of the working tapes can be detected. These latter cannot be so effectively guarded against accidental damage as the standards.

§ (42) Theory of Tapes in Catenary.—If a heavy, uniform, and inextensible string is stretched between two points the equations of the curve assumed are

$$x = cu,$$

$$y = c\cosh u = c\left(1 + \frac{u^2}{2!} + \frac{u^4}{4!} + \dots\right),$$

$$s = c\sinh u = c\left(u + \frac{u^3}{3!} + \frac{u^5}{5!} + \dots\right),$$

where s is the length measured along the curve from the lowest point, c is the length of string whose weight is equal to the tension at the lowest point, and u is an independent variable; also the tension at any point on the curve is equal to the weight of a piece of string equal in length to the y of that point. Hence if w is the weight per unit length, T_0 the tension at the lowest point, T_1 and T_2 the tensions at points (x_1y_1), (x_2y_2) respectively, then $c = T_0/w$, $y_1 = T_1/w$, $y_2 = T_2/w$.

If l is the length of the string $(= s_2 - s_1)$,
X the horizontal distance $(= x_2 - x_1)$,
h the difference in height between the ends $(= y_2 - y_1)$,

the problem is to find X in terms of X_0 (the value of X when $h = 0$) and h.

$$X = x_2 - x_1 = c(u_2 - u_1),$$

$$l = s_2 - s_1 = c(\sinh u_2 - \sinh u_1)$$

$$= 2c\cosh\frac{u_2 + u_1}{2}\sinh\frac{u_2 - u_1}{2}.$$

Similarly

$$h = 2c\sinh\frac{u_2 + u_1}{2}\sinh\frac{u_2 - u_1}{2}$$

and $$\frac{l^2 - h^2}{4c^2} = \sinh^2\frac{u_2 - u_1}{2} = \sinh^2\frac{X}{2c},$$

call $$\frac{l^2 - h^2}{4c^2} = z.$$

Then

$$X = 2c\sinh^{-1}\sqrt{z},$$

$$= 2c\sqrt{z}\left(1 - \tfrac{1}{6}z + \tfrac{3}{40}z^2 - \tfrac{5}{112}z^3 + \dots\right)$$

$$= \sqrt{l^2 - h^2}\left(1 - \tfrac{1}{6}z + \tfrac{3}{40}z^2 - \tfrac{5}{112}z^3 + \dots\right).$$

Also $$y^2 - s^2 = c^2(\cosh^2 u - \sinh^2 u) = c^2,$$

hence $$y_2^2 - y_1^2 = s_2^2 - s_1^2,$$

and $$l(s_2 + s_1) = s_2^2 - s_1^2 = y_2^2 - y_1^2 = h(y_2 + y_1),$$

$$l(s_2 - s_1) = l^2,$$

hence $$2ls_1 = h(y_2 + y_1) - l^2,$$

$$2ls_2 = h(y_2 + y_1) + l^2,$$

and $$2l^2(s_2^2 + s_1^2) = h^2(y_2 + y_1)^2 + l^4;$$

but $$2c^2 = (y_2^2 + y_1^2) - (s_2^2 + s_1^2),$$

hence $$4l^2c^2 = 2l^2(y_2^2 + y_1^2) - h^2(y_2 + y_1)^2 - l^4$$

$$= l^2(y_2 + y_1)^2 + l^2h^2 - h^2(y_2 + y_1)^2 - l^4$$

$$= (l^2 - h^2)\{(y_2 + y_1)^2 - l^2\},$$

therefore $$z = \frac{l^2 - h^2}{4c^2} = \frac{l^2}{(y_2 + y_1)^2 - l^2}.$$

If, therefore, the mean tension at the two ends of the tape is kept constant, *i.e.* if $(y_2 + y_1)$ is constant, then z is constant, and

$$X_0 = l\left(1 - \tfrac{1}{6}z + \tfrac{3}{40}z^2 - \dots\right),$$

whence

$$X = \sqrt{l^2 - h^2}\,.\,\frac{X_0}{l} = X_0\sqrt{1 - \frac{h^2}{l^2}}.$$

To find l, put $l = X_0 + \lambda$, where λ is what is sometimes called the "sag," then

$$\lambda = l - X_0 = 2(s - x) = 2c\left(\frac{u^3}{3!} + \frac{u^5}{5!} + \frac{u^7}{7!} + \dots\right)$$

$$= 2x\left(\frac{x^2}{3!c^2} + \frac{x^4}{5!c^4} + \frac{x^6}{7!c^6} + \dots\right);$$

but $$4c^2 = (y_2 + y_1)^2 - l^2 = \frac{4T^2}{w^2} - l^2,$$

where T is the standard tension applied to the ends, hence if T is n times the weight of the tape,

$$T = nlw,$$

and
$$c^2 = \frac{T^2}{w^2}\left(1-\frac{1}{4n^2}\right),$$

and
$$\lambda = 2x\left\{\tfrac{1}{6}x^2\frac{w^2}{T^2}\left(1-\frac{1}{4n^2}\right)^{-1} + \tfrac{1}{120}x^4\frac{w^4}{T^4}\left(1-\frac{1}{4n^2}\right)^{-2}+\dots\right\}.$$

It is desirable that n should be large, never less than 10 and generally about 20. If $n=10$, the second term of the equation for λ is

$$\tfrac{1}{60}\cdot\frac{X_0^5}{2^5}\cdot\frac{1}{n^4l^4}\left(\frac{4n^2}{4n^2-1}\right)^2.$$

This is less than $X_0/18 . 10^{-6}$, similarly it is less than $X_0/306 . 10^{-6}$, when $n=20$. In such circumstances this can be neglected and we have

$$\lambda = \frac{X_0^3}{24}\cdot\frac{w^2}{T^2}\left(1-\frac{1}{4n^2}\right)^{-1}$$
$$= \frac{X_0^3}{24}\cdot\frac{w^2}{T^2}\left(1+\frac{1}{4n^2}+\frac{1}{16n^4}+\dots\right).$$

The second term of this is less than $X_0/24n^2 . 1/4n^2$, *i.e.* less than $X_0/96n^4$, and can frequently be neglected.

The formula $X=X_0\sqrt{1-h^2/l^2}$ is not in a convenient form for calculation, as the actual value of l will vary for each span measured. Call L the actual length of the tape between its zero marks at standard temperature and tension, S the nominal length of the tape, and L′ the actual length at temperature t above the standard temperature, then $X_0=S+a_0$, where a_0 is the error of the tape found when it is standardised. If α is the coefficient of expansion of the tape, we have

$$L' = L(1+\alpha t) = (X_0+\lambda)(1+\alpha t) = (S+\lambda+a_0)(1+\alpha t).$$

In the field we actually measure the difference a_1 between l and L′, hence

$$l = (S+\lambda+a_0+a_1)(1+\alpha t).$$

Here a_0 depends on the accuracy with which the tape is marked, a_1 on the accuracy with which the trestles are spaced, and αt on the temperature. With care there should be no difficulty in keeping (a_0+a_1) less than 10 mm., and with $n=10$, λ will be about $X_0/2400$, αt will never be more than 10^{-4}, consequently $(\lambda+a_0+a_1)$ should never be more than $X_0/1200$, and $(\lambda+a_0+a_1)(\alpha t)$ will never be more than $X_0 . 10^{-7}$ and usually much less. It can therefore be neglected. We may therefore put $l=S+A+\lambda$, where $A=a_0+a_1+S\alpha t$, and also $X_0=S+A$.

The formula for X now becomes

$$X=(S+A)\left\{1-\frac{h^2}{(S+A+\lambda)^2}\right\}^{\frac{1}{2}};$$

expanding we get

$$X=(S+A)\left\{1-\tfrac{1}{2}\frac{h^2}{S^2}\left(1+\frac{A+\lambda}{S}\right)^{-2} - \tfrac{1}{8}\frac{h^4}{S^4}\left(1+\frac{A+\lambda}{S}\right)^{-4}-\dots\right\}.$$

As shown above, $A+\lambda$ can without trouble be made less than $10^{-3}S$, hence if we neglect terms involving $(A+\lambda)^2/S^2$ we are neglecting a quantity less than $\frac{1}{18}S10^{-6}$ even when $h/S=1/3$, and generally very much less. For practical purposes, therefore,

$$X=(S+A)\left\{1-\tfrac{1}{2}\frac{h^2}{S^2}\left(1-2\frac{A+\lambda}{S}\right)-\tfrac{1}{8}\frac{h^4}{S^4}\left(1-4\frac{A+\lambda}{S}\right) - \tfrac{1}{16}\frac{h^6}{S^6}\left(1-6\frac{A+\lambda}{S}\right)-\dots\right\}$$

$$=S\left(1-\tfrac{1}{2}\frac{h^2}{S^2}-\tfrac{1}{8}\frac{h^4}{S^4}-\tfrac{1}{16}\frac{h^6}{S^6}-\tfrac{5}{128}\frac{h^8}{S^8}-\dots\right)$$

$$+S\frac{A+\lambda}{S}\left(\frac{h^2}{S^2}+\tfrac{1}{2}\frac{h^4}{S^4}+\tfrac{3}{8}\frac{h^6}{S^6}+\tfrac{5}{16}\frac{h^8}{S^8}+\dots\right)$$

$$+A\left(1-\tfrac{1}{2}\frac{h^2}{S^2}-\tfrac{1}{8}\frac{h^4}{S^4}-\tfrac{1}{16}\frac{h^6}{S^6}-\tfrac{5}{128}\frac{h^8}{S^8}-\dots\right)$$

$$+A\frac{A+\lambda}{S}\left(\frac{h^2}{S^2}+\tfrac{1}{2}\frac{h^4}{S^4}+\tfrac{3}{8}\frac{h^6}{S^6}+\tfrac{5}{16}\frac{h^8}{S^8}+\dots\right).$$

As $A(A+\lambda)/S$ is less than $\frac{1}{2}S10^{-6}$, it is negligible even on slopes of 1 in 2, so, neglecting this,

$$X=S-S\left(\tfrac{1}{2}\frac{h^2}{S^2}+\tfrac{1}{8}\frac{h^4}{S^4}+\tfrac{1}{16}\frac{h^6}{S^6}+\tfrac{5}{128}\frac{h^8}{S^8}+\dots\right)$$

$$+A+A\left(\tfrac{1}{2}\frac{h^2}{S^2}+\tfrac{3}{8}\frac{h^4}{S^4}+\tfrac{5}{16}\frac{h^6}{S^6}+\tfrac{35}{128}\frac{h^8}{S^8}+\dots\right)$$

$$+\lambda\left(\frac{h^2}{S^2}+\tfrac{1}{2}\frac{h^4}{S^4}+\tfrac{3}{8}\frac{h^6}{S^6}+\tfrac{5}{16}\frac{h^8}{S^8}+\dots\right),$$

and we can write simply

$$X=S+A-P+Q+R,$$

where

$$P=S\left(\tfrac{1}{2}\frac{h^2}{S^2}+\tfrac{1}{8}\frac{h^4}{S^4}+\tfrac{1}{16}\frac{h^6}{S^6}+\tfrac{5}{128}\frac{h^8}{S^8}+\dots\right),$$

which can be tabulated once for all in terms of h for any standard tape length;

$$Q=A\left(\tfrac{1}{2}\frac{h^2}{S^2}+\tfrac{3}{8}\frac{h^4}{S^4}+\tfrac{5}{16}\frac{h^6}{S^6}+\tfrac{35}{128}\frac{h^8}{S^8}+\dots\right),$$

which can be tabulated for any standard tape length in terms of h and A;

$$R=\lambda\left(\frac{h^2}{S^2}+\tfrac{1}{2}\frac{h^4}{S^4}+\tfrac{3}{8}\frac{h^6}{S^6}+\tfrac{5}{16}\frac{h^8}{S^8}+\dots\right);$$

this is always small and can be tabulated in terms of h for any given tape.

Strictly speaking, λ depends on X_0, but as X_0 will differ very slightly from S, R can be calculated on the assumption that $X_0=S$, and no appreciable error will be introduced.

Tables I., II., and III. for P, Q, and R will give an idea of the value of the corrections. They are calculated for S=24 m., T=10 kgm., w=0·01732 kgm., whence λ=1·728 mm. P is the usual correction for slope; it is always to be subtracted from the measured length of the base, and is always important. Q will vary in sign with A. and only becomes of importance on steep slopes and when the trestles are badly spaced. R is the correction for the change in shape of the catenary on a slope; it is only of importance on steep slopes, or when a low tension is being used; it is always to be added to the measured length of the base.

So far it has been assumed that the tape is inextensible, but provided that the mean tension is kept constant, and the tape is not stretched beyond its elastic limit, this assumption will produce no error. The formula developed above assumes that the mean tension at the ends is kept constant; if this be so, it can be shown that the true mean tension is sufficiently constant to make no appreciable error.

TABLE I

In practice the standard tension is applied at one end of the tape, and it makes a difference whether this is the higher or lower end of the tape. The error caused is made up of two parts, (1) the elastic extension of the tape, and (2) the change in the shape of the catenary. The change is small in any case, but not negligible on steep slopes. If each span is measured once with the standard tension applied at the upper end and once with the tension applied at the lower end, error (1) will obviously cancel out in the mean, and it can be shown that error (2) will also cancel out almost entirely so that the residual error is quite negligible. These errors can thus be easily avoided.

It remains to consider the accuracy attainable with this method of base measurement. The errors can be divided as follows:

(i.) *Errors in Standardising the Tapes.*—This is most important, as a proportional error in the standardisation of the tape gives the same proportional error in the final result. A probable error of about $0{\cdot}5\mu$ should be attainable.

(ii.) *Errors in the Readings.*—In taking readings on the millimetre scales an error greater than 0·2 mm. should be very rare. This will give a probable error of about 0·06 mm. for one reading of one scale. If twenty readings are taken in all, the probable error for one tape length will be about 0·02 mm. As this error is in no way systematic, the error for the whole base will only increase as the square root of the number of tape lengths, so the error for a 5 km. base measured with 24-m. tapes would only be about $0{\cdot}07\mu$.

(iii.) *Errors due to Temperature.*—In reasonable conditions the temperature of the tape should be known to within 1° C., which would give a maximum error of $0{\cdot}5\mu$ for any one span. The error in the mean should be much less than this, probably not more than a tenth.

(iv.) *Errors due to Change in the Tension.*—If the tension is applied during the measurement by an apparatus different from that used when the tape is standardised, a constant error may be introduced, which may be serious. An increase in tension acts in two ways—(*a*) by flattening the catenary, (*b*) by stretching the tape, the error caused by a change in tension δT being

$$2\lambda\frac{\delta T}{T}+\nu l\delta T,$$

where $1/\nu$ is the cross-section multiplied by Young's modulus. If $\delta T/T=0{\cdot}01$ the error due to (*a*) will be about $1{\cdot}5\mu$, and that due to (*b*) about $3{\cdot}0\mu$, ν being about 0·0007. The standard tension should therefore be kept constant to within $\frac{1}{10}$th per cent to ensure an error not greater than $0{\cdot}5\mu$.

(v.) *Errors due to Change in Weight due to Dirt, etc.*—A change in w will produce a change in the shape of the catenary, and will alter λ by an amount $2\lambda\delta w/w$, and with the standard wire when $\lambda=1{\cdot}72$ mm., $w=17{\cdot}32$ gm., a change of 1 per cent in w will cause an error of 0·035 mm., or $1{\cdot}5\mu$.

(vi.) *Errors due to Assuming Incorrect Values for* T *and* w.—Such incorrect assumptions will lead to an incorrect value for λ. If the tape has been standardised on the flat, and then used in catenary, it is necessary to know λ with the same accuracy as A, and any errors in the values assumed for T and w will produce the errors given above (iv. and v.) for a *change* in T and w. If the tape has been standardised in catenary the correction R is the only one affected, and the error introduced will always be less than $\delta\lambda$, and generally very much less. With $h/S=0{\cdot}5$, δR is about $0{\cdot}3\delta\lambda$.

$$\delta\lambda-2\lambda\frac{\delta T}{T}+2\lambda\frac{\delta w}{w},$$

hence δR is less than

$$0{\cdot}6\frac{\delta T}{T}+0{\cdot}6\frac{\delta w}{w},$$

hence an uncertainty of 1 per cent in T or w will only produce an error of about $0{\cdot}2\mu$, even on very steep slopes, when using the ordinary 24-m. wire.

(vii.) *Errors due to Inaccurate Measurement of* h.—An error in h affects all three corrections P, Q, and R, but P is the most important.

$$\delta P=\frac{h}{S}\delta h+\frac{1}{2}\frac{h^3}{S^3}\delta h+\ .\ .\ .\ ,$$

which increases rapidly as h increases. A probable error of 1·5 mm. in h is easily obtained, in this case $\delta P=0{\cdot}00006h$, if $h=2$ m. for every span the probable error of P per span is 0·12 mm., or 5μ. This error, however, will largely cancel out, and for a base of 200 spans the probable error will only be $5/\sqrt{200}$, or $0{\cdot}35\mu$; even with $h=4$ it will still be under $0{\cdot}7\mu$. With care the probable error of h can be reduced to 0·5 mm., in which case slopes of $\frac{1}{5}$ can be measured, still keeping the final probable error below 1μ.

(viii.) *Effect of Change of Gravity.*—If the tape is standardised in one place, and used at another, the effect of change of g must be considered. An increase in the value of g will increase T and w, both in the proportion $\delta g/g$. The increase in T will increase l by an amount $\nu l T\delta g/g$, and this can, if necessary, be allowed for. As w/T remains constant λ will not be appreciably affected. If the tension be applied by a spring and not by a weight, T will remain constant, but w will alter. In this case l will remain constant but λ will be slightly increased, and this can also be allowed for.

(The tables for correction due to change in shape of the catenary on a slope are incorrect, being about double the correct amount.)

Report of U.S. Coast and Geodetic Survey, 1892, App. 8.

A. E. Young, *Phil. Mag.* xxix. 90 (considers the effect of the rigidity of the tape).

A paper by G. H. Knibbs (*Journal of the Royal Society of New South Wales*, xix. 20) on "A System of Accurate Measurement by Means of Long Steel Ribands," gives formulas which apply more especially to the method by which the sag correction is eliminated by altering the tension.

C. W. Adams, in a paper on "The Measurement of Distances with Long Steel Tapes," read before the Victorian Institute of Surveyors in 1888, gives tables for the sag corrections for a number of cases.

The last three papers apply more to accurate traverse work than to base measurement.

TARTARIC ACID, OPTICAL ROTATORY POWER OF

§ (1) HISTORICAL.—The optical rotatory power of tartaric acid was discovered in 1832 by Biot,[1] who devoted one of his longest memoirs [2] to a detailed account of its properties when mixed with water, with alcohol, and with wood-spirit. Biot found that tartaric acid, when "dissolved in different fluid media, exercises on the planes of polarisation of light a special power, which distinguishes it from all other substances studied hitherto." These had agreed with quartz in obeying, at least approximately, Biot's law of inverse squares, according to which the rotation is proportional to the reciprocal of the square of the wave-length of the light.[3] This agreement had been verified in the case of turpentine, alone and mixed with ether, and of cane-sugar dissolved in water, (i.) by comparing the tints with those produced by equivalent plates of quartz, and (ii.) by eliminating the effects of rotatory polarisation with the help of a quartz plate of opposite sign acting as a compensator. When, however, tartaric acid was compared with quartz, no such parallelism was observed, the rotations of the common dextro-rotatory acid for the chief colours being as follows: [4]

	Quartz.	Tartaric Acid.
Red	18·00°	38° 7′
Orange . . .	21·40	40 29
Yellow	23·99	42 51
Green	27·86	46 11
Blue	32·31	44 40
Indigo	36·13	42 9
Violet	40·88	39 38

Similar phenomena were observed when tartaric acid was dissolved in alcohol,[5] but Biot found that "when it combines with basic substances in the same media, it loses its special action and imprints on the products the properties common to all bodies endowed with rotatory power." [6]

§ (2) INFLUENCE OF WATER.—Biot discovered that "in aqueous solutions of tartaric acid at a given temperature, the rotatory power of the acid calculated for each simple ray is always of the form $A + Be$, where e represents the proportion by weight of water in the solution." [7] This law was illustrated by plotting a against e for a series of wave-lengths, in a diagram (*Fig.* 1) which resembles the "Characteristic diagram" of Armstrong and Walker.[8] Biot's linear law is only an approximation, but it enabled him to predict that the rotatory power A of the anhydrous acid, for the red light transmitted by glass coloured with cuprous oxide, would change sign at 23° C., being positive above this temperature and negative below it.[9] This prediction was verified, after an interval of over ten years, when Laurent [10] in 1849 discovered a method by which moistened tartaric acid could be fused and cooled to a transparent glass in thicknesses up to 76 mm.; a column 70 mm. in thickness at 3·5° C. then

gave $[\alpha]_{red} = -2{\cdot}787°$, where Biot's calculations gave the value $-2{\cdot}752°$. Quite recently these experiments have been extended by Bruhat,[1] who has measured the rotatory powers of the fused or glassy acid at temperatures ranging from 15° to 185° C., and for colours ranging from w.l. $430\mu\mu$ to $681\mu\mu$; these rotations are therefore available as limiting values to check the formulae used to express the influence of dilution with water on the rotatory power of the acid. Thus

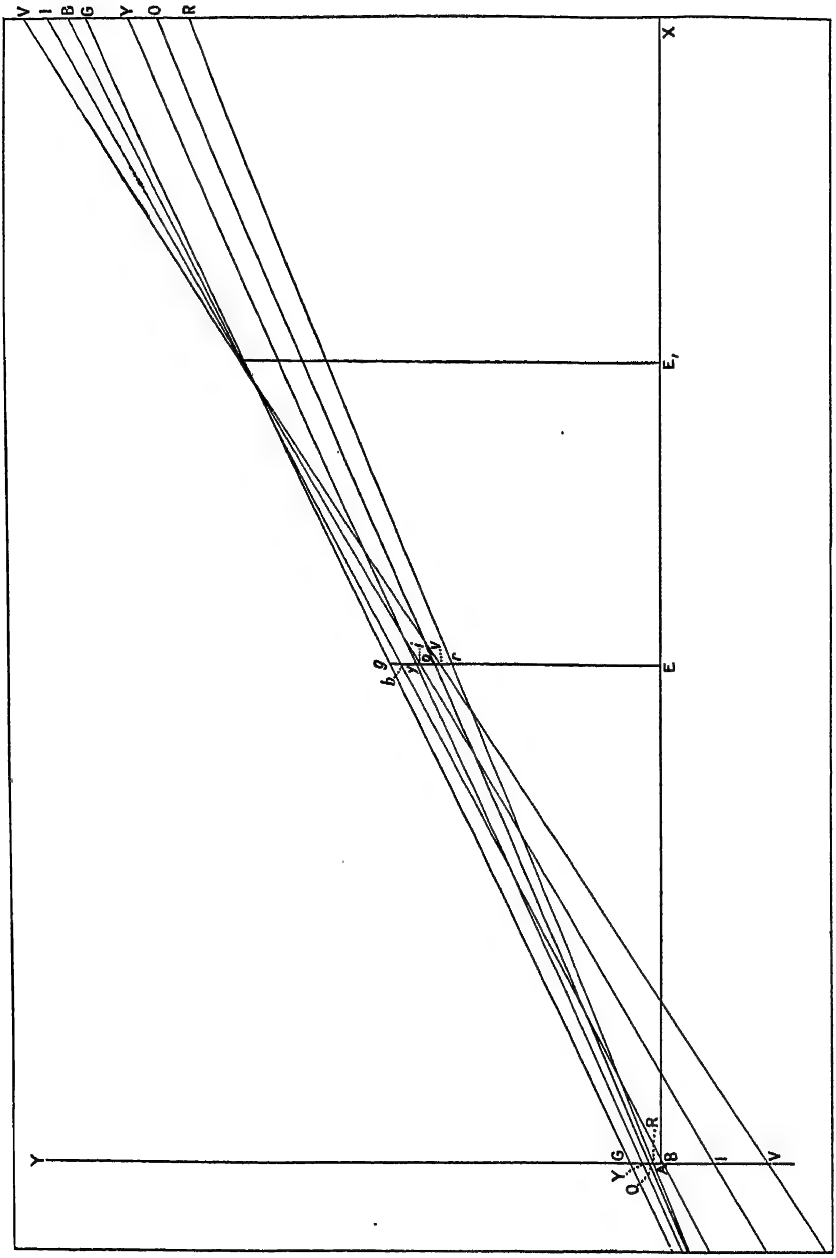

FIG. 1.

[1] *Trans. Faraday Soc.*, 1914, x. 89.

Winther[1] made use of a parabolic formula to express his measurements, which were not covered by the linear law; but this parabolic formula gives larger errors for the anhydrous acid than does the linear formula. The most recent investigations have shown that an equation with five arbitrary constants would probably be required to express accurately the relationship between rotatory power and concentration; apart from this, a linear law is probably the best approximation, *e.g.* the following formulae are correct at $e=0\cdot55$ and $0\cdot85$, and do not differ very widely from the observed values even at $e=0$.

§ (3) ROTATORY DISPERSION IN TARTARIC ACID AND ITS ESTERS.—Although the rotatory dispersion of tartaric acid and many of its derivatives is highly anomalous, it has been found that the rotatory powers of methyl and ethyl tartrate (*Fig.* 2), both as homogeneous liquids and in a wide range of solutions, can be expressed by formulae of the type[2]

$$\alpha=\frac{k_1}{\lambda^2-\lambda_1^2}-\frac{k_2}{\lambda^2-\lambda_2^2}.$$

In this formula the positive and the negative term are *each* of the type that serves to express the rotatory power of the large array of substances which exhibit "simple" rotatory dispersion, as expressed in the formula

$$\alpha=\frac{k}{\lambda^2-\lambda_0^2}.^3$$

This result is in accordance with the view of Biot, subsequently elaborated by Arndtsen,[4] that anomalous rotatory dispersion can be produced by, and is commonly due to, the incomplete compensation of the rotations of two compounds, opposite in sign but of unequal dispersive power, so that complete compensation is only possible for one wave-length at a time.

The dispersion curves for tartaric acid resemble those for the esters very closely, *e.g.* Bruhat's curve for the specific rotatory power of glassy tartaric acid at 44·6° is

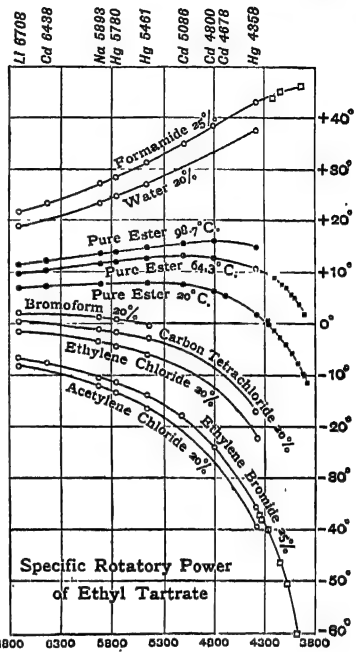

FIG. 2.

identical with, and can be superposed on, Winther's curve for methyl tartrate at 80°; there can, therefore, be no doubt that the glassy acid behaves as a lower homologue of the esters. The dispersion-curves for aqueous solutions of the acid, which are shown graphically in *Fig.* 3, can also be represented by the same formula as in the case of the esters, the values for the constants in a few typical cases being as follows:

TABLE II

§ (4) Other Derivatives of Tartaric Acid.—In the case of the tartrates of the alkali metals, the principal anomalies noted in the acid disappear, as Biot recorded in 1837; thus the solutions are consistently dextrorotatory and the rotations increase progressively with diminishing wave-length (*Fig.* 4), in some cases in close approximation to the law of inverse squares. A careful study of these rotations[1] has shown, however, that they cannot be expressed by the one-term equation which applies to cases of "simple" rotatory dispersion, but require a formula with two terms, just as in the case of the acid; the negative term is, however, very much smaller, so that the rotations are positive throughout the visible and part of the ultra-violet spectrum. The most interesting of the derivatives of tartaric acid are boro-tartaric acid and tartar emetic, since these alone amongst the substances hitherto investigated give dextrorotations obeying the "simple" dispersion law. In the case of tartar emetic the rotations become negative when the salt is dissolved in concentrated potassium hydroxide, but these solutions, like those of the original salt, exhibit simple rotatory dispersion.

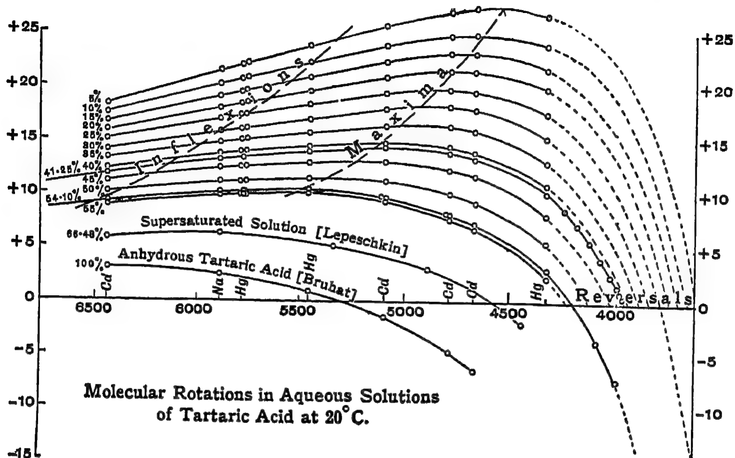

Fig. 3.

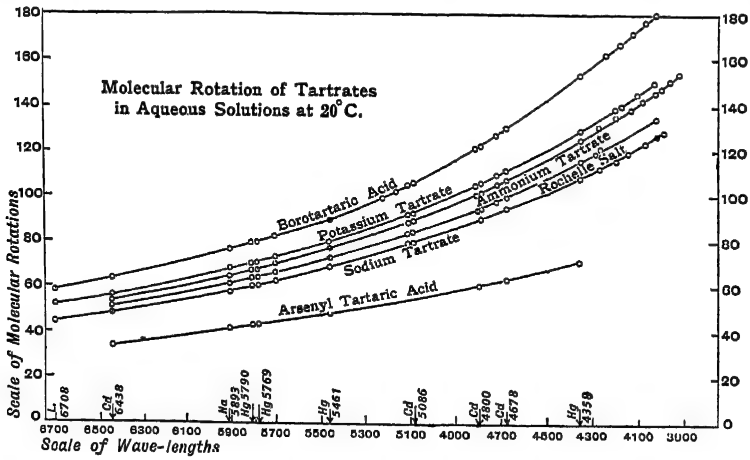

Fig. 4.

§ (5) Origin of Anomalous Rotatory Dispersion.—The vast majority of optically-active compounds, including the secondary

[1] Lowry and Austin, Bakerian Lecture, 1921.

alcohols, and the sugars, exhibit simple rotatory dispersion, although they may contain a considerable number of asymmetric carbon atoms, often in close association with the unsaturated linkages to which so many optical anomalies are due. The structural formula $HO \cdot CO \cdot CHOH \cdot CHOH \cdot CO \cdot OH$ commonly assigned to tartaric acid gives no hint as to why this acid and its esters should give anomalous rotatory dispersion, when the closely related sugars do not. It is therefore probable that this formula is not a complete representation of the molecular structure of the acid as it exists in the fused state or in solution, although it may perhaps provide a correct picture of the structure of the solid crystalline acid. In the case of nitrocamphor [1] it has been proved that the solutions contain a labile isomeride of opposite rotatory power, which is reconverted into the original compound when the solutions are allowed to crystallise. This labile isomeride has not been isolated, although several of its derivatives are known; these possess a high dextrorotation, whereas the parent substance is laevorotatory in most solvents. A satisfactory explanation of all the observations is given by assuming that in solution a reversible isomeric change takes place, as represented by the scheme

$$C_8H_{14}\Big\langle\begin{matrix} CH\cdot NO_2 \\ | \\ CO \end{matrix} \rightleftarrows C_8H_{14}\Big\langle\begin{matrix} C:NO\cdot OH \\ | \\ CO \end{matrix}$$

Nitrocamphor. Pseudonitrocamphor.

This phenomenon is usually described as "dynamic isomerism."

In the case of tartaric acid the evidence for the existence of a labile isomeride in solution is less complete, since it is not possible to follow the progress of the isomeric change by means of the changing rotatory power or "mutarotation" of the freshly dissolved material; but the solutions have all the optical properties of a mixture of isomerides of opposite rotatory power and unequal dispersion, and there are no observations which contradict the view that the hypothesis of Biot and Arndtsen as to the origin of the anomalous dispersion can be applied.

The structure to be assigned to the labile form of tartaric acid has not yet been determined, although derivatives of both forms are now known (see § (4) above) which exhibit simple rotatory dispersions of opposite sign and unequal magnitude.

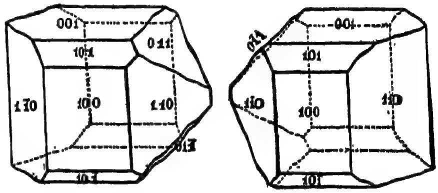
§ (6) DEXTRO- AND LAEVO-TARTARIC ACID. —In virtue of the two asymmetric carbon atoms which it contains, tartaric acid can exist in four modifications, of which two are optically active and two inactive. These may be represented conventionally thus:

$$\underbrace{\begin{matrix} HO\cdot CH\cdot COOH \\ | \\ HOOC\cdot CH\cdot OH \\ d\text{-Tartaric acid.} \end{matrix} \qquad \begin{matrix} HOOC\cdot CH\cdot OH \\ | \\ HO\cdot CH\cdot COOH \\ l\text{-Tartaric acid.} \end{matrix}}_{\text{Racemic acid (inactive).}}$$

$$\begin{matrix} HO\cdot CH\cdot COOH \\ | \\ HO\cdot CH\cdot COOH \end{matrix}$$

meso-Tartaric acid (inactive).

Racemic acid was discovered by Kestner in 1822, and regarded as an "isomer" of the common tartaric acid, which Scheele had described in 1769; but it was not until 1848–53 that Pasteur, by carefully sorting out the crystals of sodium ammonium racemate, proved that racemic acid is a mixture of the common dextrorotatory tartaric acid with an



Dextro-tartaric Acid. Laevo-tartaric Acid.

FIG. 5.

equal amount of an enantiomorphous laevorotatory acid. The properties of this acid are an exact replica of those of the dextro-acid except as regards rotatory power, crystalline form, etc., where a reversal of sign is possible. All the phenomena of anomalous rotatory dispersion, which have been described in the previous paragraphs for dextro-tartaric acid, are therefore repeated in laevo-tartaric acid, but with the sign of the rotations reversed.

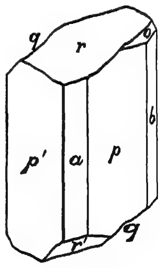


FIG. 6.

The relationship between rotatory power and crystalline form which exists in the case of quartz (*q.v.*) is found again in tartaric acid and the tartrates. Thus the crystalline forms of *d*- and *l*-tartaric acid, as shown in *Fig.* 5, are enantiomorphous just like dextro- and laevo-quartz. On mixing these two acids, however, they unite to form a racemic acid (*Fig.* 6) which crystallises in a form in which enantiomorphism does not occur. All the

[1] Lowry, *Trans. Chem. Soc.*, 1899, lxxv. 211.

metallic tartrates unite in a similar manner with their isomerides, giving rise to inactive double-salts or "racemates" in which no enantiomorphism exists. In one solitary instance, however, namely, in the case of sodium ammonium tartrate, the racemate breaks up, at temperatures below 26°, into the two component tartrates, which therefore separate from cold solutions in enantiomorphous crystals of equal and opposite rotatory power; it was by the study of this unique case that Pasteur was led to the discovery of the relationship between optical activity and crystalline structure and to the experiments which culminated in the isolation of laevo-tartaric acid. TELESCOPE, THE

The aim of this article is to describe the telescope as a physical instrument, defined by the limitations which are imposed upon it by the purposes to which it is directed, by the construction of its optical parts, and by the geometrical features of its support or mounting. This will exclude the description of some forms, the interest in the construction of which is purely astronomical or which are otherwise restricted to special technical application. It will limit the theory to those geometrical cases that subserve the purpose of rendering visible inaccessible and distant objects. In essence, the method of making a distant object accessible is to replace it by the image of it which a converging lens or mirror forms near its principal focus. This image may then be impressed upon a photographic plate, or examined visually with a second lens. In the latter case the second lens or eyepiece is treated as part of the telescope. This difference separates the two cases so widely, as problems of optics, that they will require in large measure separate theoretical treatment, different features rising into importance or dropping out of it, in the one case or the other.

§ (1) Geometrical Theory.—We shall begin by rehearsing the results of geometrical optics as far as they apply to the visual telescope consisting of an objective and eyepiece. The standard case—to which any other actual ones are approximate—for an object given "at infinity," places the image also "at infinity," since the normal eye at rest brings a parallel beam to a focus on the retina. Hence, regarded as a general optical instrument, the telescope is a degenerate case, with all the cardinal points at infinity and the focal length infinite also. Only one case need be considered, namely, that in which objective and eyepiece both act like converging lenses. The Galilean combination, in which the eyepiece is a negative lens, is now obsolete even as a field glass, though it has found application elsewhere in the telephoto lenses of cameras. In regard to eyepieces it is customary to distinguish one of the two standard forms, the Ramsden, as positive, and the other, the Huyghens, as negative. But in theory both are of the same type, acting like a single converging lens, in which the anterior principal focus precedes the anterior unit point, the essential difference being that for the Huyghens eyepiece this principal focus lies between the two lenses and is therefore inaccessible for spider threads or the apparatus of measurement. In fact the Huyghens eyepiece, turned round, is used as a magnifying lens under the name of Wollaston's doublet. See below, § (6).

Moreover, as far as simple point-to-point correspondence goes, any combination of lenses used as objective or as eyepiece differs from the ideal "thin lens" only in separating the two unit points. Suppressing this difference, we may summarise all the cases under a single model.

Let A, a (*Fig.* 1) be the positions of the objective and eye lenses respectively, or of

Fig. 1.

the (united) unit points of the objective- and eye-combinations, the lenses being treated as thin; F, F′, f, f' the anterior and posterior principal foci of these. In the present case F′ and f coincide. Let $\Phi = \mathrm{FA} = \mathrm{AF}'$, $\phi = fa = af'$. Now any ray entering parallel to the axis will emerge parallel to the axis, its distance from the axis being reduced by the factor $af/\mathrm{AF}' = -\phi/\Phi = -1/m$, say. It follows that if Qq is the image of any object Pp, the linear magnification is $-1/m$, the same for all distances. To find the relative

positions of P, Q, call R the intermediate focus. Then[1]

$$\frac{\Phi^2}{\mathrm{FP}}=\mathrm{RF}'=\mathrm{R}f=\frac{\phi^2}{f'\mathrm{Q}},$$

or $$\mathrm{FP}=m^2 . f'\mathrm{Q}.$$

If P is to the left of F, Q is to the left of f'. Equally, if P_1, P_2 be any two objects and Q_1, Q_2 their images,

$$P_1P_2=m^2 . Q_1Q_2.$$

It is to be noted that F, f' are themselves a pair of conjugate points. So also are points at infinity.

If M be the object which gives an image at a, and N the image of an object at A, we have

$$\mathrm{MA}=m . \mathrm{A}a=m^2 . a\mathrm{N},$$

and the object space and image space are divided up into corresponding regions as follows (*Fig.* 2):

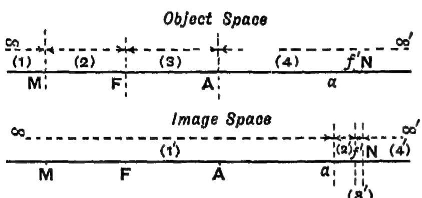

Fig. 2.

For rays not parallel to the axis, the construction is obvious. If y, y' are the relative breadths of object and image, and β, β' the angles between original rays 1, 2 and the corresponding emergent rays 1′, 2′, we have (*Fig.* 3)

Fig. 3.

$$y=\beta . P_1P_2,\ y'=\beta' . Q_1Q_2;$$

but $$P_1P_2=m^2 . Q_1Q_2$$

and $$y=-m . y',$$

so that $$\beta'=-m\beta,$$

and the magnification of angle between any two rays is the same for all positions, as, of course, follows from the general theorem that the angular magnification is the reciprocal of the linear magnification. The apparent distance for any object is simply $1/m$ times the actual distance.

[1] See "Lenses, Theory of Simple," § (3).

The field of view is governed by the apertures $2b$, $2B$ of the eye glass and objective.

The object glass gives as image (*Fig.* 4) a ring of radius $NN'=B/m$, which is the "exit-pupil," through which all rays meeting the

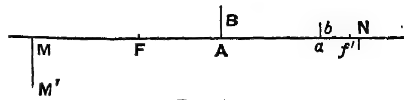

Fig. 4.

object glass pass on emergence. Similarly, the eye glass is the image of a ring $M'=bm$, and this ring is the "entrance-pupil," through which, again, all incident rays must pass. It follows that the field of view which receives full illumination is of angular radius $(bm-B)/MA=(b-B/m)/Aa$, while the radius of partial illumination extends to $(b+B/m)/Aa$. It will be remarked as evident that, apart from considerations of full and partial illumination by the object glass, the field commanded by the eyepiece is simply b/Aa, and if $b/B=m=\phi/\Phi$, no beams except those parallel to the axis will pass completely through the instrument.

By an increase of the aperture the fully illuminated field is diminished, while the partially illuminated field is increased.

Any beam of light filling the object glass of radius B, and emerging through the exit-pupil of radius, say, p_0, is thereby intensified in the ratio $(B/p_0)^2$, or m^2. But if the beam issues from an object of finite area, it will be spread on emergence over an image increased in angular area in the same ratio, and the "brightness of the image will be equal to the brightness of the object," except for loss by absorption and reflection of light in the telescope. To see the significance of this statement clearly, the part played by the eye must be considered.

In *Fig.* 5 Pp is an object; two rays PA, pA meeting the object glass at A emerge as QN, qN. If the eye be placed so that N is its ante-nodal

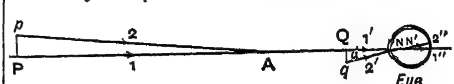

Fig. 5.

point, these rays proceed in parallel directions through N′ the post-nodal point, and the area of the retina covered by the image is seen to be $m^2\times$ that which would have been covered had the telescope been removed and the eye placed at A. Two qualifications, however, fall to be noticed. The retina is not continuous, and fails to recognise stimuli as distinct which fall, it is supposed, on the same element of its structure. These elements subtend angles of about 1 minute of arc at N′. Hence, if Qq

subtends less than this angle at N, the intensification of the beam which the object glass effects will not be dissipated in its effect on the retina, and the brightness of a "point-source" will be increased by a telescope in the ratio m^2. Or, rather, in comparing the light gathered by the telescope with what the eye unaided would acquire, we have the ratio B^2/p^2, where p is the radius of the pupil of the eye, and not m^2, which is equal to $B^2/p_0{}^2$. Hence, for a telescope applied to a point-source, the intensification of light is constant and not dependent on the magnification employed, apart from changes in the pupil of the eye; but if applied to a finite area the intensity is never increased, and when the magnification is sufficiently high it is diminished in the ratio $(p_0/p)^2$. Thus, for example, taking the diameter of the pupil of the eye as one-fifth of an inch, with a five-inch telescope the intensification of the light of a star would be about 25^2 times, equal to 7 magnitudes, while the background of the sky would be progressively darkened, if the eyepiece employed gave a magnification above 25 times; a power of 100 would darken it 16-fold.[1]

§ (2) Defects of the Simple Theory.—This is the primitive theory of the telescope. We must now indicate how it is modified by actual circumstances, namely, (1) aberrations, or faults in the theory of strict linear correspondence[2] in the object and image space; (2) diffraction phenomena; and (3) chromatic qualities of the glass employed, and other considerations.

In dealing with these points we may now pass also from the visual telescope to the photographic instrument and direct attention to the faults of the field produced by the objective at its principal focal plane, treating the eyepiece briefly afterwards from the point of view of its capacity to correct some of the faults.

The telescope is distinguished from other image-forming systems as an instrument in which the ratio of semi-aperture to focal length is small, seldom reaching the value 1/10. The angular radius of the field considered is of the same order. These are the elements upon which the geometrical aberrations depend, with numerical factors arising from the curvatures of the refracting or reflecting surfaces, their separations, refractive indices, etc. In such a case the aberrations can be expressed in a series proceeding by ascending odd powers of the aperture ratio and the angular radius of the field.

Thus, if the exact expression for size and position were worked out, for the image corresponding to any given object, if we retain only terms of the first order of the angular radius, we have the exact linear correspondence of object and image field sketched above; but if we retain the third order of both the variables jointly, we have a treatment of aberrations sufficient for the telescope.

§ (3) Von Seidel's Five Aberrations.—Under the above limitation the independent aberrations are five in number only, for all pairs of conjugate foci, as was shown by Seidel.[3] Supposing only one is present at a time, they permit of simple description. Using B, Φ as above, so that 2B/Φ is the aperture ratio, let β be the angular distance of the object point from the axis of the telescope. Let $\delta_1 G$, etc., represent the aberrational coefficients expressed in terms of the curvatures and refractive indices of the lenses.[4] Then we can describe the matter as follows:

(i.) *Spherical Aberrations.*—Rays which are originally parallel to the axis, from different zones of the object glass, strike the axis at different points (*Fig.* 6). It follows that the whole beam is collected within a "least circle

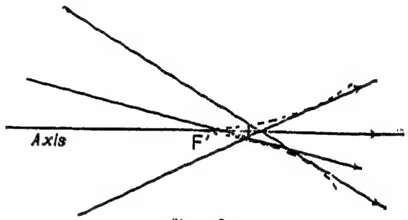

Fig. 6.

of aberration" at a certain distance from the principal focus. The angular radius of this circle can be shown to be $\frac{1}{8}B^3/\Phi \,.\, \delta_1 G$, and it comes after the principal focus by a distance $\frac{3}{8}B^2\Phi \,.\, \delta_1 G$. The extreme aberration is $\frac{1}{2}B^2\Phi \,.\, \delta_1 G$.

(ii.) *Coma.*—For an oblique ray, for the same zone, different points do not bring to coincidence parallel rays impinging on them. Rays from diametrically opposite points of the zone intersect, but the intersections are distributed round a circle (*Fig.* 7), the centre of which is displaced, by an amount equal to its diameter, from the focus corresponding to the middle of the object glass; in consequence the light from a point is distributed in a flare or fan, of 60° opening, with its tip at the linear focus. The "comatic radius" is $\frac{1}{2}\beta \,.\, B^2/\Phi \,.\, \delta_2 G$. The condition $\delta_2 G = 0$, implying equality of magnification for different zones, is sometimes known as the Fraunhofer condition, and sometimes as Abbe's sine condition, from the form it takes for wide angle systems,

[1] On the use of night glasses, for terrestrial objects, cf. Rayleigh, *Collected Works*, ii., Art. 82, 96.
[2] For further details see "Optical Calculations," § (2).

[3] *Ast. Nach.*, 1853, xxxvii.
[4] Methods of calculating these coefficients will be found in "Optical Calculations."

for which naturally it is of supreme importance. It is of hardly less importance for astronomical photography, and in the Newtonian reflector with the high aperture-ratios employed, the presence of coma spoils the images and scatters the light most seriously when the field is wide.

(iii.) and (iv.) *Astigmatism and Curvature of the Field.*—These are faults depending upon the square of angular radius of the field. Rays from different points of the objective are not

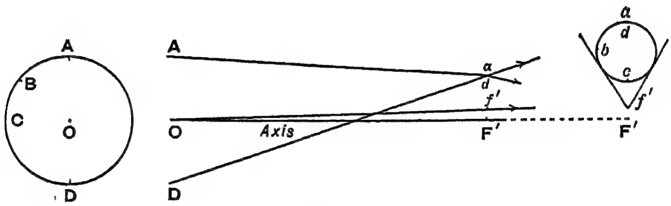

FIG. 7.

brought to any one focus. They do, however, all meet two "focal lines," a secondary focal line in the plane of the axis, and a primary perpendicular to it (*Fig.* 8), while midway between the two lines they all pass within a certain "focal circle," which gives the best approach to stigmatic representation. The curvature of the field may be considered to be that of the surface upon which the focal circles lie. The radius of the focal circle is $\frac{1}{2}\beta^2 . B/\Phi . \delta_2H$, and

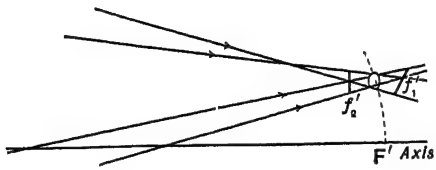

FIG. 8.

the curvature of the field $1/\Phi . (\delta_3G+\delta_2H)$,—two independent quantities. The condition which is somewhat erroneously known as Petzval's "condition for flatness of field" implies $\delta_3G=-\delta_2H$, and only gives a flat field if $\delta_2H=0$ or if the system is otherwise made stigmatic.

(v.) *Distortion.*—This is a representation of the object field on the image field stigmatically, but on a scale that varies with the angular radius β. The angular measure of distortional displacement is denoted by $\beta^3/F . \delta_3H$.[1]

As a simple example we may write down the values of these coefficients for the concave mirror of radius R, and therefore focal length R/2. We have $\delta_1G=-(1-e)/R^2$, $\delta_2G=-1/R$, $\delta_3G=0$, $\delta_2H=-1$, $\delta_3H=0$, where e measures the departure of the figure from a spherical shape, $e=1$ corresponding to a parabolic section. The distortion is zero. The comatic displacement is $2\beta . B^2/R^2$, directed outwards; for example, with an aperture $\Phi/5$, this reaches 10″ at a distance of 34′ from the centre of the field; for the same figure the radius of the least circle of aberration is $(1-e)\times 6''\cdot 4$.

For a system of two thin lenses in contact, the values of the coefficients may be written down in terms of curvatures and refractive indices, and furnish a good guide to the actual case of an ordinary objective, since the aberrations are not greatly altered by small separations between the surfaces. Denote by C_1, C_2 the curvatures of the anterior and posterior faces of the first lens, reckoned positive when convex to the ray, $1/n$ its refractive index, and write $k=(1-1/n)(C_1-C_2)$, $\mathfrak{p}=kn$, $q=(1+1/n)(C_1+C_2)$, so that k is the reciprocal of the focal length, $\mathfrak{p}$ is Petzval's expression, and q measures the distribution of curvature between the faces for given focal length, and distinguish the like quantities for the second lens by an accent; then, omitting δ_1G, the expression for which is too complicated to be of much service, we have

$$k+k'=K=-\frac{1}{\Phi},$$

$$\begin{aligned}K\delta_2G &= -\tfrac{1}{2}(nkq+n'k'q') \\ &\quad -\tfrac{1}{2}nk^2-n'kk'-\tfrac{1}{2}n'k'^2-(k+k')^2 \\ &= -\tfrac{1}{2}(nkq+n'k'q') \\ &\quad -\tfrac{1}{2}(n-n')k^2-(1+\tfrac{1}{2}n')(k+k')^2,\end{aligned}$$

$$\delta_3G=-\left(1+\frac{\mathfrak{P}}{K}\right) \qquad \mathfrak{P}=\mathfrak{p}+\mathfrak{p}'$$

$$\delta_2H=-1,$$

$$\delta_3H=0.$$

Hence for a pair of thin lenses in contact the distortion is zero, the radius of the focal circle depends only on the aperture ratio B/F, and not at all upon the curvatures of the faces; the same is approximately true of the curvature of the field. The comatic displacement, $2\beta . B^2/F . \delta_2G=2\beta B^2K\delta_2G$, gives an outward directed fan when positive, and inward when negative. Examining the expression we

[1] For further particulars on these coefficients of aberration see Sampson, *Phil. Trans.*, 1912, ccxii. 149; 1913, ccxiii. 27.

see that it cannot be zero unless one at least of the quantities kq, $k'q'$ is negative, corresponding to $C_1^2 < C_2^2$, $C_1'^2 < C_2'^2$, or the anterior faces flatter. Roundly speaking, a lens bulged outward towards the incident light gives coma directed towards the axis, and conversely.

Since little or nothing can be done with astigmatism and curvature of the field, these are usually passed over, and the faults of the objective considered[1] under the heads: (1) the difference of points of concurrence of rays originally parallel to the axis, according as they strike the object glass centrally or at the rim, *i.e.* a measure of the extreme spherical aberration; and (2) the difference of focal lengths for rays falling in these manners; this is equivalent to a determination of the comatic displacement as a difference of magnification, zone by zone. There are further considerations of the chromatic changes in these aberrations, namely, in the position of the principal focus for paraxial rays, in the principal focal length, and the chromatic difference of spherical aberration. The correction of this last fault is known as Gauss's Condition. The questions of chromatic correction are considered below.

§ (4) Practical Treatment of the Aberrations.—For visual work and for photographic work confined to the centre of the field, the presence of a moderate degree of coma would matter little, did it not make the definition sensitive to small faults in "squaring-on" the objective. For small cemented objectives a more common and often a gross fault is error of centring. Each lens surface possesses a definite axis and "centre," being the line joining the centres of the anterior and posterior spherical surfaces and the points where this line meets the surfaces respectively. For the two constituents of a doublet the centres of contiguous faces must be set in coincidence. The further condition that the directions of the axes must also coincide will then provide for itself if the inner surfaces are of equal radius and in contact. If such a fault is present the definition is deteriorated generally, the best being located off the axis, and if the objective is rotated in its cell, the image usually describes a circle in the field. For larger glasses, in which proper care has been exercised in the manufacture, this fault is not so much to be feared.

It must be recognised that refined optical theory has not played a large part in the development of the great astronomical object glasses. The doublet, with small ratio of aperture to focal length, is the simplest optical combination. Mathematical optics makes its performance and possibilities intelligible, but their most appropriate field of application lies in the complicated, wide-angle systems required in the camera and the microscope. The most celebrated makers of lenses have been men not much versed in theory, or have openly said it was of little use to them. Fraunhofer may be admitted as an exception. His successor Merz was the greatest maker of object glasses in the middle of last century. In particular he made a 15-inch lens for Harvard College Observatory. William Simms was engaged to examine this lens for purchase, and has left an interesting report[2] upon it, in which he says: "Mr. Merz's means of proving his object glasses are not such as appear to me best qualified to lead to a correct result. . . . It is merely the examination of a printed paper, not by directing them to the heavens, which in all cases, where it is practicable, is certainly the most desirable." Neither Alvan Clark nor Thomas Cooke was a man of theoretical training; they were rather consummate artists and craftsmen. G. Calver is of the same type. An account by Grubb[3] of the making and testing of objectives must be read in relation to its date, but it expresses the view referred to with great emphasis:

> *Object glasses cannot be made on paper.* When I tell you that a sensible difference in correction for spherical aberration can be made by half an hour's polishing, . . . you will see that it is practically not necessary to enter upon any calculation for spherical aberration. We know about what form gives an approximate correction; we adhere nearly to that, and the rest is done by figuring of the surface. To illustrate what I mean. I would be quite willing to undertake to alter the crown or flint lens of any of my objectives by a very large quantity, increasing one and decreasing the other so as to still satisfy the conditions of achromatism, but introducing theoretically a large amount of positive or negative spherical aberration, and yet to make out of the altered lens an object glass perfectly corrected for spherical aberration.

It would be idle to disregard these examples, though it may be thought that they are bad models to follow, and that theory must finally justify itself. In fact it has already done so, in the case of the two objectives of H. D. Taylor referred to in § (5) (iv.). The much simpler case of making a mirror, with its proper parabolic figure, used to be in the same position; in consequence the older mirrors are systematically deeply over-corrected; but the development of the knife-edge method of measuring the figure in different zones[4] has made the realisation of geometrical correctness of form a certainty.

The great difficulty in testing a lens arises from its convex surfaces. The spherometer is

[2] *Harvard Annals*, 1846, I. p. cx.

[3] Royal Institution, 1886.

[4] Cf. C. D. P. Davies, *Mon. Not.* lxix. 355, and below, § (11). See also "Objectives, Testing of Compound," § (3) (ii.).

in the first place not delicate enough for optical work, and in the second, occupying a great deal of time, only compares with one another a number of separate points of the surface. The lens is therefore put together and examined as a whole, an artificial star near the eye end sending its light through the lens to a plane mirror which reflects it back again through the lens, forming an image that is examined close to the principal focus. The error in performance of any spot of the objective is here doubled, and may be examined with some facility, and though it is not possible to say which of the convex surfaces contributes the fault, it is immaterial, since the fault can be removed by figuring the anterior surface as the most convenient. If local variations of refractive index of the glasses occur, they might equally be dealt with by local figuring. Given sufficient skill, with the aid of these tests, lenses can be made to perform up to the theoretical limit of resolution imposed by the wave structure of light (see § (7) below).

§ (5) DETAILS OF LENSES. (i.) *Alvan Clark.*—Perhaps owing to the tentative character of the work of the great artists, there are not many numerical particulars available of the most celebrated lenses. Alvan Clark's two greatest lenses, the Lick telescope (36 inches) and the Yerkes telescope (40 inches), are similar in character. The curves of the former are given in the *Lick Observatory Publications*, i. 61, as follows (adjusting the signs to the usual convention, + for a surface convex to the incident ray):

$$R_0 = +259\cdot5 \text{ inches} = -R_2.$$
$$R_4 = -239\cdot6 \text{ inches}, \quad R_6 = +40{,}000 \text{ inches}.$$

The surfaces R_4, R_6 are separated by 6·5 inches. The refractive indices are not stated. The glass was by Feil of Paris. These curves are in general agreement with those given by Steinheil and Voit[1] as representative of the great American objectives, except that these authors make R_1 somewhat greater than R_2, and the concavity of the fourth surface more pronounced; the calculated aberrations they give show a fine performance, a minute residual coma and minute difference of focal length for colour being the only faults that remain. The separation of the lenses helps to satisfy the Gauss condition.

(ii.) *Thomas Cooke.*—Thomas Cooke worked from curves in which, approximately, for refractive indices for the D ray 1·518 and 1·620 respectively,

$$R_0 = 2\cdot000, \quad R_2 = -3\cdot000, \text{ double convex.}$$
$$R_4 = -2\cdot815, \quad R_6 \text{ large}, \quad \text{double concave.}$$

The second and third surface are contiguous. These leave a certain amount of residual inward directed coma, but are found so sound and convenient in practice that the firm he founded still adheres to them. The correction for spherical aberration is made by the anterior surface of the flint lens almost wholly, leaving the fourth surface to be modified at will to meet faults of achromatism.

(iii.) *Fraunhofer.*—The correction for coma requires the crown lens to be somewhat flatter in its anterior surface, and the flint lens to be a meniscus. The associated condition, known usually as the Sine Condition, Seidel called by Fraunhofer's name, because it is nearly satisfied in a celebrated Königsberg objective of 6·2 inches, by Fraunhofer. The radii for this lens are, to an arbitrary unit,

$$R_0 = +\cdot838, \quad R_2 = -\ \cdot334, \quad \mu_1 = 1\cdot529.$$
$$R_4 = -\cdot341, \quad R_6 = -1\cdot173, \quad \mu_3 = 1\cdot639.$$

These leave a residuum of outward directed coma. To satisfy completely the conditions for freedom from spherical aberration and coma, Steinheil[2] showed they should run

$$R_0 = +\cdot696, \quad R_2 = -\ \cdot363.$$
$$R_4 = -\cdot372, \quad R_6 = -1\cdot650.$$

Comparison between the numbers indicates clearly enough how correct was Fraunhofer's appreciation of what was required.

(iv.) *Taylor's Triple Objective.*—The difficulties of constructing a large objective are so great that simplicity of design is the dominating consideration. But there are two triple combinations, both due to H. D. Taylor, that have established themselves in astronomical work in spite of this. The first (*Fig.* 9) is the photo-visual object glass. By using three lenses and choosing suitable glasses the combination is rendered perfectly achromatic, and is referred to further below, on the question of achromatism. But the extra surfaces permit more choice in the curves, while securing absence of spherical aberration and coma. Thus the third, fourth, and last surfaces are concave and may be tested by reflection; the second radius is exactly equal to the third, and the fifth to the fourth, permitting their truth to be tested also one by one. Only the first surface remains to be tested in the combined system. The utmost skill and precaution are of course required in centring such a system. It has been found practicable to make them with an aperture F/18, without introducing undesirably large angles of incidence on the inner surfaces. The other triple system is the well-known Taylor

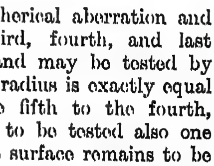

FIG. 9.

[1] *Angewandte Optik*, p. 179. Case 8a*.

[2] *Sitzungsber. k. Bayer. Akad.*, 1889, xix. 413.

photographic lens (*Fig.* 10). A description is given of one of 10 inches aperture and 45 inches focal length, constructed for Mr. Franklin Adams, in *Monthly Notices*, lxiv. 613, but one has been constructed recently for Mount Wilson Observatory to work up to an aperture F/2. The objective consists of three separated lenses, the first and third of dense barium crown glass and the middle one of flint glass. The crown lenses are double convex, their outer surfaces being the more curved; the first lens is of lower power than the third, and the distance from the first lens to the second is about half as great again as from the second to the third. Separation of the lenses permits astigmatism and curvature of the field to be corrected, coma is also corrected, and for a sufficient range of colour, spherical aberration is corrected for the neighbourhood of the ordinary photographic region of the spectrum, so that the images of stars are truly stigmatic up to a radius of $7\frac{1}{2}°$ from the axis.

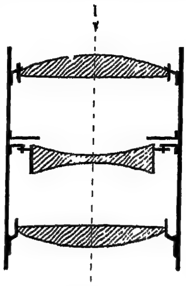

FIG. 10.

§ (6) THE EYEPIECE. (i.) *Huyghens.*—In conjunction with the optical performance of the objective should be considered, for visual use, the eyepiece. The traditional Huyghenian is still made, without much variation, and proves quite satisfactory for cases where micrometer wires or other focal scale is not required (see *Fig.* 11).

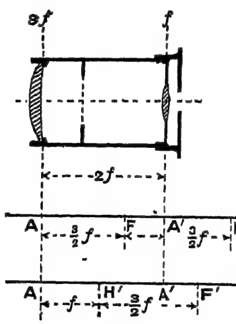

FIG. 11.

The principal focus corresponding to an emergent parallel beam lies within the combination, three-fourths of the way from the field lens to the eye lens, and the power is twice that of the field lens and two-thirds that of the eye lens. The term "negative" applied to this eyepiece is a misnomer, as remarked already, the order of the cardinal points being the same as for a converging lens. In fact, reversed, the combination is known as a magnifying lens, under the name of the Wollaston Doublet, an object at Φ′ being inspected by an eye placed beyond A.

(ii.) *Ramsden.*—With less reason the traditional Ramsden eyepiece is also preserved for micrometer work (*Fig.* 12). Its prominent defect is that particles of dust upon the field lens are visible with the eye lens, as blurs and smudges badly out of focus. A much better form, though it sacrifices breadth of the field of view somewhat, is a single triple cemented achromatic lens, as recommended by Steinheil (*Fig.* 13), which besides gives a flatter field and ample clearance from the micrometer wires. Owing to the fact that in visual work the object is invariably examined in the middle of the field, lateral aberrational or chromatic faults are of minor importance. But it is possible in some measure to compensate the inevitable curvature of field and astigmatism of the objective with those of the eyepiece, especially with the Steinheil form, which leaves some liberty in construction. The same is true of colour, but as the eye itself is not strictly achromatic, the discussion is rather academic than useful, because eyepiece and eye together should be regarded as a united combination for conveying to the retina the image formed in the focal plane of the objective, and in practice the eye is used in such a way as to minimise faults that are present.

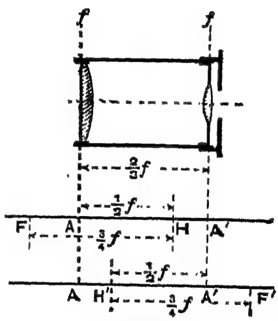

FIG. 12.

§ (7) DIFFRACTION.—A further consideration, limiting the use of geometrical optical theory, is the bearing of diffraction[1] upon the conclusions. A parallel beam of light emerging from a star to which the axis of a telescope is directed, is not brought to a point focus upon the axis, even if spherical aberration is corrected for all colours. It is distributed in a certain ring pattern over the whole focal plane, the central fact being that the diameters of the rings depend upon the ratio of the wave-length of the light to the aperture of the telescope. Thus F and B, denoting as before the focal length and semi-aperture of the telescope, λ the wave-length, and r distance from the axis, so that r/F is the circular measure of the angular radius of the ring in question, it is found that if we put

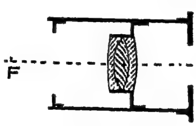

FIG. 13.

$$\frac{r}{F}=\left(\frac{\lambda}{2B}\right)\cdot\omega,$$

[1] See "Diffraction Gratings, Theory," § (4).

where ω is a numerical factor, we have zeroes of illumination for the values

$$\omega = 1{\cdot}220,\ 2{\cdot}233,\ 3{\cdot}238,\ 4{\cdot}241,\ 5{\cdot}243,\ \ldots$$

and within these rings respectively is comprised a fraction of the total illumination amounting to

$$\cdot 839,\ \cdot 071,\ \cdot 028,\ \cdot 015,\ \cdot 009,\ \ldots$$

while the maximum brightness occurs for the values

$$\omega = \cdot 000,\ 1{\cdot}635,\ 2{\cdot}679,\ 3{\cdot}699,\ 4{\cdot}710,\ 5{,}717,\ \ldots$$

and at these points the relative intensities are

$$1{\cdot}0000,\ \cdot 0175,\ \cdot 0042,\ \cdot 0016,\ \cdot 0008,\ \cdot 0004,\ \ldots$$

The only telescopic feature permitting control of this phenomenon is the aperture. If this is increased the angular diameters of the rings are all diminished in proportion. It is of interest to note that if the objective is reduced to an annulus by a central stop, the rings are somewhat diminished in diameter, but at the expense of much less favourable distribution of the proportions of the light between them, the shares of the outer rings being increased. Numerically, considering, say, a 10-inch object glass and the D-ray, the diameter of the spurious disc of a star lying within the first dark ring would be 0″·98. Hence the images of the members of a close pair would be more or less superposed if their distance was less than 1″; but much within this a good eye would detect the elongation of the united image, as indeed was found in practice by S. W. Burnham, who discovered when using a 6-inch objective by Alvan Clark many double stars the separation of which lay beyond this theoretical "resolving power."

Owing to the shorter wave-length of actinic rays it might seem that photography was better circumstanced than the eye for receiving small images, but it is well known that this is not the case. From a variety of reasons, the photographic image spreads; and indeed the diameters can be used as measures of the star's magnitude. If the smallest recorded images are of less diameter than 2″ or 3″, the results would as a rule be considered very favourable.

§ (8) Optical Glass.—So far we have spoken of the geometrical modification of the beam of light; we shall now consider briefly the characteristics of the glasses[1] out of which the lenses are constructed. Apart from the limitations which technical difficulties of glass manufacture impose, geometrical discussions are merely mathematical exercises. The earliest telescopes were made with a single lens as objective, and in consequence suffered severely from dispersion, the images for different colours being ranged along the axis. The focal length was made as great as possible, and, for example, D. G. Cassini discovered two of the satellites of Saturn, Tethys and Dione, with telescopes of 100 ft. and 136 ft. in length respectively. But since the separation as well

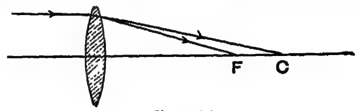

Fig. 14.

as the size of the images corresponding to, say, the rays C, F (*Fig.* 14) would increase proportionately with the focal length, it is an error to suppose that increase of focal length was any cure for chromatic faults, except in so far as the narrow beam does not allow spreading of any description. Achromatism was discovered and the principles published by John Dollond about 1760,[2] though achromatic lenses had been made before him by Chester Moor Hall, a private gentleman, as early as 1733. Making the converging lens of crown glass, the principle was to annul wholly the dispersion while only partly annulling the deviation by associating with the crown lens a divergent lens of greater proportionate dispersive power. This was found in "flint" glass or "English crystal," a dense and brilliant glass, which contained as base a silicate of lead. To obtain large homogeneous pieces of flint glass, free from striae, for negative lenses, proved a very difficult technical problem. It was solved by P. L. Guinand of Neuchatel, about 1800, whose secret was to stir the pot of melted glass with a fireclay rod to the last possible moment, and, allowing it to cool by itself, to take its natural fractures as marking off lumps of homogeneous constitution. When a large one was found this was softened again and moulded into the form of a disc. This secret he taught to Fraunhofer's firm in Bavaria and to Fraunhofer's successors, Merz and Mahler, by whom it was jealously guarded, so that in the middle of the nineteenth century they were the only people who could produce an objective of even so moderate a size as 8 inches diameter. Guinand, however, returned to Neuchatel, and his method passed to his son H. Guinand, and in succession to Feil, Mantois, and Parra in Paris, and through one of H. Guinand's collaborators, G. Bontemps, who took refuge in this country in the political disturbances of 1848, to Messrs. Chance in Birmingham. All the greatest lenses in the world, so far produced, excepting the 32-inch at Potsdam,[3] came from one or other of these firms. Their productions were, however, conservative, and a separate revolution in glass-making came from the researches

[1] See also article "Glass."

[2] *Phil. Trans.*, 1758, p. 733.

[3] Even these glasses, by Schott & Co., are of the old types.

of Abbe, Zeiss and Schott in collaboration at Jena, about 1880, investigating the effects of different constituents in glasses, with a view to finding stricter proportionality of dispersion over the whole spectrum, and generally to providing the greatest possible range and variety of refractive index and dispersion. In consequence of this the old terms *flint* and *crown*, though still employed, no longer imply the composition of the glass, nor its density, nor mean refractive index. The former term is reserved for glasses of high dispersion and the latter for glasses of low dispersion.

In spite of great technical improvements thus recently effected, defects in homogeneity of optical glass intrude themselves on the optician's calculations. Turrière states [1] that local anomalies of two or three units in the third decimal place are often found to affect refractive indices, whereas the calculations have been made assuming the constancy of the indices up to the fifth place. Moreover, it has not been found possible to avoid leaving some trace of mechanical strain from the process of annealing. This fault, which may be detected with the polariscope, will impair the definition with some traces of double refraction, which presumably would alter with the temperature.

We may take as representative of the glasses, out of which the great majority, at any rate, of the existing large refractors are constructed, Hard Crown (No. 605 of Chance's list) and Dense Flint (No. 361); the specifications of these glasses are the following, given as adhered to with considerable accuracy from one melting to another:

	Hard Crown.	Dense Flint.
Refr. index n_C	1·5150	1·6165
n_D	1·5175	1·6214
n_F	1·5235	1·6337
n_G	1·5284	1·6442
Dispersive power $(n_D-1)/(n_G-n_F)$	60·5	36·1
$(n_C-n_D)/(n_G-n_F)$	·294	·285
$(n_D-n_F)/(n_G-n_F)$	·706	·715
$(n_F-n_G)/(n_G-n_F)$	·554	·608

Glasses have been discovered in which the proportionality of dispersion is closer than for this pair, indeed practically complete, but they have proved liable to tarnish with exposure and age.

§ (9) Achromatism. (i.) *For Visual Use.*—In making the colour corrections there is one element in the construction which is disposable, the distribution of power between the crown and flint lenses, or two, if we add a small permissible separation of the lenses. The actual results attained are investigated by a method devised by Vogel, who set a direct vision spectroscope of small dispersion to receive the cone of rays from a bright star, say Vega or Arcturus. If the rays were brought to a focus the spectrum seen would be no broader than the star disc, and in fact for any setting of the spectroscope along the axis constrictions are seen which correspond to the wave-lengths in focus at that setting. The results—which agree precisely with what could be forecasted theoretically, as shown by H. D. Taylor [2]—are exhibited in the following table from measures of the Vienna 27-in. (Grubb, glass by Chance), the Pulkowa 30-in. (Alvan Clark, glass by Feil), and the Lick 36-in. (Alvan Clark, glass by Feil). The Vienna and Lick telescopes may be said to be identical, while the Pulkowa instrument can claim some superiority, but even for this it is to be noted that the image formed by the F-ray will be spread over a spurious disc 5″ in diameter, when the D light is brought to a point focus. Fine detail of varying colour, for example planetary surfaces, cannot be brought to a single satisfactory focus, and would suffer in definition accordingly.

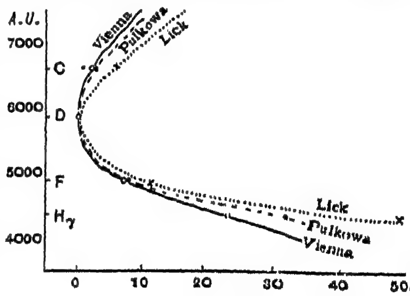

Fig. 15.

In the table on following page, *df* measures the setting required to bring into focus the line referred to, and *hff* is the angular diameter of the circle in which the cone of rays for that wave-length would meet the focal plane for the D-ray. See also *Fig.* 15.

The comment cannot be avoided that anything approaching true achromatism is impossible of attainment with the traditional objective of two lenses failing the production of types of glass that are quite unknown at present. The greater the telescope, with its increased light-grasp and wider separation of the foci, the more prominent the fault becomes. The optician has not enough scope allowed to produce his effects. As already remarked, H. D. Taylor has shown that a perfectly achromatic object glass can be made with three lenses, and has made such objectives up to any size for which the discs of glass were available. See *Fig.* 9.

[1] *Optique industrielle*, 1920, p. 25, a most useful work.

[2] *Mon. Not.* lv. 67.

* Cf. Keeler, *Ast. Soc. Pacific*, ii. 258.

The lenses are made of three of Messrs. Schott's glasses, L_1 of Baryta Light Flint (O. 543, $n_D = 1·564$), L_3 of Light Silicate Crown (O. 374, $n_D = 1·511$), and L_2 of a Boro-Silicate Flint (O. 658, $n_D = 1·547$). With this arrangement, very simple compared to photographic combinations for camera lenses, faults of colour can be [1] and are completely corrected, and at the same time a field given which is free from coma and spherical aberration. The separation of the second and third lenses assists the correction of the chromatic difference of spherical aberration (Gauss's condition).

(ii.) *Photographic Lenses.*—The correction of a lens for photographic purposes is a simpler problem than one designed for visual use, since for ordinary plates the effective rays are confined to a much narrower region of the spectrum. The problem is otherwise similar. Of more complicated constructions the only one that has been made with the large apertures peculiar to astronomical work is the Taylor lens referred to above, p. 847, made of three separated units [2] (see *Fig.* 10, p. 848). The original of this lens has the following description : [3]

Aperture, 6·5 inches; focal length, 43 inches.

L_1	R_0 +10·64			
		t_1 = 0·83		n_D = 1·5180
	R_2 −72·45			
		t_3 = 4·39		
L_2	R_4 14·54			
		t_5 = 0·33		n_D = 1·6035
	R_6 +10·35			
		t_7 6·85		
L_3	R_8 +67·35			
		t_9 0·49		n_D 1·5180
	R_{10} −13·00			

The refractive indices are those of a silicate crown for the first and third lens, and a light flint for the middle lens. But the design possesses great flexibility. It has been made up to apertures of 10 inches, and to focal lengths as small as twice the aperture; further, it has given rise to an extensive series of derived forms. The lens is intended for photography, and visual distinctness is not demanded from the design.

§ (10) REFLECTING TELESCOPES.—The reflecting telescope claims three great advantages over the refractor: it deviates alike rays of every wave-length; its performance depends upon its surface only and not upon the interior constitution of its glass, nor on the chromatic balance of two separate glasses, nor diminishes in effectiveness as the scale increases owing to absorption; and the objective consists of only one surface, the correctness of which is assured by an easy and very sensitive laboratory test. Accordingly, as might be expected, in respect to dimensions and aperture ratio, reflectors have completely outrun refractors. While the greatest refractor is of 40 inches aperture with a ratio of aperture to focal length of 1 : 19, and is not likely at present to be superseded, there are in use reflectors of 60 inches (Mount Wilson), 73 inches (Victoria), and 100 inches (Mount Wilson), in each case with an aperture ratio of 1 : 5, and with accessory appliances which permit the same mirror to be used when required at enormous effective focal lengths of 100 feet, 134 feet, and even higher. If greater ones are desired there is no reason to suppose we have reached the limit in gain of power, or in possibility of construction, though the difficulties of temperature control become very formidable in these large sizes. The question then presents itself, why the refractor holds its own so well as it does. A few sentences will be devoted to this question later on.

Speculum metal ("Turner's Metal" copper, 4 atoms = 68·2 per cent, to tin, 1 atom = 31·8 per cent, as used by the Earl of Rosse, Rowland, and Brashear) has virtually gone out of use except for small pieces, because once it is tarnished the mirror must be remade. It is besides a worse reflector than silver. And it is heavy, and difficult to make and work. On the other hand, it is remarkably durable.

[1] For the calculation see H. D. Taylor, *Mon. Not.* liv. 328.
[2] H. D. Taylor, *Mon. Not* lxiv. 614.
[3] H. D. Taylor, *Applied Optics*, 1906, p. 182.

Some old mirrors, dating certainly from Herschel's day, are still in perfect order. But silver deposited on glass is the standard construction. The problem of figuring the glass correctly is simplified by the fact that there are no elements of construction to dispose of at will. In order to correct spherical aberration at the principal focus, the figure must be a paraboloid; distortion is absent, but coma cannot be removed, and astigmatism and curvature of the field are present as in the refractor.

In regard to the two aberrational features that are necessarily present both in the mirror and in usual objective doublet, we see from the particulars given above, § (3), that for the same aperture and focal length the radius of the focal circle, or the separation of the focal lines, is the same for both, while the radius of curvature of the field is equal to F for the mirror, while it is about three-eighths of this amount for the lens. As regards the coefficient of coma, it is no more than occurs in the Fraunhofer lens referred to in § (5) (iii.) ($\delta_2 G = -0{\cdot}500/F$, compared to $\delta_2 G = -0{\cdot}467/F$). An impression of a limited field of good definition attaches usually to reflectors, but this is derived solely from the large aperture ratio which is allowed to them.

The reflector is used in three forms: first, for direct photography without any second mirror, the plate holder being placed at the principal focus (*Fig.* 16); second, for visual and general work in the Newtonian form with a flat mirror placed at 45° to the beam, throwing the principal focus out to one side at the upper end of the tube (*Fig.* 17); and third, when very large scale and long focus are required, as a Cassegrain, with a convex mirror placed on the axis with its principal focus beyond the principal focus of the great mirror, so as to reduce the convergence of the beam. The great mirror is usually pierced with a central hole and the beam received on a plate holder or spectroscope behind it (*Fig.* 18).

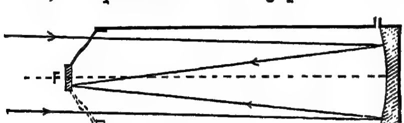

FIG. 16.

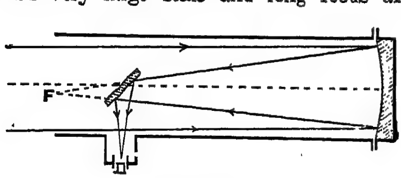

FIG. 17.

If F_1, F_2 are the foci of the two mirrors A_1, A_2, and F the emergent focus, the focal length of the combination is increased by the factor A_2F/A_2F_1. An ordinary value of this magnification might be fourfold. With this value the coma of the combination would be no more than belongs to a simple mirror of the same focal length. The curvature of the field would be increased, being about four times as great as for the original mirror: to correct for spherical aberration, if the mirror A_1 is parabolic, the section of A_2 requires to be an hyperbola, its measure e being about 3 where $e = 0$ gives the circle and $e = 1$ the parabola.[1]

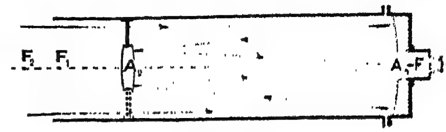

FIG. 18.

§ (11) TESTING A MIRROR. The possibility of producing truly paraboloidal or other figures in mirrors of large size depends upon having a sensitive and easy means of measuring a fault. This is found in Foucault's knife edge method (*Fig.* 19).

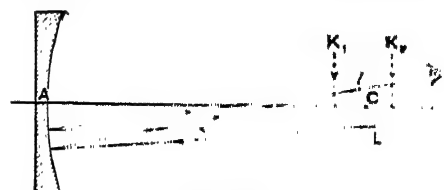

FIG. 19.

If C is the centre of curvature for A, L a point source or "artificial star" close to C, l the point of the beam reflected from any spot of the mirror, received by the eye at E beyond l, then if the beam is cut off gradually by a knife edge moving across from left to right at K_1 within the focus l, the spot of light on the mirror will seem to the eye to be obscured from right to left, but if it moves at K_2 the movement of shadow will be from left to right. Hence the position of the actual focus for any spot of the mirror can be determined precisely. A very good idea of the figure and faults of the whole mirror can be gained at a single glance, and if a series of diaphragms are prepared exposing the surface in successive zones, with very little preparation and with surprising certainty the centres of curvatures of the different zones can be laid down.[2] If the mirror is parabolic, these will not give the same point C, but will move towards the surface from C by an amount $\frac{1}{4}B^2/R$, supposing the source L is kept fixed during the observations.

[1] For a discussion of the correction of the Cassegrain see Sampson, *Phil. Trans.* ccxiii. 27.

[2] For an excellent account of the detail of this method see C. D. P. Davies, *Mon. Not.* lxix. 355.

A convincing test of the delicacy of the method is furnished if an assistant places his hand in the way of the beam near the mirror, when the undulations caused by the ascending currents of air its warmth produces will be seen immediately.

Moreover, the method is not restricted to visual application. Photographic records of the appearances have been obtained by J. Hartmann for the Potsdam 32-inch refractor,[1] and by P. Fox for the 40-inch Yerkes telescope,[1] which show upon examination much minute detail that would escape the eye; as, for example, epicycloidal traces of the motion of the polishing tool. These "focograms" have besides the invaluable quality that they can be compared with similar records of other instruments taken at other times.

A convex mirror, or a flat, or one of very small concavity, cannot be tested directly by this method. But it is usually possible to devise a combination with some converging system, the character of which is already proved, so as to test their performance. Or a flat may be tested with another known flat, by examining the formation of Newton's rings between them.

§ (12) Loss of Light in a Telescope.—We must now consider the whole loss of light, and the modification of its character in passing through a telescope.

(i.) *Refracting Telescopes.*—In transmitting light through glass surfaces, there is a loss at each surface by reflection. For direct incidence, theory indicates that the proportion so lost is $(\mu-1)^2/(\mu+1)^2$, where μ is the refractive index for the ray concerned; and for freshly polished glass this accords closely with experiment.[2] It may be taken, therefore, as between ·04 and ·05 per surface. In the case of objectives with separated lenses there will be four such occasions for loss; for small objectives the inner cemented surfaces do not give rise to any sensible loss, and therefore transmit some 10 per cent more of the light. The losses by absorption have been investigated by H. C. Vogel[3] for a number of glasses, including ordinary Silicate Crown and ordinary Light Flint (O. 203 and O. 340 of Schott's list), which are suitable for large telescopes. For the visual spectrum these glasses are very transparent, but O. 340 with a thickness of 10 cm. to 15 cm. transmits no light at all of wave-length less than 3760 A.U., and shows a sharply defined absorption band at 4186 A.U., and a weaker and diffuse one about 4370 A.U. The crown glass O. 203 also shows the former band. Otherwise the progression of absorption was regular and not strikingly different for the two glasses. Vogel gives a table from which the following is an extract, showing the amount of light transmitted by objectives of different thicknesses. In calculating for reflection, four surfaces of separation are allowed for. The aperture would, as a rule, be about six times the total thickness.

Thickness of Objective in cm.	Intensity of Transmitted in terms of Incident Light.			
	With allowance for Absorption only.		With allowance for Absorption and Reflection.	
	Visual Rays.	Actinic Rays.	Visual Rays.	Actinic Rays.
4	0·93	0·84	0·77	0·69
6	·90	·77	·75	·63
8	·87	·71	·72	·58
10	·84	·65	·70	·53
12	·82	·60	·67	·49
14	·79	·55	·65	·45
16	·76	·50	·63	·41
18	·74	·46	·61	·38
20	·71	·43	·59	·35

It will be noticed that the balance that may exist between visual and actinic rays in different sources of light will be transformed, and in different manners, by different objectives, so as to give, for example, inconsistent results in such research as that of the effective wave-lengths of stellar images.

(ii.) *Reflectors.*—Measurements of the relative intensity of light of different wave-lengths are acquiring great and growing importance, and it should be noted that reflectors of all types also exercise selective treatment of different rays. The following table (Hagen and Rubens) shows the percentage of light reflected from silver and a few other metallic surfaces. It will be noticed that silver deposited on the front of a glass plate is distinctly more effective than when deposited on the back, apart from absorption by the glass.

Percentage of Light reflected from Metals

Wave-length.	Silver.	Platinum.	Gold.	Speculum Metal.	Silver behind Glass.	Mercury behind Glass.

[3] *Astrophys. Journ.*, 1897, v. 75.

A silver surface, therefore, cannot be approached by any other, so long as it remains in good order, both for the visual and the actinic region of the spectrum. But in the ultra-violet, about λ3160, for a short range, it becomes almost transparent, the percentage of light reflected being hardly more than from clear glass. This limits its application, for example, in some photo-electric researches. But in the same region an ordinary large object glass is completely opaque.

§ (13) General Considerations.—It will be realised that some of the defects of a telescope considered in the foregoing pages are irremovable with the means allowed, and some of the requirements are mutually incompatible. But usually in each observation one or another consideration will be predominant.

So long as coma is not aggressive, a wide field may be dispensed with in a large number of observations: for example, in transit work, where a good field of 15′ radius gives ample time to take the observation, or in double star measures and micrometer work generally; and in all other classes of direct visual work where the object is brought to the centre of the field for examination; and in work with a slit-spectroscope, whether visual or photographic. Equally in these cases curvature of the field and astigmatism play no part.

In some classes of photometric work no good image at all is wanted; the star is deliberately thrown out of focus, preparatory to estimating its total light.

Again, photographic work, where a correct delineation of a field of stars is required, may be divided into different classes according to the scale or focal length. With a focal length of 20 feet, a field 1° across covers a circle 5 inches in diameter. It would be easy to secure a correct field of so small a diameter, and more would not be asked of such an instrument, if only because the plates would be inconveniently large. If we want large fields we go to the other extreme and employ, as, for example, for the Franklin-Adams chart, a Cooke lens of aperture 10 inches and focal length 45 inches, which gives sensibly correct pictures of 15° diameter, with a flat field. There would be some distortion in such a picture, and the scale would be comparatively small. But the plate is not used for measurement but for enumeration; or it is used for photography of nebulae or comets, where increase of scale without increase of aperture loses the detail by diffusing it.

Midway between these extremes we have the telescopes of the Astrographic Catalogue; these are each, as near as may be, of 3438 mm. focal length, so that on the image 1 mm. represents 1 minute of arc; a field 2° square is photographed, which allowing for margin gives a plate about 6 in. × 6 in. On this scale over ten thousand plates are required to cover the sky—the mere difficulties of numbers will speak for themselves. The object glasses, 340 mm. = 13·5 in. diameter, were specified to be free from coma, but astigmatism and curvature of the extreme images are easily marked, the former by the images taking the form of two short crossed lines, and the latter by the lower density of stars recorded, owing to fainter stars failing to impress themselves when their light is a little diffused. Such a plate can be measured right up to its limits for the relative co-ordinates of the stars, but is quite unsuited for work of the highest accuracy, for instance for stellar parallax.

The reflector is well suited for all classes of visual observation, except transit work; and particularly suited for the spectroscope, owing to its light-gathering power. It is unapproachable for photographs of nebulae, but has been but little used for fields of stars designed for measurement, owing to the irremovable coma which vitiates its field, and which becomes prominent in the large aperture ratios with which the reflector is usually made. In somewhat the same way methods and instruments must be selected so as to avoid the intrusion of residual chromatic faults. A great refractor is usually applied to faint objects; if applied to bright ones, there is a blue glare in the field of disturbing intensity. This may be removed by using for such observations a colour screen which shuts out the blue rays. In the same way, by excluding rays that are not wanted, very perfect photographs have been obtained with the Yerkes 40-in. refractor, which is corrected visually, by interposing a yellow colour screen and using yellow sensitive plates. The loss of speed is of course very great. Again, a telescope corrected visually can be applied to photography, or conversely, by interposing a lens in the beam which collects to a focus the rejected rays. All the field except the centre is thereby sacrificed, but this does not matter if the purpose is to employ a slit-spectroscope.

As remarked above, a region of investigation which promises to occupy growing importance is the distribution of light in different parts of the spectrum. This is a matter that has hardly been considered, in view of its importance. All telescopes in use modify the distribution they record, each in a different way, and reflectors in a way that changes with the condition of the silvered surface.

§ (14) Mounting of Telescopes: The Transit Instrument.—We shall now describe briefly the principles of mounting telescopes, but, as explained in the beginning of this article, we shall avoid as far as possible astronomical detail, and direct attention to the geometrical and mechanical problem.

The Transit Instrument is designed for measuring relative position of points on the

sky, or, given these, the orientation of the observer in latitude and hour angle with respect to them. The two problems are logically interlocked, but by a process of sifting, familiar in astronomy, they are gradually and effectively separated from one another. The necessity for the measuring instrument is the greatest fixity, subject to commanding the whole sky. The ordinary standard form aims at sweeping the meridian with the optic axis. This requires (1) two pillars built up from the ground, carrying "Y"s at the same level and standing E. and W. with respect to one another; (2) a massive axis, with its ends resting on the "Y"s as bearings; (3) a telescope fastened at right angles to this axis; this telescope is made in two symmetrical pieces, the object glass and eye end being interchangeable if desired, and bolted to the "cube" which forms the middle of the axis, and which is perforated to allow the beam of light to travel through. General stability and constancy is sought by making all the supports massive, and relieving by counterpoises on adjustable springs the greatest part of the pressure on the "Y"s. There are, however, temperature or other seasonal changes to allow for. The former are dealt with as far as possible by considering symmetry as a rigorous requirement of the design. In the Cape Transit Circle as well, to guard against local differences, the telescope proper is completely enclosed in a copper sheath, and the instrument house moves bodily away from it in two halves. But finally it is assumed in the resulting observation that the telescope shows traces of complete maladjustment, *i.e.* three degrees of freedom, the coefficients of which can only be derived by special check observations. Particulars of the processes would carry us too far into astronomical details. The print (*Fig.* 20), derived from Messrs. Troughton & Simms's Catalogue, shows the Cape Transit Circle (6-in. objective), and examination of it will show how the principles are put into practice.

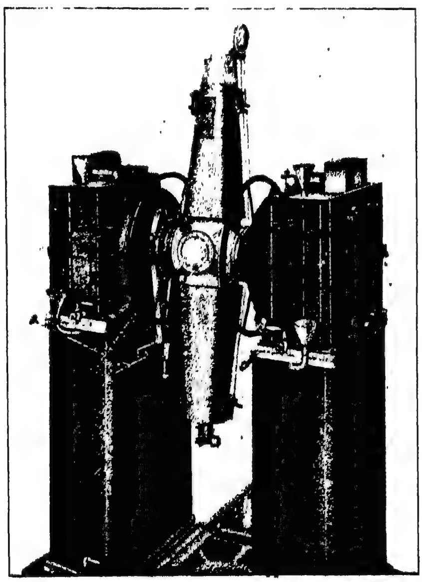

FIG. 20.

§ (15) EQUATORIAL.—For the examination of an individual object, or for photographing or measuring a particular field, a certain time up to an hour or several hours is required, and the telescope must be endowed with motion which cancels the earth's rotation. That is to say, it must rotate east to west about an axis parallel to the earth's poles, at a rate which would give one revolution per day. The construction, then, is that of a massive axis pivoted so as to lie parallel to the earth's axis and geared by a clamp when desired to clockwork which gives it the necessary motion. This polar axis carries perpendicular to itself the declination axis, about which the telescope itself is capable of rotating. If the telescope is turned about the declination axis, and the polar axis turned until a desired object is in the field of view, and then clamped, the clockwork will keep it pointed on the object. There is a variety of ways in which these purposes may be carried out.

(1) The polar axis may be prolonged beyond its bearings and terminate in a pair of journals in which the declination axis swings; (2) the polar axis may be pivoted at its extremities and be built up in the form of a frame or cage in the midst of which the telescope swings upon its declination axis; (3) the declination axis may be attached in two separate pieces to opposite sides of the telescope and, broken itself, support the telescope symmetrically; (4) the declination axis may be prolonged on both sides of the polar axis, carrying the telescope attached by bands to a cradle upon one side, with a counterpoise upon the other. All these forms are made and are illustrated in *Figs.* 21, 22, and 23 on p. 856.

These illustrations show the constructions of the three great reflectors made in recent years. The weights of the moving parts of these instruments are very great. For the Canadian telescope (73") at Victoria, Vancouver Island, the polar axis weighs 10 tons, the declination axis 5, the mirror, cell, and tube together 12 tons, and the whole instrument 55 tons. To bring pieces of such size within the range and accuracy of "fine" mechanical work is a great feat of exact engineering. In the case of the

two Mount Wilson telescopes the weight is carried chiefly by large discs plunged in baths of mercury; the Victoria telescope relies upon ball bearings, and the counterpoising is so perfect and the movement so frictionless that a pressure of 3 lbs. weight applied at the end of

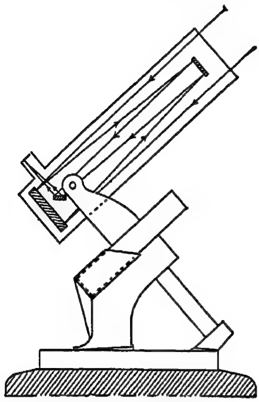

FIG. 21.—Fork, 60″.

the declination axis suffices to turn it. In these great telescopes, designed for grasping very faint objects, it is essential that the clockwork driving should be as perfect as the optical work, otherwise the image on the photographic plate is diffused and the advantage of size is lost. Driving differs from the optical

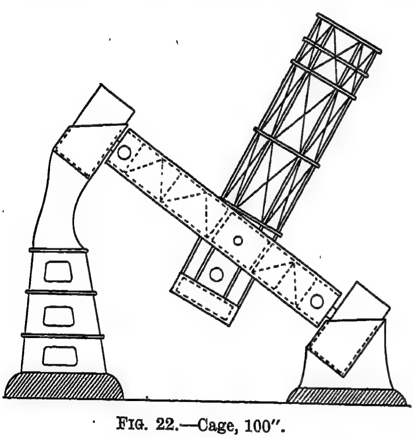

FIG. 22.—Cage, 100″.

work in this, that it is subject to control. A star is kept under visual observation, bisected by a pair of cross-wires; when a bright star is available it is a good plan to form a disc by throwing it out of focus and bringing this disc to bisection by two heavy wires which are visible without illuminating the field. This visual supervision is usually made with an accessory "guiding" telescope fixed to the same frame, but the most perfect way is to have the plate holder constructed with an eyepiece attached to it so that the actual set of the plate may be observed directly. When the clock drive requires to be accelerated or retarded, it is essential that this should be done with no jar whatever. Differential gear thrown in and out of action accomplishes it. If the clock carries an arbor making one revolution per second, the standard clock may be made to exercise automatic control in applying the

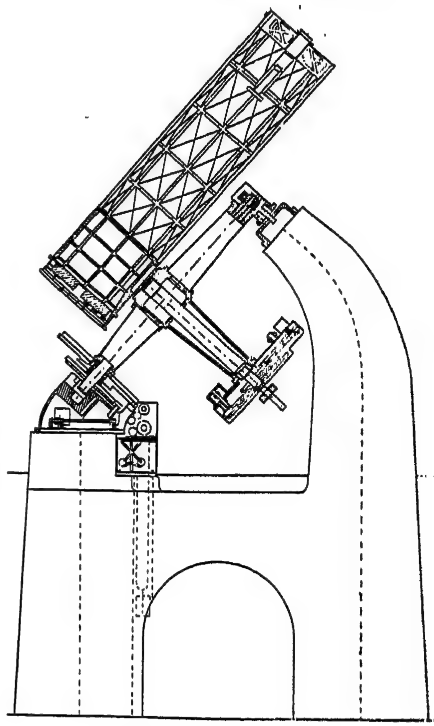

FIG. 23.—Counterpoise, 73″.

gear, though this does not dispense with personal watching. For automatic control, a simple gear, which is said to work well, is a sector of soft iron, attached on the one-second arbor, and revolving so as to pass near the poles of an electromagnet which a signal from the clock makes live once every second. But most of the methods of automatic control are prejudicial to smooth running.

The mounting of a refractor is nearly always made by prolonging the declination axis beyond its journals and attaching the declination axis as a cross-head, carrying the telescope at one end and a counterpoise at the other. For this form there are two, reversed, settings for any object, like the "changes of face" of a theodolite, and, generally speaking, one or

the other setting may be inaccessible. The cross-head should not be too short, otherwise in some positions the eye end will foul the supporting pillar and cut short an observation by necessitating change of face in the middle of it.

Fig. 24 shows a good example of modern construction, an 18-inch visual telescope for the observatory of Rio de Janeiro, by T. Cooke & Sons. Beside the great telescope are two cameras, each of 70 inches focal length and furnished with 10-inch Cooke lenses. For the use of these cameras a 10-inch follower is provided, or the great telescope itself could serve as a visual guider.

Consideration of these designs will show that the refractor permits a more symmetrical, compact, and stronger mounting than the reflector, the tube being closed at both ends. Its optical condition is also not liable to variation. Both these are very important considerations, and will account for a certain amount of just preference for the refractor. A third consideration is less reasonable but is probably present. Difficult as the optical problem of making the object glass of a telescope is, in comparison with the mechanical problem of mounting it, the most expensive part of a telescope arises in building its dome, mount, and clockwork. A mirror is very much easier and cheaper to make than an object glass of the same power, and when so much is spent upon accessories there is perhaps some inclination to complete them with the more costly optical provision. Generally, one would say that a reflector deserves to have an even greater proportion of use in large optical work than it gets at present.

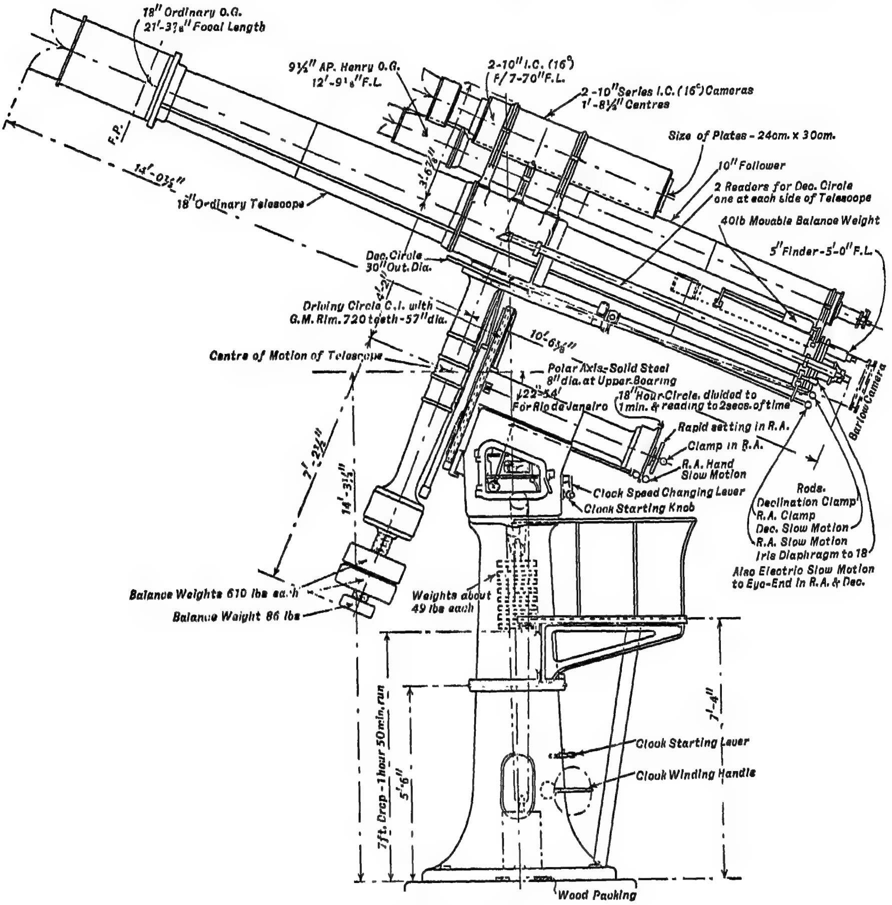

FIG. 24.—Rio, 18″.

§ (16) THE COELOSTAT.—In place c
ing the daily rotation with the
there is an alternative of keeping the
fixed and reflecting the rays into it

sometimes followed in the case of the sun, where there is ample light, because the use of long focus lenses and spectroscopes presents fewer difficulties if they are kept in a horizontal (or a vertical) plane. It is accomplished by one of two methods. The simplest device is the coelostat (*Fig.* 25). If S is any point upon the sky, and N gives the direction of the normal to a plane mirror, then if SNS′ is a great circle and SN = NS′, S′ gives the direction of the reflected ray which arrives from S. Hence it is plain that if N is made to move along the equator with half the speed of the daily rotation, the ray S may be reflected to any fixed point S′ lying on the small circle of south polar distance equal to the north polar distance of S; in particular it may be sent horizontally to one or other of the two points S_0' in which this circle cuts the horizon. And the image of the field round S will remain stationary and not rotate as S moves across the sky. On the other hand, the horizontal direction in which the ray is sent is not open to choice. To send it in a prescribed direction a second, fixed, plane mirror would be required.

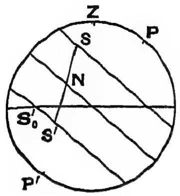

FIG. 25.

§ (17) THE HELIOSTAT.—Foucault's Heliostat, on the other hand, will send the beam constantly in any chosen direction (*Fig.* 26). AB is directed to the pole, TN is the normal to the mirror; then if TB = BN, a ray arriving in the direction BN is reflected from the mirror in the direction BT. Hence if there is a universal joint at T, and the rod TN slides through a well-fitting sleeve at N, and BN is clamped to AB so as to point at the polar distance of the sun, then giving the united piece AB + BN a movement equal to the apparent daily rotation, the mirror will send the beam out in the direction BT, which may be any desired direction. The universal joint at T is made by furnishing the cell of the mirror with a pair of horizontal pivots which rest on the two arms of a large solid fork, which itself is capable of free rotation about a vertical axis. A disadvantage attending the Heliostat is that the image of the sun which is formed rotates, the north polar point of the sun passing from one side of the vertical to the other.

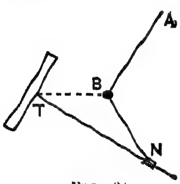

FIG. 26.

R. A. S.

TELESCOPE OBJECTIVES, TESTING OF. See "Objectives, Testing of Compound."

TELESCOPES, SMALL

§ (1) GENERAL PROPERTIES. Telescopes are optical instruments designed to enable comparatively distant objects to be observed on a uniform magnified scale. The image formed on the retina is thus increased in a ratio independent of the distance of the object, and the value of this ratio is called the magnifying power of the instrument. Paradoxical as it may seem, this result is achieved by presenting for inspection to the eye a diminished virtual image of the object, the ratio of the size of this image to that of the object being the reciprocal of the magnifying power. The explanation of this paradox whereby the image on the retina varies inversely as the size of the immediate object viewed directly by the eye is vital to a proper understanding of the telescope.

It follows from the ordinary theory of refraction through a lens[1] that if x is the separation parallel to the axis of two object planes which have images magnified in the ratios G_1 and G_2 respectively, and if x' is the corresponding separation between the images,

$$x' = x \, . \, G_1 \, . \, G_2,$$

provided the refractive indices of the object and image spaces are equal. If, now, the case of a telescope of magnifying power P is considered, the image of every transverse object is diminished P times, so that $G_1 = G_2 = 1/P$, and if y is the length of a transverse object the image is of length y' where $y' = y/P$. Among the objects in the object space is the first lens of the telescope, and in nearly all cases the eye is placed as nearly as possible at the image of this lens. The distance of any particular object from this lens may be identified with x in the above formula, and x' is then the distance of the image from the eye. The relation between them is

$$x' = \frac{x}{P^2},$$

that is to say, the apparent distance of the object from the eye has been diminished as the square of the reduction in the linear dimensions of the object. Thus, although the image is less than the object, it is so much nearer the eye that the final result is that the telescopic image appears to have been enlarged in the ratio in which, in fact, it has been diminished. Put in another way this is a particular illustration of the well known law that the angular magnification varies inversely as the linear magnification.

The relation between x and x' shows that the range of ocular accommodation required

[1] See "Lenses, Theory of Simple," § (7); also "Optical Calculations," § (7).

in viewing a perfect image in a telescope is equal to that called into play when the same objects are viewed by the eye from a nearer point, such that the retinal images are equal to those seen from the further view point through the telescope. The only difference, in fact, apart from any due to imperfections in the instrument, is the incorrect perspective in the telescopic view for an image of the apparent size obtained by the use of the telescope. Owing to instrumental defects a much greater range of accommodation is, in fact, required, and special provision is made for this purpose in the telescope focussing adjustment.

It will be gathered from what has already been said that the telescope is peculiar among optical instruments in forming images of all real objects at a finite distance from the instrument. Thus it is only when celestial bodies are under examination that the emergent beams of light are parallel with an instrument in normal adjustment. Notwithstanding this, it is permissible, in dealing with the construction of the telescope, to consider only the light emanating from infinitely distant objects. The image of an infinitely distant object being itself at infinity, the condition characteristic of telescopes in the notation used in "Optical Calculations" is evidently

$$K=0,$$

and equations (31) of that article then show that the magnification is independent of the distance of the object, and since the magnifying power is the reciprocal of the linear magnification, the desirable conditions for all rays in terms of the magnifying power Γ are

$$\frac{\partial K_{1,n}}{\partial K_1}=\Gamma, \quad \frac{\partial K_{1,n}}{\partial K_n}=\frac{1}{\Gamma}.$$

From equations (33) it is seen that the relations between the incident and emergent direction cosines of the ray are

$$\frac{M'}{M}=\frac{N'}{N}=\Gamma,$$

and not the tangent law which is usually assumed to hold, viz.

$$\frac{M'}{M}=\frac{N'}{N}=\frac{L'}{L}\Gamma.$$

A further quantity of importance is the magnitude of $\partial^2 K_{1,n}/\partial K_1 \partial K_n$, or D; this is of the dimensions of a length, and may be interpreted in terms of the distance of the centre of rotation of the eye from the last surface of the telescope when the eye is in its most favourable position. The value of this eye distance is D/Γ, and similarly the image of the last surface of the telescope in the rest of the system lies in the object space at a distance DΓ from the first lens. D may be given any finite value that is desired by changing the scale of the whole instrument, so it is necessary in considering its value to consider the length of the complete instrument, or alternatively the focal length of a selected component lens. The value of D in comparison with the apertures of the lenses determines the field of view of the telescope.

§ (2) Galilean Telescope.—The simplest telescope consists of two lenses, the essential relations being in terms of paraxial quantities

$$\kappa_1=\frac{\Gamma-1}{t\Gamma},$$

$$\kappa_2=\frac{1-\Gamma}{t},$$

$$D=-t,$$

so that

$$\frac{1}{\kappa_1}+\frac{1}{\kappa_2}=t.$$

If Γ is positive, so that the telescope presents erect images to the eye, one lens is positive and one negative, the image of either lens formed by the other being virtual. This is the construction used in the Galilean telescope (*Fig.* 1). The chief merits of the instrument, apart from

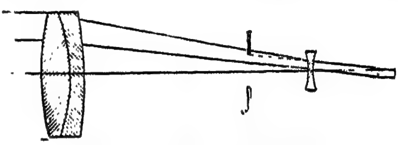

Fig. 1.—Galilean Telescope.

its cheapness, are the brightness of the field due to the small absorption of light. The chief defects are the small field of view resulting from the negative value of D. The chief use of this telescope is for low magnifications —say 2 to 5—and for night observation at sea. In an average instrument the "apparent field," measured by the angles corresponding to the extreme values of M′ when N′=0, is about 16°, the value in practice being nearly independent of the magnification. In theory it should be possible to obtain apparent fields which increase as the magnification falls. The real field, which corresponds to the extreme values of M with N=0, is evidently obtainable with sufficient accuracy by the relation

Apparent field = Real field × Magnifying power.

§ (3) Astronomical Telescope.—If the image presented to the eye is inverted, corresponding to a negative value of Γ, both lenses are positive, and the desirable position for the eye is external to the instrument. Considerable advantages, however, result in this case by utilising three separate lenses, as

described below. An ordinary form is shown in *Fig.* 2. It will be observed from the preceding formulae that

$$\kappa_2 = -\kappa_1 \Gamma,$$

and this result may be extended to telescopes generally, however complicated their structure.

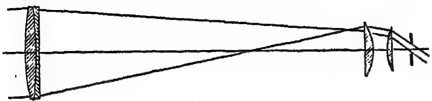

FIG. 2.

In fact, the equations already referred to give at once for all values of λ

$$\Gamma = -\frac{K_{\lambda+1,n}}{K_{1,\lambda}} = \frac{\partial K_{\lambda,n}}{\partial K_\lambda} \bigg/ \frac{\partial K_{1,\lambda}}{\partial K_\lambda}.$$

When there are three lenses the two separations, t_1 and t_2, and D may be given arbitrary values. The powers of the lenses are then given by

$$\kappa_1 = \frac{1}{t_1} + \frac{1}{D\Gamma} + \frac{t_2}{Dt_1},$$

$$\kappa_2 = \frac{1}{t_1} + \frac{D}{t_1 t_2} + \frac{1}{t_2},$$

$$\kappa_3 = \frac{1}{t_2} + \frac{\Gamma}{D} + \frac{t_1}{Dt_2}.$$

For comfortable use D should not be numerically less than 25Γ mm., its sign agreeing with that of Γ. If the apertures of the lenses are denoted by a_1, a_2, a_3 respectively, the maximum useful aperture under normal conditions is determined by

$$a_1 = e|\Gamma|,$$

where e is the largest diameter of the pupil of the observer's eye when using the instrument. Under ordinary conditions a value for e of about 6 mm. may be adopted. This determines the aperture of the objective, and a knowledge of the performance of objectives of various relative apertures enables an upper limit to be assigned to the value of κ_1. In good instruments values of $a_1\kappa_1$ as high as 0·3 or 0·35 may be found. The remaining quantities follow readily on considering the field of view. The useful rays are effectually limited by two stops in the object space, the images in the front part of the instrument of the second and third lens apertures. The image of the third lens, as has been seen, is of diameter $a_3|\Gamma|$, and is a distance $D\Gamma$ in front of the first lens. The image of the second lens is of diameter

$$\left|\frac{a_2 D\Gamma}{t_1 + t_2\Gamma}\right|,$$

and is situated a distance

$$\frac{t_1 D\Gamma}{t_1 + t_2\Gamma}$$

in front of the first lens. As $t_1 + t_2\Gamma$ tends to be small it is simpler to consider the latter limit as a cone through the first lens aperture of semi-angle $\tan^{-1}(a_2/2t_1)$. The effect of the two apertures is to enable the whole aperture of the objective to transmit useful light for an angular field determined by the smaller of the two ratios a_2/t_1 and $|a_3/D| - |a_1/\Gamma|$, with an outer zone of the field corresponding to the space between this limit and the smaller of the two ratios a_2/t_1 and $|a_3/D| + |a_1/\Gamma|$. In this zone the brightness of the image continuously diminishes from the inner to the outer limit because only a diminishing portion of the area of the objective receives light which is eventually transmitted to the image space. It is customary to include about one-half of this outer zone in the field of view, and a metal diaphragm is placed where the real image of distant objects at the limiting angle is formed to give a sharp edge to the field. The case of practical importance is when both D and Γ are negative and the powers of all the lenses are positive. A telescope of this kind is the foundation of the well-known prismatic telescopes usually combined in pairs for binocular vision. A positive value is always secured for $t_1 + t_2\Gamma$, and this has a direct influence on the correction of the component lenses for colour. The system will be automatically maintained in telescopic adjustment for another colour if t_1 and t_2 remain unchanged in the expressions for κ_1, κ_2, κ_3 while D and Γ are changed. Suppose that D and Γ become $D(1+d)$ and $\Gamma(1+\gamma)$ where d and γ are small. If the new value of each κ is obtained by introducing a factor $(1+1/\nu)$, evidently the first approximations are

$$\frac{\kappa_1}{\nu_1} = -\frac{d+\gamma}{D\Gamma} - \frac{t_2 d}{Dt_1},$$

$$\frac{\kappa_2}{\nu_2} = \frac{Dd}{t_1 t_2},$$

$$\frac{\kappa_3}{\nu_3} = -\frac{\Gamma(d-\gamma)}{D} - \frac{t_1 d}{Dt_2}.$$

Now small variations in D with the colour are not of serious importance, so that the second lens need not be corrected for colour. If this lens is of a crown glass the variation of D over the visible spectrum may be of the order of 4 mm. If the value of d in terms of ν_2 is substituted in the other equations, it is found that

$$\frac{\kappa_1}{\nu_1} = -\frac{\gamma}{D\Gamma} - \frac{(t_1 + t_2\Gamma)\kappa_2 t_2}{D^2\Gamma\nu_2},$$

$$\frac{\kappa_3}{\nu_3} = \frac{\Gamma\gamma}{D} - \frac{(t_1 + t_2\Gamma)\kappa_2 t_1}{D^2\nu_2}.$$

Obviously the image will be visibly imperfect unless γ is very small, and the proper principle

for the correction of the external lenses is shown by making it zero. Since Γ is negative and all the other terms positive, ν_1 should be positive and ν_3 negative, that is, the objective should be under-corrected for colour and the eye lens over-corrected. If the sign of $t_1+t_2\Gamma$ were reversed, so that the eyepiece were of the Huygenian rather than the Ramsden type, the requirements as regards these two lenses would be reversed also. The determination of the precise data for the construction of these lenses can follow the lines described under "Optical Calculations." When prisms are inserted for the erection of the image between the lenses the effect of the thickness of the glass—equivalent to a variation in t_1—must be taken into account. It is worth noting that when the second and third lenses which form the eyepiece are regarded as a separate instrument, the conditions for the chromatic correction which follow from the above equations when both these lenses are of the same glass are inconsistent with that usually given, viz.

$$2t_2=\frac{1}{\kappa_2}+\frac{1}{\kappa_3}.$$

The correct condition in this case is

$$2t_2=\frac{1}{\kappa_2}\left(1+\frac{t_2}{t_1}\right)+\frac{1}{\kappa_3},$$

and this approximates to the usual form when t_2 is small compared with t_1. The desirable separation on this theory is always greater than that given by the ordinary rule, and reaches a value twice as great when the first principal focus of the field lens is situated at the objective.

§ (4) Terrestrial Telescope.—Telescopes having four or more separated lenses may be discussed in a similar way. The principal aim in introducing additional lenses is usually to present an erect instead of an inverted image to the eye, so that a form with positive values for D and Γ is desired. It will suffice, by way of example, to consider a system of five separated lenses.

Let $$t_rt_{r-1}\kappa_r-t_r-t_{r-1}=k_r,$$

and regard k_2 and k_4 as independent variables. Then the powers of the odd lenses are determined from

$$\kappa_1=\frac{1}{t_1}+\frac{1}{D\Gamma}+\frac{t_2}{t_1k_2}+\frac{k_4}{Dk_2},$$

$$k_3=\frac{t_1t_3}{k_2}+\frac{t_2t_4}{k_4}+\frac{Dt_2t_3}{k_2k_4},$$

$$\kappa_5=\frac{1}{t_4}+\frac{\Gamma}{D}+\frac{t_3}{t_4k_4}+\frac{k_2}{Dk_4}.$$

In practice there are limitations to the extent to which k_2 and k_4 may be varied independently of one another, and a restriction it appears natural to adopt is that k_3 will be small, so that the even lenses, which are likely to be field lenses, will be approximately in conjugate planes with respect to the third lens. As D is to be positive this implies that k_2 and k_4 will differ in sign. A further limitation the designer will wish to bear in mind is the value of the sum of the powers of all the lenses. If this is too large the curvature and astigmatism will tend to be inconveniently great. The value of this sum is

$$\Sigma\kappa=\frac{(D-k_2-k_4)^2}{Dk_2k_4}+\frac{(1-\Gamma)^2}{D\Gamma}+\frac{t_1t_2\kappa_2^2}{k_2}+\frac{t_3t_4\kappa_4^2}{k_4},$$

two terms being positive and two negative. In special cases these expressions are unsuitable, for k_2 or k_4 may be zero. Ambiguity in these instances may be avoided by treating k_3 as an independent variable, and the formulae become

$$\kappa_1=\frac{1}{t_1}+\frac{1}{D\Gamma}+\frac{k_3k_4-t_2t_4}{Dt_1t_3},$$

$$\kappa_5=\frac{1}{t_4}+\frac{\Gamma}{D}+\frac{k_2k_3-t_1t_3}{Dt_2t_4},$$

$$\Sigma\kappa=\frac{(1+\Gamma)^2}{D\Gamma}+\frac{1}{Dt_1t_2t_3t_4}\{k_3(k_2t_1t_3+k_4t_2t_4)-(t_1t_3+t_2t_4)^2\}+\frac{k_2}{t_1t_2}+\frac{k_3}{t_2t_3}+\frac{k_4}{t_3t_4}+\frac{2}{t_1}+\frac{2}{t_2}+\frac{2}{t_3}+\frac{2}{t_4}.$$

If $k_2=0$,

$$k_4=-\frac{Dt_2}{t_1},$$

and similarly, if $k_4=0$,

$$k_2=-\frac{Dt_3}{t_4}.$$

To determine the character of the chromatic correction necessary in the components, it will be observed that if latitude is allowed in D control of the two external lenses alone is necessary to ensure that the system remains a telescope of magnifying power Γ as the colour changes. It may, in the first place, be assumed that the even lenses are of a single glass of the same melting. In the particular case

$$k_2=k_3=0,\quad \nu_2=\nu_4=\nu,$$

$$\Sigma\kappa=\frac{(1-\Gamma)^2}{D\Gamma}+\frac{2(t_1+t_2)(t_2+t_3)}{t_1t_2t_3}-\frac{(Dt_2-t_1t_3+t_2t_4)^2}{Dt_1t_2t_3t_4},$$

$$Dt_2t_3(1-\nu d)=(t_1+t_2)t_3t_4+(t_3+t_4)t_1t_2,$$

indicating a negative value for νd. Also

$$\left(\frac{1}{\nu_1}+d\right)\left(\frac{1}{t_1}+\frac{1}{D\Gamma}-\frac{t_2t_4}{Dt_1t_3}\right)=\frac{d}{t_1}-\frac{\gamma}{D\Gamma}-\frac{t_2(t_2+t_3)}{t_1^2t_3\nu_2},$$

and $$\left(\frac{1}{\nu_5}+d\right)\left(\frac{1}{t_4}+\frac{\Gamma}{D}-\frac{t_1t_3}{Dt_2t_4}\right)=\frac{d}{t_4}+\frac{\Gamma\gamma}{D}.$$

Thus if $\Gamma = t_1t_3/t_2t_4$, the fifth lens requires to be achromatic, and either the first and third must be separately achromatised or one must be under- and the other over-corrected, the relation between the amounts being

$$(t_2 + t_3)\nu_1 + \Gamma t_4 \nu_3 = 0.$$

It is preferable to depart somewhat from this condition, so avoiding having lenses in sharp focus with the image. If the real images precede the second and fourth lenses, the fifth lens must be over-corrected for colour but the first and third lenses must form an under-corrected combination. If the images follow the second and fourth lenses the fifth will be under-corrected, and the first and third together will be over-corrected. The modifications involved when k_3 is not zero are easily traced, and on the principles already illustrated lead readily to the justification of the form adopted for the terrestrial eyepiece when the last four lenses are of a single glass. When large fields of view are desired the third lens should be built from more than one glass to enable the spherical aberrations to be properly controlled.

Telescopes consisting of five separated lenses are largely used as gun-sights. In this case one of the real images lies in a plane in which cross lines are placed, either fine metal wires or lines etched on a flat glass surface. Provision is made for the illumination of the lines for night use, the light falling on the wires from the eyepiece side, or in the case of etched lines, entering the glass plate through a polished edge.

§ (5) Prismatic Telescopes and Binoculars.—The three-lens inverting telescope is usually converted into an erecting telescope by the insertion of erecting prisms. Many different forms have been employed, in some of which the prisms lie between the lenses, while in others they precede them. In a few military instruments the prisms are also utilised to change the direction of sight, as in gun-sights to be used against aircraft. In the most usual form (*Fig.* 3) two isosceles right-angled prisms are used, with their principal planes at right angles, the light entering and leaving each prism by the hypotenuse and being reflected at each of the equal faces. The effect of each prism is to reverse the direction in which the light travels and to invert the image in the principal plane of the prism, but not in the perpendicular plane. The two prisms together thus produce the inversion required while the light emerges travelling in its original direction, though the emergent axis is of course displaced relatively to the incident axis. Advantage is taken of this displacement in binocular telescopes to secure as large a separation as possible between the centres of the objectives while obtaining the eyepiece separation necessary for comfortable use with both eyes. The effect is to increase greatly the stereoscopic power of the instrument, that is, the extent to which the varying distances of objects from the observer is made evident by the slight eye adjustments necessary to bring their images on corresponding retinal areas. It is easily seen that, referred to the unaided eye as a standard in which this power is represented by unity, the stereoscopic power is equal to

$$\frac{\text{Magnifying power of telescope} \times \text{Separation of objective centres}}{\text{Separation of eyepiece centres}}.$$

The action of the prism is very easily determined geometrically in simple cases, and in complex examples a polar diagram enables the effects of any number of reflections to be traced without difficulty.

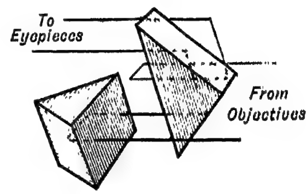

Fig. 3.

When there are two plane reflecting surfaces inclined to one another at an angle α, as in *Fig.* 4, the figure illustrates that any ray incident in a principal plane is deviated through an angle 2α. When the ray does not lie in a principal plane of the figure its projection on the principal plane follows the above law, and its component parallel to the reflecting planes is unaffected. If, then, α is a right angle and the paths considered are portions of a ray inside a prism, the angles made with the third face by the ray before and after the double reflection are equal, and the incident and emergent angles in air are also equal. The essential condition is therefore that the large angle of the prism should be a right angle, the equality of the other angles being unimportant. The fact that in considering changes of direction only the projection in a principal plane need be considered enables a simple geometrical con-

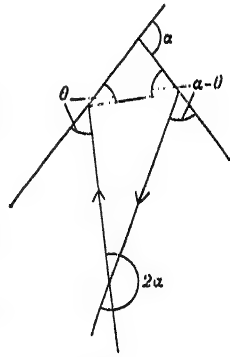

Fig. 4.

struction to be used, in which the path of a ray is represented by a straight line. Let ABC (*Fig.* 5) represent a principal section of a prism, and PQ a portion of the path of a ray within the prism which meets the sides in the order AC, AB, BC, AC. Let ABC′ be a triangle on AB, such that AB divides AC′BCA

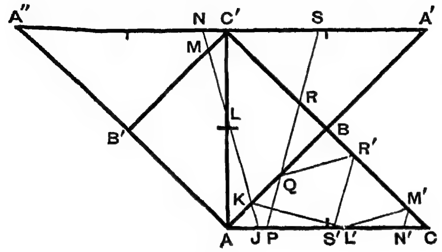

FIG. 5.

into two symmetrical triangles with AC′=AC, BC′=BC. Similarly on BC′ let A′BC′ be constructed symmetrically with ABC′. It is then easy to see that the actual ray path PQR′S′ corresponds to the extended straight line PQRS. The prism will produce no dispersion if C′A′ is parallel to AC, that is, if $2A+2C=\pi$, or if B is a right angle, and the prism is exactly equivalent to a plane parallel block of glass whose thickness is equal to the hypotenuse AC of the prism.

The prism is mounted in such a way that incident rays can only enter the face AC in the half nearer to A, and only rays which emerge in the half nearer C can proceed further through the instrument. Evidently, in addition to such a ray as PQRS, it is possible for a ray like JKLMN, which meets the sides in the order AC, AB, AC, BC, AC, to emerge, and the final direction may be parallel to that of R′S′, though the incident rays made angles of opposite signs with the normal to AC. Such rays evidently cause a laterally inverted image [1] to be superposed upon that previously considered, and steps must be taken to prevent this. If the angle made by the ray with the normal to AC is not small, the ray will meet AB and B′C′ at small inclinations, and the light which eventually reaches A″C′ will be too faint to be troublesome. The rays which make a small angle with the normal may be stopped by cutting a slit symmetrically across AC parallel to the line of intersection of AB and BC. From the images of this slit in the diagram it is evident that this simple device is adequate to prevent this "ghost" image, and that its only direct effect is to necessitate a somewhat larger prism to transmit the useful light than would otherwise be the case.

[1] It may be noted that the character of the image in this respect depends upon the number of reflections being even or odd.

The size of the prism is evidently important. The larger the prism the longer the ray path in the prism, so that variation in the size involves variation in the image position, and for a manufactured instrument the variation in size must be confined within narrow limits. The shaping of the base to fit in its seating is quite a distinct question. There will, in practice, be a limit to the permissible difference in the base angles, as a large inequality would involve a loss of light owing to the vertex of the prism, which is truncated, intruding into the region in which rays travel. These considerations, together with the fact that variations from a right angle in the vertical angle are only important on account of the prismatic effect of an error, lead to the conclusion that very great accuracy in the angles is not essential. Errors of the order of a minute of angle will be permissible: [2] this value may be contrasted with an accuracy of about a second necessary in a right angle when light may be incident first on either of the planes forming the angle.

If one of the prisms of a pair, situated in the way necessary to convert an inverting into an erecting telescope, is rotated so that its principal plane is brought into parallelism with that of the other prism, there is in one direction no inversion at all, and that in the other direction is a reinversion of the first inversion; in other words, no inversion has been effected. It may be inferred that the image rotates through twice the angle described by the prism. If, then, the principal planes of the two prisms are not at right angles to one another, the image of a vertical object will be inclined to the vertical. It is therefore necessary for the ridge of each prism to be very closely perpendicular to the longer axis of the base. The same principle shows that pyramidal error in one prism produces the same effect as an error in the right angle of the other prism. Advantage is sometimes taken of this effect to combine together a pair of prisms which tend to compensate one another's defects when these are too great to allow of the use of one of them with a normal prism.

It has already been seen that the prisms must be mounted in a way which prevents an alteration in the direction of their principal planes. When the prisms are placed between the objective and eyepiece it is equally important to prevent a translation of a prism in the direction of its length. The figure (*Fig.* 6) shows that the effect of such a movement is to displace the emergent rays through twice the distance through which the prism is moved. As a consequence of such a

[2] Tolerances of three minutes for the right angle, five minutes for the 45° angles, and three minutes for the pyramidal error have been proposed for service instruments. See *Report of the Committee on the Standardisation of Optical Instruments*, H.M.S.O.

displacement, rays from a point on the axis of the objective, which should emerge parallel to the axis, will form an image off the axis of the eyepiece, and the emergent rays will be

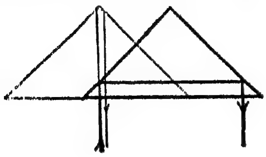

FIG. 6.

deviated. Thus rays through the two telescopes of a binocular, which should emerge in parallel directions, will be inclined to one another, and unless this inclination is small the instrument cannot be used, particularly for continuous observation, without causing discomfort to the observer. One of the most important details in a prismatic binocular is thus the means taken to ensure that the prisms are held immovable in their seatings. The method must not involve local strain in the prism, as this is liable to cause fracture, in addition to deterioration in the image. To secure correct adjustment within suitable limits the objective is usually mounted in a cell carried by two eccentric rings, which can be locked in any required azimuths. This device is illustrated in *Fig.* 7, where the small circle represents the area to any point of which the centre of the objective can be brought, as is desired.

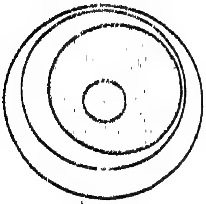

FIG. 7.

The error resulting from inaccurate adjustment of the instrument is of the same kind as would be produced by the use of a direct vision binocular in which the axes of the two telescopes were inclined to one another. It has thus been common to describe the error as "inclination of the axes," though this explanation is not strictly correct. The tolerable limits of error naturally refer to the inclinations of the two emergent beams, and are independent of the magnifying power. As would be expected, a much greater error can be allowed when the beams diverge on leaving the instrument, so that the eyes are required to converge, than when the beams converge, or have a relative inclination in the vertical plane. If the permissible errors of the emerging beam are translated into inclination of the axes, the amount of error allowable depends upon the power, but below a power of 8 it is customary to have fixed limits of error for the axes, as the attainment of the more stringent standard for low powers offers no difficulty. These axis errors may reach three minutes in the vertical plane and six minutes in the horizontal without causing discomfort to the observer.

Prismatic binoculars are generally mounted so that the two telescopes may rotate about an intermediate hinge, thus permitting the separation of the eyepieces to be varied from about 55 to 70 mm. If the optical axes of the telescopes are not parallel to the axis of the hinge, the inclination of the telescope axes will vary with the interocular distance. In testing binoculars it is accordingly customary to measure the errors of want of parallelism for three distinct interocular values.

A further adjustment of importance in any instrument in which the two eyes are used simultaneously is a means of focussing each telescope independently. The most satisfactory method is the direct one of mounting each eyepiece in a cell which may be moved in or out by a screw of very coarse pitch.

This very brief description of the principal adjustments which are necessary in a prismatic binocular suffices to indicate the complexity of the instrument in assembling its

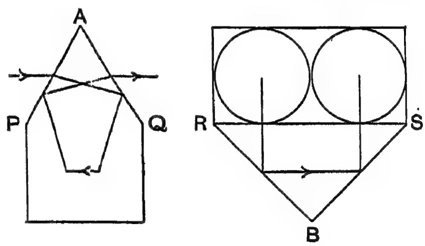

FIG. 8.

parts. In many designs attempts are made to avoid this by the use of external prisms. Other forms are illustrated in the article on German telescopes.[1] Another design is shown in the accompanying figure (*Fig.* 8), taken from a paper by H. Dennis Taylor.[2] The lower portion of the prism is of the "roof" type. The chief advantages of this prism are its compactness and the need for a single prism only. From the figures of its development (*Fig.* 9) it is readily seen that the roof angle B must be very closely a right angle, since parallel rays of the same beam must continue parallel whether their final positions are determined by developing the prism about RB and S′B or about SB and R′B. The development in the perpendicular plane shows that the bisector of the angle A must be perpendicular to the roof ridge.

[1] See "Telescopes of German Design."
[2] *Transactions of the Optical Society*, xxii. 63.

If, as in the illustration (*Fig.* 8), the prism is so enlarged to give increased stereoscopic power that the projections of the entrance and exit pupils do not overlap, the roof prism is used as an ordinary right-angled prism, and the accuracy necessary is not greater than in the

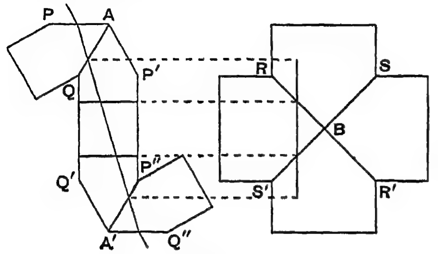

FIG. 9.

right angles of the prisms of the ordinary type of binocular.

§ (6) ANASTIGMATIC TELESCOPES.—In the paper just mentioned, Taylor describes a telescope in which the curvature and astigmatism of the image are corrected simultaneously. This implies the satisfaction of the Petzval condition, and therefore the presence of negative lenses in the instrument other than those used to remove chromatic aberration. The accompanying figure (*Fig.* 10) shows a section of the instrument taken from the paper. The objective is of approximately normal type. In front of the real image is placed a very powerful system of negative lenses N of fluor crown glass, achromatised with an extra dense flint. This lens is essential for the attainment of the desired correction, and forms an image of distant objects approximately in the plane of the field stop *dd*. The use of the negative lens in this position causes a large real image to be formed, corresponding to a focal length appreciably greater than the distance of the objective O from *dd*. The field lens F is necessarily a powerful lens to deviate to the eye lenses E_1 and E_2 the diverging beams which form the real image. F is made of dense barium crown glass to secure a high refractive index with a low dispersion. E_1 and E_2 are placed close together, separate lenses being necessary to attain the desired aperture ratio. The positive components are of light baryta flint glass and the negatives of extra dense flint. The corrections obtained resemble those of the most perfect photographic lenses, and the apparent field reaches 56 degrees. The telescope illustrated is of magnifying power 10, but systems of lower powers have been constructed. Two such telescopes may be mounted as a binocular by the addition of two of the prisms illustrated in *Fig.* 8, in front of the two objectives.

The chief difficulty in the construction of telescopes having their fields corrected in this way lies in the limited range of glasses, which necessitates the use of decidedly large curvatures in the component lenses, unless the number of lenses is much larger than is usual in normal designs. In theory there is no difficulty, as may be shown by considering a particular type of construction. As is well known, achromatic lenses can be made to yield images corrected for spherical aberration and coma for an object occupying a definite position. If in a train of lenses corrected in this manner the image formed by each lens occupies for the next succeeding glass the position of the object for which the latter is corrected, it is evident that the image produced by the entire instrument will be free from spherical aberration and coma. Under these conditions the curvature of the primary and secondary images produced by each individual lens will be less than that of the corresponding objects by the amounts $\kappa(3+\varpi)$ and $\kappa(1+\varpi)$ respectively, where κ is the paraxial power of the component and ϖ is its Petzval coefficient. It follows that the conditions for the simultaneous removal of curvature and astigmatism are

$$\Sigma\kappa=0 \text{ and } \Sigma\kappa\varpi=0,$$

the sums being extended to include every component lens. In practice these conditions

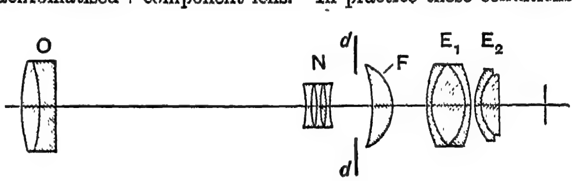

FIG. 10.

will need slight modification owing to the presence of higher order aberrations which must be partially compensated by those of lower order. The important feature of this particular solution is that the position in which the negative lenses occur in the system is immaterial, so it is at once evident that a solution is possible in which they are placed near the real image, the one position in which the divergence they tend to produce will not be an insuperable obstacle in the way of controlling the positions of the rays on emergence.

§ (7) NUMERICAL RESULTS.—The following table gives the leading dimensions and properties of some of the best-known patterns of telescopes and binoculars.

Type.	Magnifying Power.	Diameter of Objective in mm.	Diameter of Emergent Pencil in mm.	Angular Field Degrees.	Apparent Angular Field Degrees.	Length in cm.
Galilean binocular .	4	50	12	4	16	10
Prismatic binocular .	6	30	5	8	50	10

Variable power gun-sighting telescope .	5 to 21	50	10 to 2·5	8 to 2	40	75

T. S.

TELESCOPES OF GERMAN DESIGN

THE general features of the optical systems employed in German telescopes are very similar to those which are to be found in British instruments.[1] The German designer, however, seems to make more use of specially designed prism systems to replace separated lenses for erecting the field of view. This characteristic, which leads to greater compactness, may be illustrated by a brief description of two German telescopic systems which the writer had occasion to dissect during the war.[2] The two instruments in question are naval gun-sighting telescopes, manufactured by Carl Zeiss, Jena.

§ (1) PERISCOPIC SIGHT.—A vertical section of the optical system is shown in *Fig.* 1. The special feature of the system is the prism D, which is also shown in perspective in *Fig.* 1A. It is of the "roof" prism type, and is designed to displace the optical axis of the instrument parallel to itself through a distance of 5·5 cm. and to reverse the field. The light enters at the face *a* (*Fig.* 1A), and is totally reflected internally at *b* and then at *c*. The light from one half of the field is next reflected from the face *d* to the face *e*, that from the other half of the field being reflected from *e* to *d*. The light then passes out of the prism at the face *c*. The path of the central ray is indicated in *Fig.* 1A by means of arrow-heads. In order to prevent overlapping or separation of the two halves of the field the angle between the faces *d* and *e*, which form the "roof" portion of the prism, must not differ from 90° by more than a few seconds.

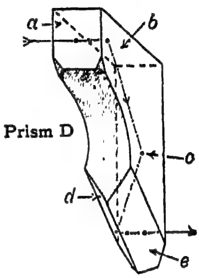

FIG. 1A.

The angles between the other faces of the prism are approximately as follow:

Angle between *a* and *b*, 60°
" " *b* and *c*, 120°
" " *c* and *d*, 52° 45′
" " *d* and *e*, 52° 45′

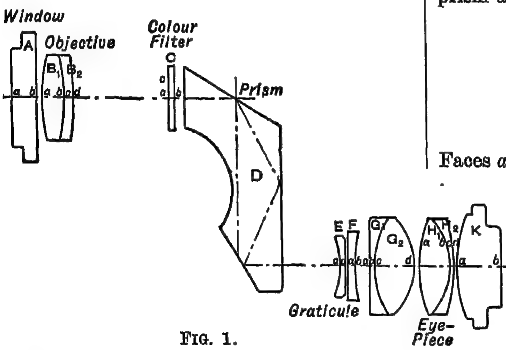

FIG. 1.

Faces *a* and *c* are parallel. This type of prism is also employed in many British instruments, particularly in dial sights, but the Germans seem to use it much more frequently.

§ (2) RIGHT ANGLE SIGHT.—A vertical section of the optical system is given in *Fig.* 2. The instrument is designed to deflect the light through a right angle, and is evidently intended for use in a position where the optical axis of the eyepiece makes an angle of 45° with the vertical, the eyepiece being directed upwards. The prism D′ in this instrument is of rather an unusual type. It is shown in perspective in *Fig.* 2A. The light enters at the face *a*′, is reflected internally at *b*′, and then at *c*′, and passes out of the prism at the face *d*′. The path of the central ray is indicated by means of arrowheads.

[1] See article on "Telescopes."
[2] For a complete description of the instruments see J. S. Anderson and A. B. Dale, *Opt. Soc. Trans.*, 1919, xx. 315.

The angles between the faces of the prism are approximately as follow :

Angle between a' and b', 45°
" " b' and c', 75°
" " a' and c', 90°
" " c' and d', 67° 30′
" " a' and d', 90°

These instruments also serve to illustrate a rather novel method of illuminating the cross-lines for night work. The cross-lines are engraved on the flat surface a of the graticule lens (F in *Fig.* 1 and F′ in *Fig.* 2), the edge of which is polished. On the outside of this lens there is mounted a cell, in a groove of which are two small glass tubes of circular cross-section and bent round in the form of rings. These tubes are filled with a fine powder which consists of a luminous compound having approximately the same luminosity as that given by the British ·2 mg. radium bromide per gr. compound. The light from this compound serves to illuminate the cross-lines when the instruments are being used in the dark. If the light should prove to have a disturbing effect in finding an object at night the illumination can be screened off by moving the cell, which contains the tubes, a short distance along the axis. This is accomplished by means of a worm-gear arrangement.

Tetra-iodo Fluorescein : a reagent for testing optical glass. See "Glass, Chemical Decomposition of," § (3) (i.).

THEODOLITE, THE

§ (1) The theodolite is not only the most important of surveying instruments, but one of the oldest. Leonard Digges in 1571 [1] describes a "Theodelitus" consisting of a graduated horizontal circle, with an "Alidade" or sight pivoted on a vertical axis through the

[1] Leonard Digges, *A Geometrical Practical Treatise, etc.*, 1571.

centre of the circle. The theodolite was therefore primarily an instrument for measuring horizontal angles, *i.e.* the angles between planes containing the vertical axis of the instrument and the various objects observed

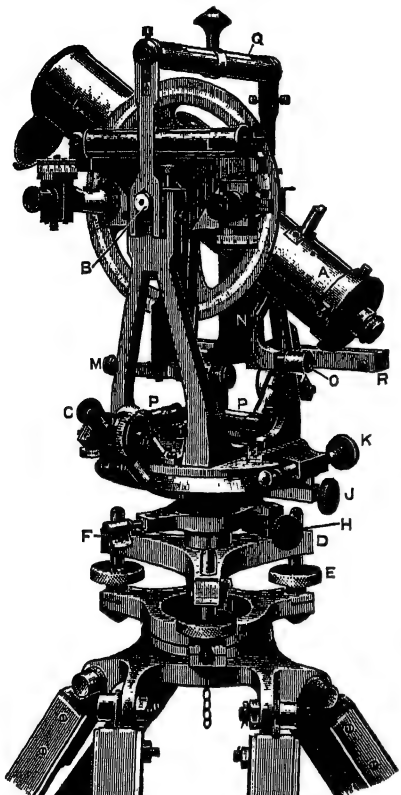

FIG. 1.

to. Digges also shows how a "quadrant" can be added so as to observe angles of elevation or depression at the same time as the horizontal angles. The theodolite as now made is generally provided with a vertical arc, and most modern instruments are made so that the sighting telescope will "transit" on its horizontal axis, *i.e.* so that it can be reversed end for end without removing it from its bearings; in this case the vertical arc (if provided) is generally a complete circle. Such instruments are known as "transit theodolites," or shortly (especially in the U.S.A.) as "transits." The instrument was first developed as an accurate portable instrument by English makers in the latter part of the eighteenth century. The 3 ft. theodolite by Ramsden made in 1787 for the Royal Society was the first which was sufficiently accurate to detect the spherical excess of terrestrial triangles. For the history of the theodolite, see Laussedat.[1]

Instruments are now made with circles ranging from 3 in. in diameter (for explorers) to 12 in. (for geodetic work).

§ (2) DESCRIPTION. — *Fig.* 1 illustrates a 6-in. micrometer transit theodolite by Troughton & Simms, and *Fig.* 2 a 5-in. example by E. R. Watts & Sons. In both cases the circles are read by micrometer microscopes to 10 seconds, and to single seconds by estimation.

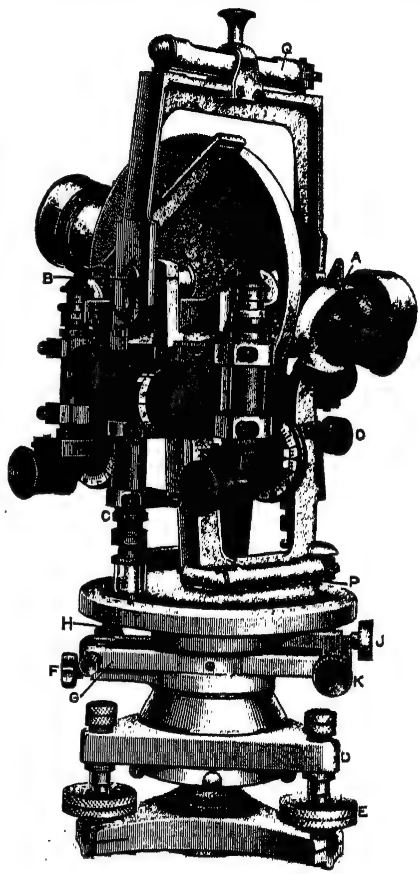

FIG. 2.

The telescope A is an ordinary astronomical telescope provided with cross hairs, and mounted on a horizontal axis B. When the instrument is in perfect adjustment, the collimation line of the telescope intersects the horizontal axis at right angles. The diaphragm can be adjusted by the screws

[1] A. Laussedat, *Recherches sur les instruments, les méthodes, et le dessin topographiques*, 1898.

shown in *Fig.* 1 (in *Fig.* 2 they are concealed by a screw-on cap). The axis B is carried by arms attached to the upper plate of the instrument. The upper plate is shaped to protect the divided circle, and carries the microscopes for reading the circle. The whole instrument is supported on a trybrach D, with three levelling screws E. The upper plate and the lower plate (carrying the divided circle) are capable of rotation independently on concentric vertical axes. A clamping screw F clamps the lower plate to the trybrach in such a manner that a small relative motion can be given by the slow motion tangent screw H. Similarly clamping screw J and tangent screw K connect the upper and lower plates. The vertical axes should intersect the horizontal axis at right angles, and at the same point in which the collimation line intersects it. An adjustment is provided for raising or lowering one end of axis B so as to make it perpendicular to the vertical axis. The vertical circle is rigidly attached to the telescope. In *Fig.* 1 the microscopes for the vertical circle are attached to an arm which also carries the sensitive spirit level L, and which is mounted rotatably on the horizontal axis, and prevented from turning with the telescope by the clip screws M. In this instrument the vertical circle with its microscopes and level is lifted out of its bearings for packing in its transport case; the vertical circle is unprotected. In the instrument shown in *Fig.* 2, the axis B revolves in segmental bearings, and is not intended to be removed from them, the microscopes and bubble L are fixed to the arms supporting the axis B, the bubble is viewed by means of a mirror, and the vertical circle is completely enclosed. When the vertical circle is read by verniers, these are always carried on an arm, as are the microscopes in *Fig.* 1. A clamping screw (not visible in either photograph, but visible in *Fig.* 3) clamps the telescope axis to the arm N, while a tangent screw O provides a slow motion. When in proper adjustment, the microscopes should read zero when the bubble L is levelled and the telescope is horizontal. One or two levels P on the upper plate provide for levelling the vertical axis. A striding level Q rests on the ends of axis B to ensure its being horizontal; this lifts off for packing, or when not required.

A diagonal eyepiece is provided for taking sights at high angles of elevation. Some instruments have a circular compass on the upper plate, while others have a trough compass that can be attached to one of the arms (R, *Fig.* 1). In some cases the main spirit level is attached to the telescope instead of to the microscope arm; this is more convenient if the instrument is to be used as a level, but less so for reading accurate vertical angles.

§ (3) Details of Construction.—These vary considerably in different instruments. *Fig.* 3 shows details of an instrument similar to *Fig.* 1. The upper plate is fixed to a coned spindle S, which revolves in the hollow spindle T carrying the circle, which again revolves in a bearing fixed in D. A nut fixed to the bottom of S prevents the withdrawal of the spindles. In small instruments the weight is sometimes taken by the coned bearings, but in larger instruments only sufficient weight should be so taken to prevent shake. *Fig.* 4 shows one method of arranging this. In order to prevent shake and take up wear in the levelling screws E, the ends of the trybrach arms are often split vertically and the sides pulled together against the screw E by the screw U (*Fig.* 3). In older instruments the thread of screws E was generally left exposed, and the wear due to dust was often considerable; in *Figs.* 1 and 3 they are shown covered in. *Fig.* 5 shows another method of arranging this; a nut V is screwed and fixed into D, and the footscrew works inside V. The upper portion of V is split, and its outer surface is coned; a dust cap W is coned inside, so that when screwed down it grips the top of V and presses it on to E.

Fig. 6 shows the construction of the lower part of *Fig.* 2. In this case, S is a hollow cylinder of hardened steel, which revolves in a fixed bearing Y, while the circle is carried by a hollow bearing T, which revolves round S. The whole weight is taken by two ball-bearings. This makes a very easy movement, and wear of the main axes is practically eliminated; a further advantage of this construction is that there is no difficulty in making the two vertical axes coincident. The hollow spindle enables the telescope to be used for centring the instrument over the station mark. A nut X prevents the spindle from being withdrawn. The whole support Y of the upper portion of the instrument has a small horizontal movement with respect to D for fine adjustment of the centring, being clamped by the screw Z; *Fig.* 3 shows a similar movement below the levelling screws.

In large instruments the double-coned bearing is not used; the lower plate is fixed direct to the base of the instrument, and, though capable of rotation, it is not provided with any slow motion.

The construction is simplified and cheapened if verniers are substituted for microscopes, but at the expense of the accuracy of reading the angles, and verniers may often be used with advantage on the vertical circles. Great accuracy of reading vertical angles is seldom required, except for certain astronomical observations, and if the theodolite is fitted with arrangements for using Talcott's method, all necessary astronomical observations for

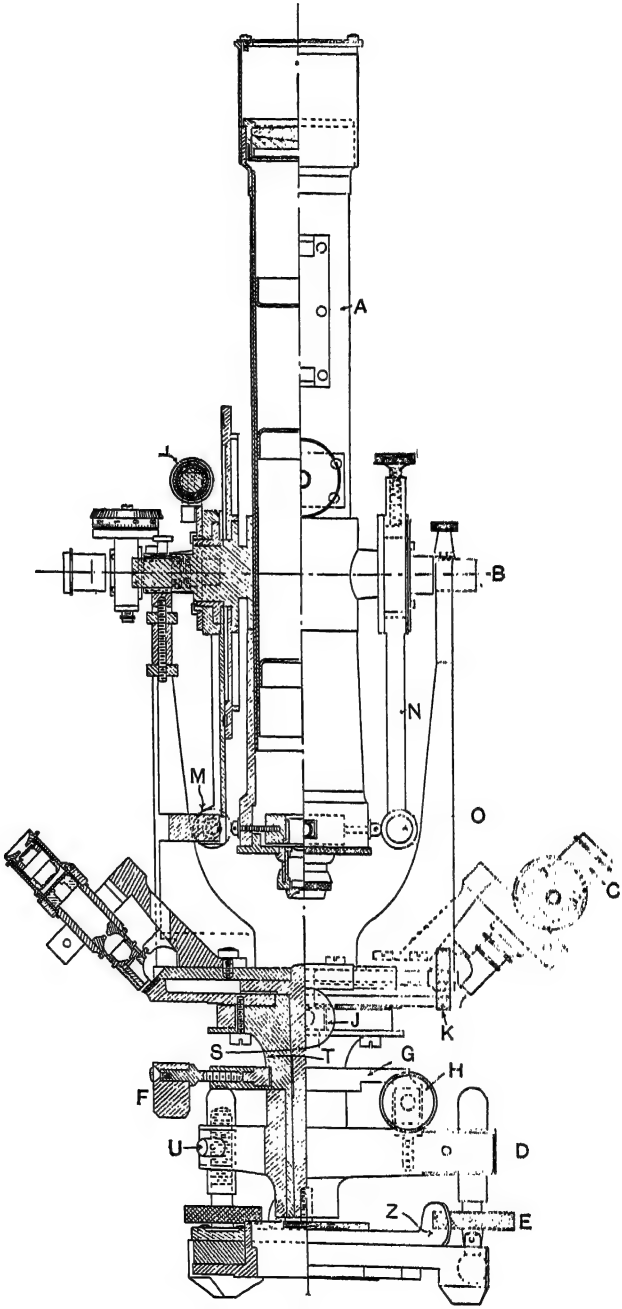

Fig. 3.

survey work can be carried out without any accurate readings on the vertical circle. See "Surveying," § (27).

§ (4) METHOD OF TAKING OBSERVATIONS.—The instrument must be set up and carefully centred over the station mark by means of a

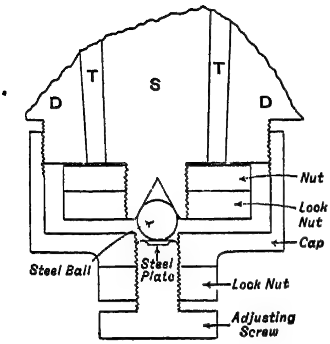

FIG. 4.

plumb-bob, or by a nadiral telescope, and the vertical axis brought truly vertical; for accurate work the most sensitive bubble available should be used for the final levelling. The eyepiece is focussed on the cross hairs and then the telescope focussed on the distant object. It should be noted that the eyepiece focussing depends on the sight of the observer and the telescope focussing on the distance of the object; the image formed by the object glass must be in the plane of the cross hairs, or the cross hairs will appear to move relative to the distant object if the observer's eye moves.

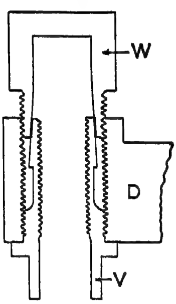

FIG. 5.

(i.) *Observing Horizontal Angles.*—The usual method is known as the direction method. The lower plate is clamped, and the telescope is turned on the first object, the object being intersected by the vertical cross hair by means of the slow motion screw. The horizontal circle is then read. The upper plate is then unclamped and the telescope swung to the right till the next object appears in the field of view, the plate is clamped and the final intersection carried out by the slow motion screw, and the circle again read. All stations are intersected in the same manner, swinging to the right, and closing on the original mark as a check. The telescope is then transited and a similar round taken swinging left. Observations taken with the vertical circle on the left and right of the telescope are known as "face left" and "face right" respectively. In all accurate work an equal number of rounds should be taken "swing right" and "swing left" and an equal number "face right" and "face left." By taking sets of rounds on different zeros, *i.e.* with different readings on the circle for the pointing on the first mark, the errors of graduation are averaged. In geodetic work at least 6 zeros are used, with two "faces" on each zero and two "swings" on each face. In tertiary work 2 zeros, 2 faces, and 1 swing on each face may suffice. The number of rounds taken depends on the accuracy required, and the accuracy attained should be judged by the closing errors of the

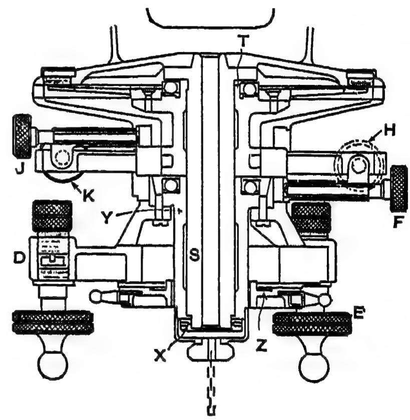

FIG. 6.

triangles rather than by the agreement of the individual measurements of the angles.

A method sometimes used is the "repetition" method, when each angle is measured separately. The one object is intersected as before and the circle read, the upper plate is then unclamped, the telescope turned on the second object, which is then intersected; leaving the upper plate clamped the lower is unclamped and the telescope turned on the first object, which is then intersected with the lower tangent screw; the whole process is repeated several times; the final angle read, divided by the number of repetitions, gives the actual angle. A similar set should then be taken on the other face. This method reduces the error due to reading the circle, and is sometimes of use, but with modern instruments the errors due to the circle readings are likely to be less than the errors due to movement of the clamps, and the method is seldom used. It is never used for geodetic work, and large theodolites are seldom provided with the necessary slow motion on the lower plate.

Some large instruments are provided with a "watch" telescope attached to the lower plate. A reference object is intersected by this and observed at intervals, with the result that any movement of the lower plate, or twist of the stand, can be observed and allowed for.

Horizontal angles are best observed with the horizontal axis unclamped.

(ii.) *Observing Vertical Angles.*—Vertical angles are best observed with the upper plate unclamped. The instrument must be very carefully levelled. The position of the bubble on the microscope arm should be noted at the time of observation, and a correction made if it is not in the centre of its run. A second reading should be made on the opposite face; this is even more important in the case of vertical angles than in the case of horizontal angles, and a reading on a single face is of little value owing to collimation errors.

§ (5) Errors and Adjustments. (i.) *Eccentricity of Circle.*—It is easily shown that if there are two or more verniers (or microscopes) evenly spaced round the circle the error due to any eccentricity of the circle with respect to its axis cancels out if the mean reading of the verniers is taken, and that the same applies for all practical purposes if the verniers are not quite exactly spaced. A small adjustment can be made if necessary in the spacing of microscopes by moving the drum and the comb, but the spacing of the verniers and the eccentricity of the circle are matters for the makers.

(ii.) *Horizontal Circle not in Plane Perpendicular to the Axis.*—The maximum error introduced is about $\frac{1}{4}a^2$, where a is the (small) angle of tilt; this error is negligible, as if a were large enough to produce any appreciable error the verniers or microscopes would be noticeably untrue on the circle.

(iii.) *Vertical Axis Vertical, but Horizontal Axis not Horizontal.*—If the horizontal axis make an angle ν with the horizontal the error introduced is $\nu \tan h$, where h is the angle of elevation of the angle observed. This error is especially important when horizontal angles are measured to points at a considerable elevation, as in astronomical observations for azimuth. The error will cancel out in the mean if observations are made on both faces, or the striding level can be used and a correction made for any dislevelment found at the moment of observation.

(iv.) *Vertical Axis not Vertical, but Horizontal Axis Perpendicular to Vertical Axis.*—The error depends on the angle a between the direction observed and the plane in which the axis is tilted, the angle of tilt β, and the elevation of the object observed h, and amounts to $\beta \sin a \tan h$. As $\beta \sin a$ will represent the actual tilt of the horizontal axis its amount can be ascertained by the striding level and a correction made if necessary.

It will be noticed that this error due to dislevelment cannot be eliminated by any method of observation, but that they only become of importance when points are being observed to at a considerable angle of elevation.

(v.) *Collimation Line not Perpendicular to the Horizontal Axis.*—In this case the line of sight traces out a small circle parallel to the great circle through the zenith. If u is the angle the collimation line makes with the perpendicular to the horizontal axis, and h the angle of elevation, then the error is $u \sec h$. If a second observation be taken after changing face the error will remain the same in magnitude but will be of opposite sign, hence the mean of the two observations will be free from this error. The collimation error can be ascertained in several ways; the two commonest are: (*a*) Intersect a distant object, nearly at the same level as the instrument, leave the horizontal circle clamped, lift the telescope out of its pivots and replace after turning through 180° about its length; if the object be still intersected the instrument is correctly collimated in azimuth, but if not the actual error is half the apparent error, and can be corrected by moving the cross hairs. This method is only possible when the telescope can be lifted out and reversed. (*b*) Intersect an object as before, transit the telescope, and revolve the upper plate till the object is again intersected. If the difference of the two readings on the horizontal circle is exactly 180° the instrument is in collimation, if not half the difference is the collimation error.

(vi.) *Collimation Line Perpendicular to the Horizontal Axis, but Distant d from the Vertical Axis.*—In this case the error is ϵ, where $\sin \epsilon = d/l$, l being the distance of the object from the instrument. This error also cancels out in the mean of two observations on different faces, and in any case can only be appreciable on short sights.

(vii.) *Vertical Cross Hair not Vertical.*—This is tested by intersecting an object, and moving the telescope in altitude, when the object should remain intersected over the whole length of the hair. If it does not, the diaphragm must be rotated till it does. Any residual error can be avoided by always intersecting on the same portion of the cross hair.

The above refer to horizontal angles, but errors (i.), (ii.), (vi.), and (vii.) apply *mutatis mutandis* to vertical angles, and are eliminated in the same way.

(viii.) *Vertical Collimation.*—All vertical angles are read with reference to a spirit-level, and when the instrument is in adjustment

and with the vernier (or micrometer) arm bubble in the centre of its run, and the verniers reading zero, the collimation line should be horizontal. This is tested by reading the elevation of any distant object on both faces, making any necessary correction for any movement of the bubble between the two observations. The elevations read should be the same; if not, the true elevation is the mean of the two readings, and the error is half the difference. The error can be removed by adjusting the bubble, by adjusting the verniers (or microscopes), or by altering the cross hairs. The last method is not good, as the cross hairs should be on the axis of the object glass; the choice between the other two methods depends on the construction of the instrument. In instruments such as those illustrated in *Figs.* 1 and 3, where the bubble is attached to the arm carrying the verniers, the true elevation of a point is found by readings on two faces. The verniers are then set to the correct reading by means of the clip screws; and, lastly, the bubble is brought back to the centre of its run by means of its adjusting screws. In instruments such as that illustrated in *Fig.* 2, where the bubble is attached to the upper plate, it must be set with reference to the vertical axis, and in this case the micrometers must be made to read correct by altering the drum, and (if necessary) the comb, or even by moving the whole microscope.

All the errors considered above, except the levelling errors, can be eliminated by suitable means of observation, but it is still desirable that the errors themselves should be small. It is sometimes only possible to observe on one face, and it is sometimes desired to pick up an indistinct object, or faint star, by setting the known angles on the circles. There remain four important errors:

(ix.) *Errors of Intersection.*—These depend on the skill of the observer, the power and optical qualities of the telescope, the character and illumination of the object intersected, the suitability of the graticule, and the steadiness and clearness of the atmosphere. In any given circumstances the error can only be reduced by taking the mean of a number of observations. It is sometimes advantageous to use a micrometer eyepiece, and obtain extra intersections by its means.

(x.) *Errors of Graduation.*—These depend on the maker of the instrument, and the best modern instruments should have no error greater than a few seconds, and in the larger instruments the maximum error should not exceed two or three seconds. The resulting errors can be reduced by taking a number of readings on different portions of the circle, *i.e.* by taking rounds of angles on different zeros.

(xi.) *Errors of Reading the Circles.*—This depends on the method of reading adopted (see article "Divided Circles"), the micrometer microscope being the most accurate. In the case of micrometer microscopes the error depends very largely on the illumination of the circle. The error can be reduced by taking a number of readings.

(xii.) *Atmospheric Refraction.*—Horizontal refraction [1] is seldom appreciable, unless the conditions are obviously unsuited for observations, or unless the line of sight grazes a building or the side of a hill; a rather noticeable case is given in the *Professional Papers of the Ordnance Survey*, No. 2, p. 11. Vertical refraction is always important.

TRANSPARENT SUBSTANCES, TESTS FOR HOMOGENEITY OF

IN making use of transparent substances, such as glass, quartz, fluorite, etc., for optical purposes it is essential to know the degree of homogeneity of the pieces of material employed. The main defects met with take the form of bubbles and striae or veins due to the presence of layers having different refractive indices. Bubbles can usually be detected by the naked eye or with the help of a microscope. Want of homogeneity may be revealed by using either of the two following methods.

§ (1) SHADOW METHOD.—This can conveniently be carried out on an ordinary spectroscope. The telescope is moved into the position in which its axis is collinear with that of the collimator. The eyepiece is removed and a fine wire is mounted so as to coincide exactly with the image of the slit. If the slit is illuminated and one's eye is placed behind the wire, the field of view will appear dark. If a parallel-sided block of glass is inserted between the collimator and telescope objectives the presence of striae will be revealed by light streaks. If the specimen is in the form of a prism the telescope must be moved round until the refracted image of the slit coincides with the wire; in this case monochromatic light should be used. If the specimen has an irregular shape or has no polished surfaces it may be immersed in a liquid of the same refractive index (for a given wave-length) and examined as in the case of a parallel-sided block. A lens may be tested without using a spectroscope: an illuminated pin-hole is set up at some distance from the lens, and if one's eye is placed at the conjugate point, any striae that may be present will appear as more or less dark streaks on a bright background. The visibility of the striae is usually improved by obscuring the image of the pin-hole either partially or almost entirely with a diaphragm; in the latter case the striae will appear bright on a dark background.

§ (2) INTERFEROMETER METHOD.—A complete discussion of this method is given in the article on "Interferometers: Technical Applications," § (5).

§ (3) TEST FOR STRAIN IN OPTICAL GLASS.—The presence of strain in optical glass is usually due to imperfect annealing, and it may be detected by means of the double refraction which is caused by the strained condition. If a specimen is placed between crossed Nicol prisms the presence of internal strains will be revealed by the appearance of more or less bright patches in the field. A convenient arrangement for obtaining a large field of view is to allow a beam of light, diverging from an illuminated pin-hole, to pass through the polarising Nicol and fall on a piece of ground glass. The specimen is then examined against the ground glass background [1] by means of the analysing Nicol. In order to increase the sensitivity of the test a wave-plate may be inserted in front of the analyser and orientated so as to give the sensitive first order violet colour between crossed Nicols, when no specimen is present. The presence of double refraction in a specimen will then be revealed by a change of the violet colour to a tint of a lower or higher order.[2]

TUNGSTEN ARC LAMP

THIS lamp, which was developed by Gimingham and Mullard,[1] forms a very convenient source of radiation for many purposes. It consists essentially of an arc between tungsten electrodes, enclosed in a neutral atmosphere of nitrogen or argon, together with an auxiliary gear for striking the arc. Its simplest form is illustrated in *Fig.* 1. The ends of a tungsten filament BB

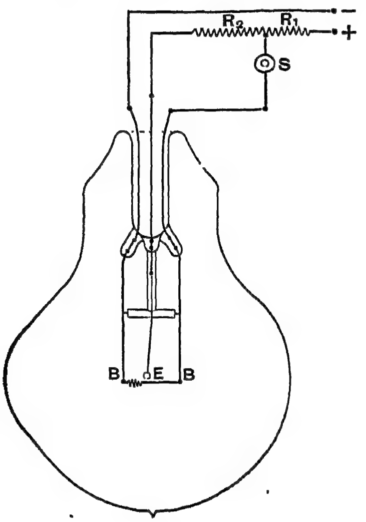

FIG. 1.

are connected through the push switch S and the resistance R_1 to a voltage supply. A bead of tungsten E, supported on a tungsten stalk, is also connected through the additional resistance R_2 to the positive pole of the supply. On pressing the switch S the filament BB is raised to incandescence and ionises the gas. When the switch is released, this enables the arc to strike between E and B. The arc is usually run with E at a temperature of the order of 2600° to 3000° abs., but it may be run up to the melting point of tungsten or, by reducing the pressure of the surrounding gas and increasing the size of the anode, at a dull red heat. In the latest form of lamp, the ioniser BB consists of tungsten wire partly straight and partly wound into a short spiral. On the straight portion is threaded a tube composed of a mixture of tungsten and certain refractory oxides, such as zirconia, yttria, or thoria. The arc first strikes on the uncovered spiral of tungsten wire and, when the electrodes warm up, passes on to the tubular portion which presents a shorter path (see *Fig.* 1). As the tube of refractory material is less liable to disintegration under the action of the arc than the tungsten wire, this device increases considerably the life of the lamp. Lamps of this type are made for candle-powers from 30 to 500 and for voltages of 100 and upwards.

For higher candle-powers a modified form of lamp has been evolved with an additional electrode of tungsten which is in the form of a square plate. The lamp has an ioniser and a bead of tungsten which are arranged exactly as in BB and E of *Fig.* 1. The additional plate of tungsten is fixed close to the bead and is connected to a double change-over switch, one position of which connects the volt supply to the ioniser and bead and the other position to the bead and plate. In the first position the polarity of the bead is positive and in the second negative. The arc is first struck between the ioniser and the bead by means of a press switch as described above, the change-over switch being in the first position. When the bead has become incandescent, the switch is thrown to the second position which enables the arc to strike between the bead and the plate. By the use of substantial electrodes, candle-powers up to 10,000 have been obtained, the size of anode for this value being 1 inch square.

The characteristics of the tungsten arc lamp are illustrated in *Fig.* 2. The normal working efficiency is taken as 0·5 watt per candle-power, and the percentage of normal voltage and candle-power as well as the watts per candle-power are shown for the lamp when run at efficiencies higher and lower than the normal. Curve A is similar to that of

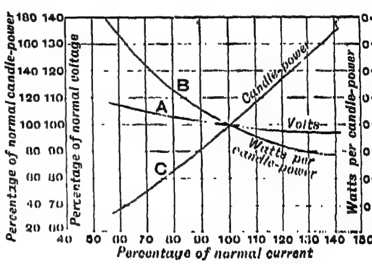

FIG. 2.

the ordinary carbon arc, but exhibits less instability. The volt drop across the arc steadily decreases with increase of current until the sputtering point is reached, when the pressure suddenly falls. The efficiency steadily rises with increasing current, reaching 0·3 watt per candle-power at the sputtering point. It should be mentioned that the figures for efficiency refer only to the energy dissipated in the lamp itself and take no account of that dissipated in the necessary

[1] *Journ. Inst. Elect. Eng.*, 1915, liv. 15.

ballast resistance. The intrinsic brilliancy at the normal working current is stated to be generally about 12,000 candle-power per square inch.

The distribution of the energy radiated from the tungsten arc in the visible spectrum does not differ appreciably from that of the tungsten filament lamp at the same temperature.[1]

The tungsten arc finds a number of useful applications where a source of light is required of small size and high intrinsic brilliancy. F. H. S.

Ulbricht Globe: a form of integrating photometer. See "Photometry and Illumination," § (47).

ULTRAMICROSCOPE, THE, AND ITS APPLICATIONS

§ (1) The Ultramicroscope.—The term "ultramicroscope" is apt to be rather misleading, as it may convey the idea that it is the name of an instrument with which one is able to see greater detail in an object than with an ordinary microscope. This, however, is not the case; the term should really be looked upon as applying to an instrument which reveals the presence of very minute particles of matter. The limit of resolution of a microscope—that is, the smallest distance between two points which can just be seen to be separated—has been theoretically deduced by Helmholtz, Abbe, and others,[1] who have shown that it depends on diffraction phenomena. The value of this smallest distance ϵ is given by

$$\epsilon=\frac{\lambda}{2a},$$

where λ is the wave-length of the light employed and a is the numerical aperture of the microscope. Now there are practical limits to the value of the numerical aperture, the maximum value obtainable with present-day objectives being about 1·53; it is not likely that this will be increased appreciably in the future. The other factor which determines the limit of resolution is the wave-length of the light used. By employing ultra-violet radiations one can reduce the value of ϵ; this has been done with success in processes of microphotography. One can see, however, that there are practical limits to the minuteness of detail that can be revealed by the microscope. On the other hand, there is theoretically no limit to the smallness of objects the presence of which can be revealed. If a sufficiently high intensity of illumination could be obtained, it should be possible to see a molecule, or rather to see the light scattered by a molecule, although it is quite impossible to differentiate molecules unless their separation is at least as great as the limiting value of ϵ. Faraday[2] was the first to look for an effect exerted on light by very fine metal particles suspended in liquid or solid media. Shortly afterwards Tyndall[3] showed how such particles could be seen by causing a beam of light to pass through the solution, the particles scattering the light in all directions. No advance was made in the systematic investigation of very minute particles until Zsigmondy turned his attention to the problem at the beginning of the present century. Together with Siedentopf, he improved the methods of observing such particles; they invented what they termed an "ultramicroscope," with which it is possible to render individual particles visible.[4] All that Faraday had been able to do was to reveal the presence of groups of particles. The important subject of colloidal chemistry, which deals with the study of colloidal particles—that is, very minute material particles in liquid or solid solution—has been developed largely as the result of Zsigmondy's pioneer work.

Since the invention of the ultramicroscope by Zsigmondy and Siedentopf a number of other forms of the instrument have been devised. The underlying principle of all types of ultramicroscope is the utilisation of dark-ground illumination. This method of illumination has long been employed in ordinary microscopy in connection with the study of such objects as diatoms. It consists essentially in illuminating an object in such a way that only the light which is scattered or diffused by the object enters the microscope, no direct light from the beam being allowed to enter the observer's eye. The different types of dark-ground illumination which are used in ultramicroscopy may be classed as follows:

(i.) *Orthogonal Illumination.*—This is the system utilised in the Zsigmondy and Sieden-

topf ultramicroscope, which is sometimes known as the "slit ultramicroscope." The optical system of the instrument is shown diagrammatically in *Fig.* 1. A beam of light from the sun or an arc lamp is focussed by means of an objective O_1 (focal length about 10 mm.) on a fine adjustable horizontal slit S. A reduced image of the slit is formed at F_1 by a second objective O_2 (focal length about 80 mm.). A narrow conical beam of light is formed at F_2 by a microscope objective M_1 acting as a condenser. If now a colloidal solution, such as a solution of colloidal gold particles, or a piece of ruby glass, which contains colloidal gold in suspension, be placed at F_2, the light scattered by the particles can be observed with a microscope M_2, whose optical axis is at right angles to the axis of the illuminating beam. What one observes is not, of course, the individual particles, but the diffraction discs formed by the light scattered from them, the general background being dark. In order to screen off any light that may be reflected from the edges of the slits an iris diaphragm I is placed between S and O_2. If desired, a polariser may be inserted between S and I. When an immersion objective is used in the observing microscope M_2, it is necessary to place a chisel-shaped diaphragm at D so as to cut off one-half of the illuminating beam and thus prevent objectionable reflection from the mount of the front lens, due to the closeness of the objective. In the slit ultramicroscope manufactured by Zeiss the optical parts of the illuminating system, together with the slit and diaphragms, are mounted on stands fitted to an optical bench.

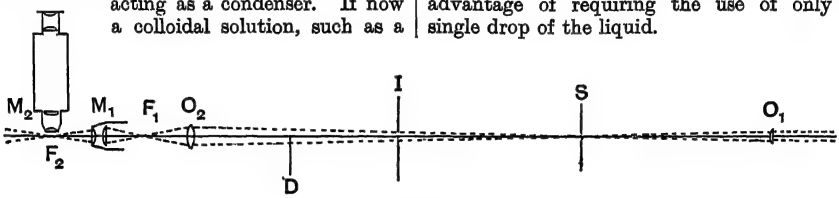

FIG. 1.

An improved form of this type of ultramicroscope was introduced some years ago by Zsigmondy,[1] who suggested as its designation the "immersion ultramicroscope." The salient feature of the new instrument is the employment of an immersion objective at M_1 in the illuminating system as well as in the observing system. In order to make this possible, portions of the front and meniscus lenses and of the mounts of the two immersion objectives are ground away at an angle of 45°, so that the objectives can be brought close enough together. The objectives have a focal length of 6 mm. and numerical aperture 1·05, the front lenses being constructed of fused quartz. The chief advantage of the new design is the greater obtainable intensity of the diffraction images, for the intensity under similar circumstances is proportional to the product of the numerical apertures of the illuminating and observing objectives. For the examination of colloidal solutions the instrument has the further advantage of requiring the use of only a single drop of the liquid.

(ii.) *Oblique Illumination*—(*a*) *Non-axial Beam without Central Stop.*—This method of illumination has been employed in different forms by microscopists for increasing the resolving power of an objective. It was first adapted for ultramicroscopic work by Cotton and Mouton;[2] the arrangement they used is illustrated diagrammatically in *Fig.* 2. A drop of the solution under examination is placed under a cover-glass on a microscope slide S, which is laid on a special block of glass G, optical contact between S and G being obtained by inserting a thin layer of cedar oil. An oblique beam of light is reflected internally from the base of G and then totally reflected at the cover-glass, so that no direct light enters the objective of the observing microscope M. The beam of light is brought to a focus in the drop of the solution by means of a condensing lens L, so that any small particles in the solution which come into the path of the beam are strongly illuminated and in consequence scatter light in all directions. Thus the particles appear as bright specks on a dark background, as in the previous case. A Fresnel rhomb may be used instead of the block G illustrated in the diagram.

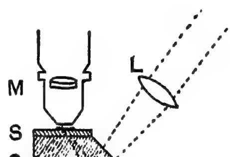

FIG. 2.

(*b*) *Axial Beam with Central Stop in Substage Condenser.*—This is another form of oblique illumination which has the advantage over the method (ii.) (*a*) of being more compact, the illuminating system forming a component part of the observing microscope. The principle of the method is illustrated in *Fig.* 3,

[1] R. Zsigmondy, *Phys. Zeits.*, 1913, xiv. 975.

[2] A. Cotton and H. Mouton, *Les Ultramicroscopes et l'objets ultramicroscopiques; Comptes Rendus*, 1903, cxxxvi. 1657; *Bull. Soc. Fr. Phys.*, 1903, p. 54.

which represents three types of sub-stage condenser specially adapted for dark-ground illumination. *Fig.* 3 (*a*) shows a vertical section of the Wenham paraboloid condenser as applied by Siedentopf.[1] It consists essentially of a truncated paraboloid of glass G, with the top of which a microscope slide S makes optical contact, a drop of the solution to be examined being placed under a cover-glass C. A central stop A below the condenser serves to cut out the central portion of the illuminating beam which is reflected upwards from a plane microscope mirror. The rays which enter the paraboloid are internally reflected at its surface and brought to a focus in the drop of solution, where they are totally reflected at almost grazing incidence. Only the light which is scattered by the particles in the solution can then enter the objective of the observing microscope. The paths of two rays X, Y of the illuminating beam are illustrated in the diagram, the directions being shown by means of arrow-heads.

A similar type of illuminating system is obtained with the cardioid condenser which Siedentopf[2] applied to the so-called "cardioid ultramicroscope." It depends on the principle that the image formation obtained by combining a spherical reflecting surface with a cardioid surface is aplanatic—that is, spherical aberration is eliminated, as is the case with the paraboloid condenser, and in addition the sine condition is fulfilled. Approximate aplanatism is attained if the cardioid surface be replaced by a spherical surface. The cardioid condenser is illustrated diagrammatically in *Fig.* 3 (*b*); it consists essentially of two glass portions G_1, G_2 cemented together, the surface of separation *a* being spherical. The rays of the illuminating beam are reflected outwards at the spherical surface *b*, and then inwards at the spherical surface *c*, coming to a focus at the object as in the previous case. An annular diaphragm is provided at B in addition to the one at A.

The Ignatowski condenser,[3] which resembles the cardioid system, is shown in *Fig.* 3 (*c*). It also consists of two glass portions G_1, G_2 cemented together. In all these forms of condenser the numerical aperture of the illuminating rays is of the order of 1·0 to 1·4.

(*c*) *Axial Illumination with Central Stop behind Objective.*—In this method the direct rays of the illuminating beam are stopped by a central diaphragm at the back of the microscope objective or by a stop formed by grinding flat and blackening a small central portion of the curved surface of the front lens of the objective. The method has the advantage of being free from centering troubles, but it suffers from the fact that the central stop alters the brightness distribution in the diffraction fringes.

§ (2) PHYSICAL APPLICATIONS OF THE ULTRAMICROSCOPE.—Although the chief applications of ultramicroscopy have been in the realms of colloidal chemistry, there are a number of important physical problems which have been developed as the result of ultramicroscopical research. For example, the study of the so-called Brownian movement has confirmed the fundamental hypotheses of the kinetic theory of liquids and gases, and contributed evidence of the existence of the molecule. The term "Brownian movement" derives its name from the work of the botanist Brown, who observed that small particles of solid matter, when suspended in liquid solution, exhibit rapid to-and-fro motions.[4] The complete investigation and explanation of this movement has been almost entirely due to the work that has been made possible by the invention of the ultramicroscope. When a colloidal solution, of gold for example, is examined by means of an ultramicroscope, the particles are seen to move about in all directions, the motion of the bright specks of light exhibiting a beautiful scintillating effect. It is impossible in the scope of this article to discuss all the details and consequences of the theories that

have been put forward to explain the Brownian movement, but it may be stated that it has practically been proved, both theoretically and by observation, that it is mainly, if not entirely, due to the collisions with the molecules of the medium in which the particles are suspended.

Smoluchowski,[1] basing his calculations on the kinetic theory, and making use of Stokes' law, worked out theoretically that the mean distance D_x, traversed in time t by a small sphere of radius a, moving in a liquid whose coefficient of viscosity is η, is given by

$$D_x^2 = \tfrac{32}{27} \cdot \frac{c^2 mt}{3\pi\eta a} = \tfrac{32}{27} \cdot \frac{R}{N} \cdot \frac{T \cdot t}{3\pi\eta a},$$

where c = mean velocity of the molecules of the medium,
m = mass of each molecule of the medium,
R = gas constant,
T = absolute temperature,
N = number of molecules in one gram-molecular weight of any substance.

Einstein,[2] by applying the laws of osmotic pressure to the motion of small particles in a liquid medium, developed the formula

$$D_x^2 = \frac{R}{N} \cdot \frac{T \cdot t}{3\pi\eta a},$$

which differs from Smoluchowski's formula in not having the factor 32/27.

Langevin,[3] from a consideration of the equation of motion of a particle moving under the action of a force due to molecular shocks, obtained the same result as Einstein.

The results of the ultramicroscopic measurement of D_x by different observers, for a large variety of particles of different sizes, have been shown to agree very closely with the values obtained from the formulae thus developed. Furthermore, observations by Perrin [4] on the time of rotation of comparatively large grains of mastic have been found to fit in with the formula, developed by Einstein, for the mean square of the angle of rotation d, in time t, namely,

$$d^2 = \frac{R \cdot T}{N} \cdot \frac{t}{4\pi\eta a^3}.$$

Perrin [5] also made observations on the relative distribution of colloidal particles of gamboge and mastic at different heights in vertical columns of their solutions, the results again agreeing with the theoretical values obtained from the kinetic theory. The remarkable agreement that has been found between observation and theory may be looked upon as a proof of the reality of the molecular and kinetic hypotheses.

A number of interesting experiments have been made in connection with the motion of ultramicroscopic particles (smoke, silver, gold, mercury, etc.) in gases.[6] Such particles have been found to be electrically charged, and by measuring the rates with which they fall in the field of gravity and in an electrical field of known intensity it has been possible to determine the charges carried by the particles. It has been found that the charge on each particle is the elementary electrical charge (that is, the charge of an electron) or a multiple of this quantity, the values obtained agreeing very closely with those derived from radioactive and electronic measurements.

Another important application of the ultramicroscope to physical problems is the study of the optical effects exhibited by colloidal solutions. The late Lord Rayleigh [7] has shown theoretically that the intensity I of the light scattered by particles, whose size is small in comparison with the wave-length of the light employed, is given by

$$I \propto I_0 \frac{(D^1 - D)^2}{D^2}(1 + \cos^2\beta)\frac{m\pi T^2}{\lambda^4},$$

where I_0 = intensity of incident light,
D' = optical density of particles (proportional to square of refractive index),
D = optical density of medium,
m = number of particles per unit volume,
T = volume of a particle,
λ = wave-length of scattered light,
β = angle between line of sight and direction of incident light.

It follows that for a given distribution of small particles the percentage of violet light scattered is very much greater than that of red light.

The ultramicroscopic examination of the light scattered by the particles in colloidal solutions has confirmed the validity of Rayleigh's law. The scattered light is, in general, partially polarised, and often completely polarised in a certain plane. The whole problem is a very complex one and has engaged the attention of a large number of workers. One of the most important contributions to the subject is that of Garnett,[8] who investigated, both theoretically and experimentally, the absorption of various colloidal solutions, metal glasses, and metallic films, his mathematical treatment being based on the electromagnetic theory. His experimental results were found to be in good agreement with theory. The

problem of the scattering of light by small particles is very important in connection with the theory of the colour of the sky.

From the above brief sketch of some of the problems involved in the examination of ultramicroscopical solutions it may be seen that the invention of the ultramicroscope has opened up a wide field of physical research which has already yielded important results in connection with molecular phenomena.

VIBRATIONS OF AIR IN A TUBE

In Acoustics and some other problems it is necessary to investigate the small vibrations of a compressible fluid such as air in a cylindrical tube. We assume that the motion of each particle is parallel to the axis of the tube, so that particles which were originally in a plane at right angles to the axis remain always in such a plane.

Let ξ be the displacement at time t of the particles originally in a plane at a distance x from the origin. Let p_0, ρ_0 be the undisturbed pressure and density of the air, p, ρ the values of these quantities at time t. The matter which was originally between two planes at distances x and dx from the origin lies at time t between planes at distances $x+\xi$ and $x+\xi+(1+d\xi/dx)dx$. Its density was ρ_0, it is now ρ; hence if A be the area of the cross-section of the tube,

$$A\rho_0 dx = A\rho\left(1+\frac{d\xi}{dx}\right)dx,$$

$$\therefore \rho = \frac{\rho_0}{\{1+(d\xi/dx)\}}. \qquad (1)$$

The force acting on this matter on the face near the origin is Ap, while on the opposite face it is $-A\{p+(dp/dx)dx\}$. Thus the equation of motion is

$$A\rho_0 dx\frac{d^2\xi}{dt^2} = -A\frac{dp}{dx}dx$$

or

$$\rho_0\frac{d^2\xi}{dt^2} = -\frac{dp}{dx}. \qquad (2)$$

To complete the solution we need to know the relation between p and ρ.

If the temperature is constant, we have

$$p = \frac{p_0}{\rho_0}\cdot\rho. \qquad (3)$$

If, as is the case with sound waves, the compressions and rarefactions of the air take place so rapidly that there is no loss or gain of heat, we have [1]

$$p = k\rho^\gamma = p_0\left(\frac{\rho}{\rho_0}\right)^\gamma. \qquad (4)$$

Combining (1) and (4) then we get

$$p = \frac{p_0}{\{1+(d\xi/dx)\}^\gamma} \qquad (5)$$

and

$$\frac{dp}{dx} = -\frac{\gamma p_0}{\{1+(d\xi/dx)\}^{\gamma+1}}\frac{d^2\xi}{dx^2}.$$

Thus the equation of motion is

$$\rho_0\frac{d^2\xi}{dt^2} = \frac{\gamma p_0}{\{1+(d\xi/dx)\}^{\gamma+1}}\frac{d^2\xi}{dx^2}, \qquad (6)$$

and remembering that we are dealing only with small motions we may neglect $d\xi/dx$ in the denominator and obtain

$$\frac{d^2\xi}{dt^2} = \frac{\gamma p_0}{\rho_0}\frac{d\xi}{dx^2}. \qquad (7)$$

Had we assumed isothermal conditions we should clearly have found

$$\frac{d^2\xi}{dt^2} = \frac{p_0}{\rho_0}\frac{d^2\xi}{dx^2}. \qquad (8)$$

These can be put into a slightly different form thus: The elasticity E of a gas is

[1] See article "Thermodynamics," § (15), Vol. I.

measured by the ratio of the small change of pressure required to produce a change of volume to the change per unit volume; thus if $-dv$ is the decrement of a volume v produced by an increment of pressure dp,

$$E = -v\frac{dp}{dv}. \qquad . \quad . \quad . \quad (9)$$

Let M be the mass, ρ the density of the volume v, v_0 and ρ_0 being initial values.

Then $\qquad v\rho = M = v_0\rho_0$

or $\qquad v = \frac{v_0\rho_0}{\rho};$

hence $\qquad dv = -\frac{v_0\rho_0}{\rho^2}d\rho$

and

$$E = -\frac{v_0\rho_0}{\rho}\frac{dp}{dv} = \rho\frac{dp}{d\rho}$$

$$= \rho k\gamma\rho^{\gamma-1}$$

$$= k\gamma \, . \, \rho^\gamma = \gamma p,$$

since $\qquad p = k\rho^\gamma.$

Or, denoting by E_0 the elasticity in the undisturbed state, we have

$$E_0 = \gamma p_0; \qquad . \quad . \quad . \quad (10)$$

hence

$$\frac{d^2\xi}{dt^2} = \left(\frac{E_0}{\rho_0}\right)\frac{d^2\xi}{dx^2}.$$

If we put $c^2 = E_0/\rho_0$, this takes the form

$$\frac{d^2\xi}{dt^2} = c^2\frac{d^2\xi}{dx^2}, \qquad . \quad . \quad . \quad (11)$$

and is the same equation as is discussed in the article "Strings, Vibration of." The general solution is

$$\xi = f(ct-x) + F(ct+x), \quad . \quad . \quad (12)$$

as can readily be verified, and represents, as there shown, waves travelling in the positive and negative directions with the velocity c or $\sqrt{(E_0/\rho_0)}$, *i.e.* the square root of the ratio of the elasticity to the density.

The statement in this form can be extended to other cases of sound motion, the term elasticity being defined with regard to the circumstances of each case.[1]

VIBRATIONS OF A ROD

IMAGINE a straight rod of uniform section A in a state of motion in which every part is moving parallel to the axis so that all points in any plane at right angles to the axis always remain in such a plane. Let ξ be the displacement at time t of a plane initially at a distance x from one end of the rod, and consider the motion of the particles in the section between this plane and one initially at a distance $x+dx$; they will at time t lie between the planes $x+\xi$ and $x+\xi+(1+(d\xi/dx))dx$.

The extension or "stretch" of the short length dx is $d\xi/dx$, and if q represents Young's modulus for the rod (see article "Elasticity," § (4), Vol. I.), the force on the face of the section nearest the origin is $-qA(d\xi/dx)$, that on the opposite face is $qA(d\xi/dx)+(d/dx)(qA(d\xi/dx))dx$. Thus the resultant force on the section is

$$qA\frac{d^2\xi}{dx^2}dx.$$

Hence, if ρ be the density, the equation of motion of the section is

$$\rho A\frac{d^2\xi}{dt^2}dx = qA\frac{d^2\xi}{dx^2}dx$$

or

$$\frac{d^2\xi}{dt^2} = \frac{q}{\rho}\frac{d^2\xi}{dx^2}. \qquad . \quad . \quad . \quad (1)$$

If we put $q/\rho = c^2$, this, it can be shown, is satisfied by

$$\xi = f(ct-x) + F(ct+x), \quad . \quad . \quad (2)$$

and represents[2] wave motion travelling with velocity c. The value of c is $\sqrt{q/\rho}$, or, as in other cases, the speed of the waves is determined by the square root of the ratio of the elasticity to the density, the elasticity in this case being measured by Young's modulus.[3]

WAVE-LENGTHS, THE MEASUREMENT OF

§ (1) INTRODUCTION. — The phenomena of coloured rings, commonly known as "Newton's Rings," were described in his *Opticks*, published in 1704, but were not explained on the basis of the undulatory theory of light until 1802, when Thomas Young (1) put forth the theory of interference of light waves, and was thereby led to make the first determinations of wave-lengths of light corresponding to the different colours. Measurements of wave-lengths corresponding to narrow spectral lines were not made until somewhat later, after the discovery of the dark lines in the solar spectrum. Newton showed by means of a glass prism that sunlight was made up of various colours, and to all observers the solar spectrum appeared to be a continuous graduation of colours until Wollaston (2) in 1802 observed distinct dark lines, which he regarded as boundaries to intervals of colour. Wollaston's discovery was forgotten until 1814, when Fraunhofer (3) repeated it and recognised that the dark lines represented definite wave-lengths in the solar spectrum. In his investigations, Fraunhofer mapped about 700 of these lines, assigning letters of the alphabet to the most prominent ones, beginning with A in the red and ending with H in the violet. These lines, still called the Fraunhofer lines, are familiar to every one who has any knowledge whatever of spectroscopy. Investigation into the possibilities of measuring the actual lengths of light waves led Fraunhofer to develop the theory of interference of light and invent the first diffraction gratings, with which he made wave-length measurements of considerable accuracy. His method (4) for measuring the wave-lengths of light by means of a grating is indeed the same as that of the present day. It is based upon the interference of rays which are diffracted upon passing through a set of equal and equidistant apertures or slits constituting the grating.

It was not until 1859 that the physical significance of the Fraunhofer lines became known. Kirchhoff and Bunsen then explained that "the dark lines of the solar spectrum, which are not caused by the terrestrial atmosphere, arise from the presence in the glowing solar atmosphere of those substances which in a flame produce bright lines in the same position." Inasmuch as these two scientists proved the existence of many terrestrial elements in the sun, it was a natural consequence that the solar spectrum itself should become the standard of reference for wave-lengths of light.

With the aid of gratings ruled on glass, Ångström made, as accurately as possible, a map of the Normal Solar Spectrum, which he published in 1868. The wave-length measurements covered the visible spectrum between the Fraunhofer lines A and H, and were expressed in ten-millionths of a millimetre to 2 decimal places. This unit of length, 1×10^{-10} metre, sometimes called the "tenth metre," but more commonly known as the "Ångström Unit" (symbolised simply by A), is now almost universally used in measurements of wave-lengths of light.

Ångström's map was superseded by Rowland's Normal Map of the Solar Spectrum, published in 1888. and based upon his invention of the concave grating. This photographic map was about 20 metres long, the maximum error in any part of the scale of wave-lengths being estimated as less than 0·01 A. Rowland's Preliminary Table of Solar Spectrum Wave-lengths, representing over 20,000 lines, was based upon determinations of the absolute wave-length of one of the D lines of sodium. The wave-lengths were given to 3 decimals in A, Rowland believing that the absolute values were correct to 1 part in 100,000, and that the errors in relative value were not greater than a millionth. For a period of twenty years practically all spectroscopic measurements were based on these values, and even at the present time they are widely used.

§ (2) THEORY AND USE OF DIFFRACTION GRATINGS IN WAVE-LENGTH MEASUREMENTS. —The simple theory[1] of the plane diffraction grating gives the wave-length of light as a function of the grating space and of the angles of incidence and diffraction (or reflection) of the light rays. *Fig.* 1 represents the cross-section of an element of a transmission grating

[1] See "Diffraction Gratings, Theory of"; also "Diffraction Gratings, Manufacture and Testing of."

in which AB′ is to be regarded as the grating space b. If light from an illuminated slit S falls as a parallel beam on the grating at an angle of incidence i with the normal, a large portion passes directly through the grating apertures, but a part of it is diffracted in the direction AC, making the angle θ with the normal. By drawing the perpendiculars BB′ and CB′, it is seen that the difference in path travelled by corresponding rays from adjacent apertures, or the retardation as it is called, is given by the sum of the lengths BA and AC, and therefore when this path difference is equal to some integral number of whole wave-lengths $n\lambda$ bright images of S in colour

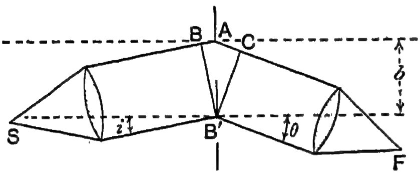

Fig. 1.

corresponding to λ are produced when the diffracted rays are brought to a focus. This condition is easily seen to be given by $BA + AC = n\lambda = b(\sin i + \sin \theta_n)$, in which n represents the order number of the spectrum.

Reflection gratings have been more successfully made than transmission gratings, and have, therefore, been more extensively used for wave-length measurements, but the law of the gratings ruled on polished plane metal surfaces is quite similar to that of gratings ruled on glass. A beam of light falls on the grating G, *Fig.* 2, making an angle of incidence i with the normal, and part of the light is diffracted at an angle θ. The perpendiculars BB′ and CC′ are drawn to show that B′C and BC′ are the retardations. In this case the total retardation is seen to be determined by $B'C - BC' = b(\sin i - \sin \theta)$. Wherever this equals one or more whole wave-lengths, $n\lambda$, a bright image is seen in colour corresponding to λ, and we have the law of the grating

$$n\lambda = b(\sin i - \sin \theta_n).$$

If the diffracted rays are on the same side of the normal as the incident rays, then the two retardations are added, so that the general equation for all the spectra must be written

$$n\lambda = b(\sin i \pm \sin \theta_n),$$

the positive or negative sign being used when the incident and diffracted rays are on the same or opposite sides of the normal respectively.

Depending on the position of the grating in relation to the collimating and observing telescope, there are five different methods of making wave-length measurements with plane gratings. To sketch these the wave-length equation or grating law may be written

$$n\lambda = b\{\sin i + \sin(\delta - i)\},$$

in which δ is the angle of deviation or $\delta = i + \theta$. (1) The plane of the grating is placed perpendicular to the collimator, so that $i = 0$ and $n\lambda = b \sin \delta$. This method was used by Fraunhofer with the first diffraction gratings for the first absolute measurements on wave-lengths of light. (2) The grating is normal to the telescope, so that $\theta = 0$ and $n\lambda = b \sin \delta$ as before. (3) Both i and θ are given values, so that $n\lambda = b(\sin i + \sin \theta)$. This was the method adopted by Ångström. (4) The deviation δ is a minimum. Writing the above equation in the form

$$n\lambda = 2b \sin \frac{(i+\theta)}{2} \cos \frac{(i-\theta)}{2},$$

it is seen that $\cos(i-\theta)/2$ is a maximum when $i = \theta$, which is the condition for minimum

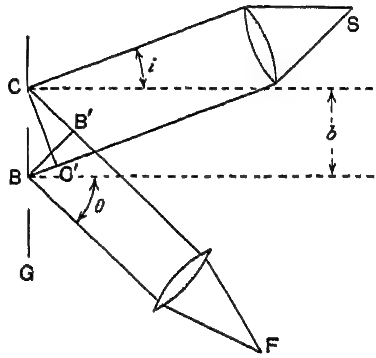

Fig. 2.

deviation δ. Then the wave-length is found from

$$n\lambda = 2b \sin \frac{\delta}{2}.$$

(5) The telescope and collimator are clamped at an angle α, and the grating rotated through the measured angle β, whence it can be shown that

$$n\lambda = 2b \sin \beta \cos \frac{\alpha}{2}.$$

In this case observations are made by adjusting the required spectral line upon the cross-wire in the eyepiece, and then rotating the grating until the reflected image is brought upon the cross-wire.

All of these methods require the measurement of the grating space b; (1), (2), and (4) require the measurement of one angle; while

(3) and (5) require the measurement of two angles.

Bell (5), whose determinations of the wave-length corresponding to D_1 received greatest weight in establishing Rowland's standards, used the second method with two glass transmission gratings and the fifth with two reflection gratings ruled on speculum metal.

All plane gratings require the use of lenses to focus the diffracted waves. These introduce chromatic difficulties in focussing, and further limitations due to absorption, so Rowland, in 1881, invented gratings ruled on spherical mirrors, so that the concave grating should focus spectra without the use of a lens. The most important characteristic of the concave grating is the simplicity with which it can be focussed. If the slit of the spectroscope and the grating be placed on the circumference of a circle[1] whose diameter equals the radius of curvature of the grating, the spectra are all in focus on this circle, illustrated by *Fig.* 3,

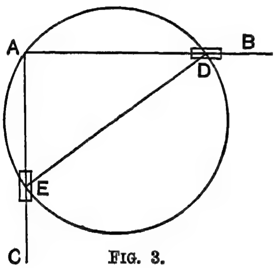

FIG. 3.

DE being the diameter of the circle and equal to the radius of curvature of the concave grating. If the slit be placed on the circumference of this circle, *e.g.* at A, the spectra are all in focus on the circumference, as at E.

With both plane and concave gratings there is great advantage obtained by forming the spectra on the normal to the reflecting surface, for this gives the so-called normal spectrum, that is, distances measured either way from the grating normal are proportional to the change in wave-length observed. Rowland devised a mounting for his concave grating which automatically kept the observing apparatus (eyepiece or camera) on the normal to the grating surface. The grating and camera, *Fig.* 3, are mounted on carriages rigidly separated by the beam DE, whose ends are constrained to move along the rails AB and AC. These rails are adjusted at right angles to each other, and have the slit at their intersection A. Every circle having the shifting beam DE as a diameter must pass through A, and if the grating is fixed normal to DE, its centre of curvature coincides exactly with E, giving a normal spectrum at that point.

[1] See "Diffraction Gratings, Theory of," § (11), Vol. IV.

Rowland's method of determining relative wave-lengths is based on a simple feature of this grating mounting in that the wave-length equation is reduced to $n\lambda = b \sin i$, when observations are made near the perpendicular to the grating. Then for a given angle i and different spectral orders, 1, 2, 3, etc.,

$\lambda_1 = b \sin i$ in the spectrum of the first order,
$2\lambda_2 = b \sin i$ in the spectrum of the second order,
$3\lambda_3 = b \sin i$ in the spectrum of the third order,
etc.,

where λ_1, λ_2, λ_3, etc., are the wave-lengths in the 1st, 2nd, 3rd, etc., orders. It follows that $\lambda_1 = 2\lambda_2 = 3\lambda_3$, etc., which means that various orders of spectra are superposed, and the wave-lengths of each are inversely proportional to the order number of the spectrum. For example, a wave-length of 6000 A in the first order spectrum will have superposed on it 3000 A in the second order and 2000 A in the third order. By measuring the lines in various orders nearly superposed on the sodium line (D_1 = 5896·156 A), Rowland first compared 14 solar wave-lengths with this standard as accurately as possible, and in a similar way obtained from these the wave-lengths of principal lines throughout the solar spectrum (6).

Another type of concave grating mounting which has been adopted by many laboratories is due to Runge and Paschen (7). This uses a lens or concave mirror to illuminate the grating with parallel light from the slit, and reduces the dispersion or scale of spectrum to about half that in the Rowland mounting, with the result that the intensity of the spectrum is theoretically quadrupled. The astigmatism in spectra given by the Rowland mounting is practically eliminated by mounting the grating in parallel light. These stigmatic slit images permit (1) the use of diaphragms in front of the slit to photograph different spectra in juxtaposition; (2) the projection of different parts of sources, of interferometer fringes, etc., on the slit for spectral analysis.

The complete theory of diffraction gratings, both plane and concave, together with detailed directions on mounting, adjusting, and using gratings for wave-length measurements, may be found in vol. i. *Handbuch der Spectroscopie*, by H. Kayser, or in *Spectroscopy*, by E. C. C. Baly. Limitations of space will not permit more on this subject here, except to call attention to a recent controversy on the validity of the fundamental law of the grating, and questioning the use of gratings for accurate measurements of wave-lengths. When in 1901 Rowland's standards were found to contain relative errors of nearly 1 part in 100,000, these errors were attributed to the erratic behaviour of diffraction gratings.

Kayser (8), in 1904, made some experiments which led him to the conclusion that the coincidence between orders of spectra is not to be depended upon. It has since been shown (9), however, that the fundamental law of diffraction gratings is true, so that the errors in Rowland's values as well as the experience of Kayser require other explanations. According to Jewell (10), the relative errors in Rowland's Table are due to disturbed apparatus and failure to recognise that corrections were necessary for the Doppler-Fizeau effect or for air-pressures and temperatures, while Goos (11) has shown that the discrepancies observed by Kayser may be explained by slight defects in the adjustment of the grating and perhaps to inattention to constant conditions in operating the sources of light. If accurate measurements of wave-lengths are to be made with gratings, stability of mounting and correctness in adjustment must be insured and temperature fluctuations guarded against. The change in the refractive index and dispersion of air (12) will cause overlapping spectrum orders observed as coincidences at one temperature to be shifted at other temperatures.

Another matter which deserves attention in connection with the use of gratings for wave-length observations is the presence of spurious lines or "ghosts," due to periodic errors in the ruling. These false lines are present in all grating spectra, and cannot be distinguished from real lines except by testing their relationship to parent lines by means of numerical ratios. Two general types of such spurious lines are known: (1) Ghosts located near the spectral line, and symmetrically placed on both sides of it; and (2) spurious lines, whose positions in the spectrum are far removed from the parent line.

False lines of the first type, generally known as the Rowland ghosts, arise from errors of ruling repeated with successive revolutions of the screw. For example, Rowland gratings ruled 20,000 lines per inch with a screw of 1/20 inch pitch have an interval of 1000 lines in which errors recur. The position of these ghosts with respect to parent lines is that of additional spectra from a grating having 1000 times the grating space; their apparent wave-lengths differ from that of the parent line by $n/1000$ times the wave-length of the corresponding line if n represents the order of the false spectrum. Anderson ruled gratings with 750 lines per revolution of a screw having 1/20 inch pitch, thus making 15,000 lines per inch, while the use of every other or every third tooth of the wheel produced gratings of 7500 and 5000 lines per inch. These gratings give ghosts at distances $n\lambda/750$, $n\lambda/375$, and $n\lambda/250$ respectively, from the parent line of wave-length λ.

Except in complicated spectra, the Rowland ghosts are usually easy to detect on account of their symmetry and proximity to the real lines, but it is much more difficult to eliminate spurious lines of the second type. Lyman (13) found spurious doublets occurring at positions corresponding roughly to $\lambda/3$ and $2\lambda/3$ in spectra produced by Rowland gratings having 14,438 lines per inch. An Anderson grating with 7500 lines per inch has been found at the Bureau of Standards to give false reproductions of a given line of wave-length λ in positions near $2\lambda/5$, $3\lambda/5$, $4\lambda/5$, $6\lambda/5$, $7\lambda/5$, $8\lambda/5$, and $9\lambda/5$. Similar false spectra have been detected in the 5000 lines per inch gratings ruled by using every third tooth in the wheel. Although these secondary lines are usually of relatively low intensity, they may, nevertheless, be very troublesome and embarrassing when recorded by the long exposures necessary to photograph the infra-red and extreme ultra-violet spectra.

§ (3) Standard Wave-lengths by Interferometer Methods.—An extraordinary degree of accuracy in wave-length measurements was made possible with the invention of the interferometer apparatus, in which a beam of light coming from a single source is first separated into two portions which are retarded relative to each other by passing over unequal optical paths, and then reunited, producing interference fringes. The interferometer method of wave-length measurement has several advantages over the grating method: the distance between two parallel interferometer plates is easily and accurately determined; it eliminates the precise measurement of angles; it permits the production of various lengths which are exact multiples of some unit; and less labour is required to make accurate comparisons of wave-lengths.

The first absolute measurement[1] of a light wave by the interferometer method was made in 1893 by Michelson (14), who determined the number of waves of three radiations from cadmium vapour which were equal in length

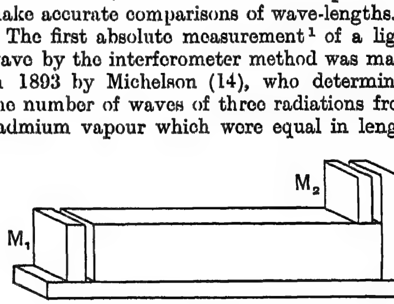

Fig. 4.

to the standard metre. Nine intermediate standards, the lengths of which were represented by the distances between the planes of two mirrors M_1 and M_2, *Fig.* 4, were constructed. The lengths of these intermediate standards were 10 cm., 10×2^{-1} cm., 10×2^{-2} cm. . . . the smallest being 10×2^{-8}

[1] See also "Line Standards," § (7), Vol. II.

cm., or about 0·39 millimetre. The optical system and two of the standards A and B are shown in the diagram, *Fig.* 5, in which C is the mirror of reference. An observer at O

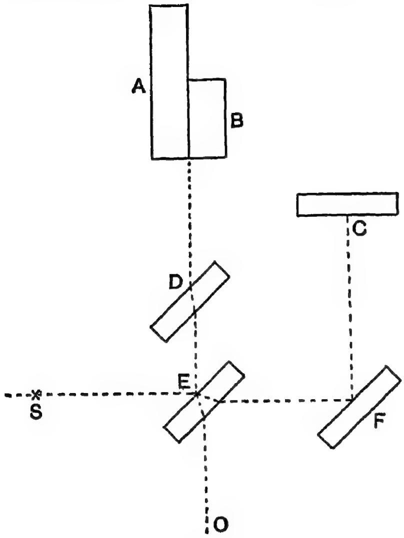

FIG. 5.

sees by reflection at the half-silvered surface E, the image of C, superposed on the four mirrors on A and B, two of which lie side by side below, and another pair above. B and C are mounted on carriages which can be moved back or forth by means of parallel screws. The length of the shortest standard was first determined in terms of the wave-length of cadmium red light. The front surface of B was adjusted to the same optical distance as C, and the reference plane C was then slowly light as a source and turning the mirrors slightly about a vertical axis gave vertical fringes, and the dark central fringe which marks zero difference of path appeared on adjacent edges of the front mirror of A and B. Then C was moved back until the dark fringes were seen in the upper mirror of B. Now when C was moved back through its own length the dark fringes again appeared in the lower mirror of B, and moving C back a distance equal to the length of B brought the fringes once more into view on the upper mirror of B. If A was exactly twice the length of B, fringes were also seen in the upper mirror on A. If A was not exactly twice B the central fringe was displaced, and the difference, in wave-lengths, between A and 2B was easily obtained from a slight tilt of the compensator D. In this way the lengths of successively larger intermediate standards were obtained in terms of wave-lengths of light. Finally the 10 cm. standard was compared with the metre by moving it through its own length 10 times. Michelson found at 15° C. and 760 mm. pressure

1 m. = 1553163·5 red waves from which λ = 6438·4722 A.
,, = 1900249·7 green ,, ,, ,, ,, = 5085·8240 A.
,, = 2083372·1 blue ,, ,, ,, ,, = 4799·9107 A.

An absolute accuracy of 1 part in 2,000,000 was claimed, while the relative accuracy might be 1 in 20,000,000.

An independent measurement of the wave-length of cadmium red radiation, in terms of the metre, was made in 1907 by Messrs. Benoit, Fabry, and Perot (15). Compared with Michelson's, their apparatus was simplified and arranged so as to reduce the dangers from

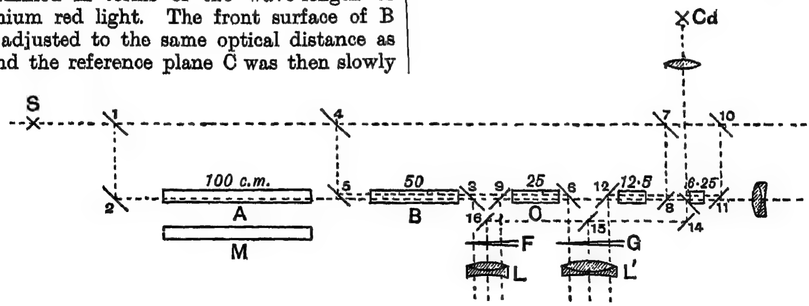

FIG. 6.

moved back to coincidence with the second surface of B, during which shift the number of circular fringes was counted as they flowed out from the centre of the interference figure.

The next operation was to compare twice the length of this standard B with the next longer one A. These were first adjusted so that their front lower mirrors were the same optical distance from E as C. Using white temperature changes in the standards by shortening the time necessary to perform the experiment. Five standards were made by separating half-silvered glass plates at distances of 6·25, 12·5, 25, 50, and 100 cm., and these were so placed that the comparisons could be made without moving any of them. The arrangement is shown diagrammatically in *Fig.* 6. As in Michelson's method, the

difference in length between one standard and the double length of the previous one had to be measured accurately. To compare A with B, for example, white light coming from S was reflected by mirrors 1 and 2, passed through A and B, mirror 5 being moved out of the way. This light was reflected by mirror 3 through a compensating wedge of air between two silvered glass plates F and into a microscope L. If A was very nearly 2B, a ray of light traversing A and twice reflected in B covered a path nearly equal to that of another ray crossing A twice and passing through B. Interference bands resulted, and from the position of the central fringe on the wedge compensator the difference between A and 2B was accurately determined in wave-lengths. Similarly, the other standards were compared, and finally the 6·25 cm. standard was measured in wave-lengths of the cadmium red radiation. The number of these waves in 1 metre was found to be 1,553,164·13, or $\lambda = 6438{\cdot}4696$ A in dry air at 15° C. and 760 mm. pressure. The probable error was one part in 10,000,000; this absolute determination of wave-length having the same accuracy as it is possible to obtain in the comparison of two metre bars. Their value differs from Michelson's by 1 part in 2,500,000, because it refers to dry air. An approximate reduction of Michelson's value to dry air gives $\lambda = 6438{\cdot}4700$ A, which checks the later value to 1 part in 16,000,000. The original memoirs should be referred to for further details concerning these beautiful experiments, which establish with extreme precision a wave-length of light as a unit of length probably more invariable, reproducible, and important than any other unit.

In 1907 the International Union for Co-operation in Solar Research made certain recommendations for the final establishment of a system of satisfactory light wave standards. The absolute value of the red radiation of cadmium as redetermined by Benoit, Fabry, and Perot was chosen as a primary or fundamental spectroscopic standard. It was further recommended that secondary standards be determined at intervals of about 50 A throughout the spectrum of the iron arc by comparison with the primary standard, using the interferometer method as devised by Fabry and Perot (16). This method is as follows: The red light from a cadmium lamp and the light from an iron arc are sent simultaneously through a Fabry and Perot interferometer, I, and the circular fringes thus formed are focussed with their centre on the slit S of a spectroscope, *Fig.* 7. The prism (or grating) separates the numerous spectral lines and permits, at P, an independent determination of the diameters of the circular fringe system produced by each line or radiation. The order of interference at the centre of a system of rings is determined for the two radiations whose wave-lengths are to be compared. Let λ be the wave-length of the cadmium red ray, and let P be the order of interference producing the first ring from the centre. The order at the centre is then $p = P + p'$, where p' is the fractional order, lying between zero and 1, to be determined from the diameter of the ring P. The whole number P is readily found from the distance between the plates. This results from trying various values of this distance with three or four wave-lengths until the computed fractional order of each agrees with its measured value (17). The order of interference at the centre ($i = 0$) is $p = 2e/\lambda$, where e is the distance between the plates, *Fig.* 8. In a direction making an angle i with the normal it is $2e \cos i/\lambda = p \cos i$.

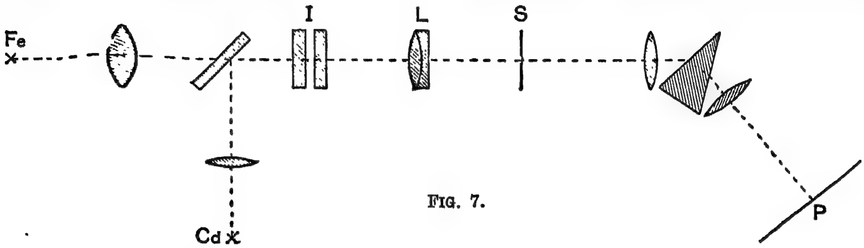

FIG. 7.

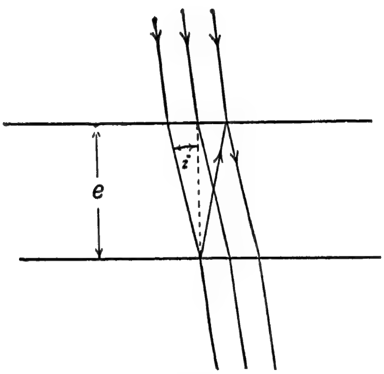

FIG. 8.

Now if x is the angular diameter of the ring P,

$$i=\frac{x}{2} \text{ and } P=p\cos\frac{x}{2}.$$

But
$$\cos\frac{x}{2}=1-\frac{i}{2}=1-\frac{x^2}{8}$$

approximately, so that

$$P=p\left(1-\frac{x^2}{8}\right), \text{ or } p=P\left(1+\frac{x^2}{8}\right)$$

and
$$p'=p-P=P\frac{x^2}{8}.$$

Similarly with a radiation of wave-length λ_1 we have

$$p_1'=P_1\frac{x_1^2}{8}.$$

The thickness of the air layer between the plates is assumed to be the same for all radiations, whence

$$\lambda(P+p')=\lambda_1(P_1+p'_1)$$

or
$$\lambda_1=\lambda\frac{(P+p')}{(P_1+p'_1)}, \quad \left(=\lambda\frac{p}{p_1}\right).$$

Substituting the above values of p' and p'_1,

$$\lambda_1=\lambda\frac{P}{P_1}\left(1+\frac{x^2}{8}-\frac{x_1^2}{8}\right).$$

If d represents the linear diameter of the ring and R the focal length of the lens which focusses the rings on the slit of the spectroscope, $x=d/R$ and

$$\lambda_1=\frac{\lambda P}{P_1}\left(1+\frac{d^2}{8R^2}-\frac{d_1^2}{8R^2}\right).$$

Slight corrections are necessary for the dispersion of the atmosphere and refractive index of air (18) at temperatures other than 15° C. and 760 mm., and for the reflection phase-change (19), which is a function of the wave-length. This method of wave-length comparisons can be applied only to waves whose lengths are already known accurately enough to allow P, the order of interference producing the first ring, to be determined without ambiguity. For this purpose an accuracy of one part in 20,000 or 30,000 is sufficient if the preliminary measurements are made with an air-plate thickness not exceeding 5 mm. The final accuracy of the comparison can be made to reach 1 part in 5,000,000.

§ (4) Standards of Wave-length.—That a train of waves emitted by a source of homogeneous light furnishes for length measurements a scale of extraordinary precision and constancy is now more or less familiar to every one, and the importance of such fundamental standards to spectroscopy, metrology, and precision optics generally is fully appreciated. For practical use very narrow (homogeneous) spectral lines must be used, and their wave-lengths should be carefully defined with respect to the conditions producing or influencing them. Several successive attempts have been made to define such a system of Standard Wave-lengths, each aiming at higher precision by making use of more refined methods of measurement or of more satisfactory light sources. The Solar Spectrum Standards first determined by Ångström in 1868, improved and extended by Rowland in 1888, have already been mentioned. The absolute measurements made by Michelson in 1893 on cadmium lines in terms of the standard metre at Paris showed that Rowland's wave-lengths were too large by 1/30,000, but spectroscopists paid little attention to this fact since there was still no reason to doubt the correctness in relative value of Rowland's numbers. In 1901, Fabry and Perot measured about 30 lines in the solar spectrum between 4643 and 6471 A by means of their interferometer, and their work revealed the fact that systematic errors existed in Rowland's Table, making the errors in relative magnitudes nearly 1 part in 100,000. The probable sources of those errors are discussed under the theory and use of diffraction gratings for wave-length measurements.

The question of standard wave-lengths was discussed at the first meeting of the International Union for Co-operation in Solar Research (21), and the necessity for establishing a new system of standard wave-lengths from artificial sources was agreed upon. At the second meeting of this Union in 1905, the following decisions (22) were reached: (1) The wave-length of a properly chosen radiation shall be taken as a primary standard of wave-lengths. The number which represents this wave-length shall be fixed one time for all; it shall define the unit of wave-length, which must differ as little as possible from 10^{-10} metre, and shall be called Ångström. (2) There is reason to choose secondary standards separated by not more than 50 Ångströms. These secondary standards shall be referred to the primary standard by a method of interference. The luminous source shall be an electric arc of 6 to 10 amperes.

In 1907 a report of the measurement by Benoit, Fabry, and Perot (22) of the wave-length of the red radiation from cadmium was presented at the third meeting of the International Union, and the following resolution was adopted (*loc. cit.* p. 20): "The wave-length of the red ray of light from cadmium, produced by a tube with electrodes, is

6438·4696 Ångström in dry air at 15° C. on the hydrogen thermometer, at a pressure of 760 mm. of mercury, the value of g being 980·67 (45°). This number will be the definition of the unit of wave-length."

The first determinations of secondary standards were reported in 1907 by Fabry and Buisson (*loc. cit.* p. 138), who measured the wave-lengths of 115 lines in the iron arc from 2373 to 6494 A by their interferometer method. Similar measurements were made by Eversheim (24) and by Pfund (25), and the mean values of the three independent determinations were adopted as secondary standards by the International Union in 1910, comprising 54 lines between 4282 and 6494 A.

The agreement between interferometer measurements of these wave-lengths is remarkably good (·002 or ·003 A), and there is reason to believe that the accepted secondary standards have a precision of 0·001 A, *i.e.* they are correct and reproducible to part 1 in several millions. This is the extreme limit which it is possible to obtain, since the most homogeneous lines of iron have a width of about 0·060 A, and a precision of 0·001 A corresponds therefore to 1/60 of the width of the line. Some of the differences between values of different observers can probably be accounted for by different arc conditions employed in different laboratories, and special investigations on the effect of arc conditions show that the wave-lengths of certain iron lines which are sensitive to pressure are also affected by current strength, length of arc, and portion of arc used. Recognition of these influences led, in 1913, to the adoption of more precise specifications of the iron arc in air as a source of international standards (26) as follows:—(1) Length of arc 6 mm. (2) Current of 6 amperes for wave-lengths greater than 4000 A, and 4 amperes or less for wave-lengths less than 4000 A. (3) Use direct current with positive pole above the negative and a potential of 220 volts; iron rods of 7 mm. diameter. (4) As a source of light use an axial part of about 2 mm. in the middle of the arc. (5) Use only iron lines of groups a, b, c, d (Mt. Wilson Classification).

It was also proposed, in 1910, that "the measurement of standards of the second order shall be extended to shorter and longer wave-lengths, and the arithmetical mean of three independent determinations shall be adopted as secondary standards." In the past ten years very little progress has been made in extending this system of secondary standards. The most extensive measurements were made by Burns, who compared directly with the cadmium primary standard the wave-lengths of 125 iron lines (27) from 5434 to 8824 A and 100 lines (28) from 2851 to 3701 A.

The wave-lengths which have been adopted as International Secondary Standards are collected in the following table:

International Secondary Standards.

3370·789	4375·934	5405·780
3399·337	4427·314	5434·527

4147·676	5192·363	6546·250
4191·443	5232·957	6592·928
4233·615	5266·569	6678·004
4282·408	5302·315	6750·163
4315·089	5324·196	..
4352·741	5371·495	..

In addition to the above determinations of secondary standards, many other measurements of wave-lengths in the iron arc spectrum have been made, some with interferometers and others with diffraction gratings, partly to set up a system of tertiary standards and partly to investigate further the effect of the operating conditions of the arc upon its wave-lengths. Among such investigations the most important in some respects appears to be that of the so-called "pole effect" on arc lines. This has been studied in some detail at the Mt. Wilson Observatory (29), where it is found that certain iron lines which are also sensitive to pressure give wave-lengths in the centre of the arc slightly different from those near the negative pole (one or two millionths), and also that this effect is somewhat reduced when, instead of using two iron electrodes, a carbon electrode and an iron one are used (30).

Corrections to wave-lengths measured in air also deserve mention in connection with the exact measurements. The Rowland system

of standards was defined in air at 20° C. and 760 mm. of mercury, and correction tables to reduce such wave-lengths or oscillation frequencies to vacuum values are given in Kayser's *Handbuch*, ii. 514. Since the new International System specifying wave-lengths at 15° C. has come into general use, there has been no uniformity in such corrections. The resulting confusion has been pointed out by Birge (31), who recommends that the recent work of the Bureau of Standards (18) on the index of refraction of air for wave-lengths from 2218 to 9000 A be referred to for these corrections in all future work. International adoption and use of the new tables will exclude all further possibility of ambiguity or question about the conversion of wave-lengths to standard air conditions or to vacuum when such wave-lengths are not actually observed under these conditions.

International co-operation ceased during the war, but a new International Astronomical Union, representing several of the allied countries, was organised in Brussels in July 1919. A new committee on Standard Wave-lengths and Solar Spectrum Tables was appointed, and this committee will, no doubt, consider the possibilities of still further improving the precision of standards and methods of measuring wave-lengths.

§ (5) WAVE-LENGTH MEASUREMENTS WITH PRISM SPECTROGRAPHS.—Diffraction gratings and interferometers are very wasteful of light, so that the prism spectrograph must be employed for spectral analysis of faint sources such as the stars, planets, low voltage arcs, etc. Wave-length measurements with prism spectrographs are generally obtained by methods of interpolation after the positions of the unknown lines are measured relative to the positions of certain well-known lines whose wave-lengths have already been accurately determined. Either graphical interpolation or an interpolation formula may be used. The graphical method requires drawing the dispersion curve of the spectroscope, *i.e.* the curve showing the relation between wave-length and corresponding deviation. This curve is obtained by measuring the deviations of well-known lines in different parts of the spectrum and then plotting these numbers against the wave-lengths on cross-ruled paper. A smooth curve traced through these points is the calibration curve of the instrument. To determine the wave-length of an unknown line it is only necessary to measure its deviation, after which the wave-length can be read directly from the curve.

Hartmann's interpolation formula is in common use, and very satisfactory for the purpose of determining wave-lengths of lines in prismatic spectra. It states the relation between wave-length λ and refractive index μ as follows:

$$\lambda = \lambda_0 + \frac{c}{(\mu - \mu_0)^{1/a}},$$

where λ_0, c, μ_0, and a are constants. For relatively short ranges of wave-length, a, which has a value of about 1·2, may be placed equal to unity, and μ may be replaced by the linear distance n between lines along the focal curve. Then

$$\lambda = \lambda_0 + \frac{c}{n - n_0}.$$

Hartmann pointed out that λ_0 is a constant for any particular spectroscope and may be determined once for all, while n_0 represents some definite point on the linear scale. The known wave-lengths λ_1, λ_2, and λ_3 and corresponding scale readings n_1, n_2, and n_3 for three lines are sufficient to calculate the three constants λ_0, c and n_0, as follows:

$$\lambda_0 = \lambda_3 + \frac{\lambda_1'(n_1 - n_2)}{S(n_3 - n_2) + (n_1 - n_2)},$$

$$c = (\lambda_0 - \lambda_3)(n_0 - n_3),$$

$$n_0 = \frac{(\lambda_0 - \lambda_3)(n_3 - n_2) + \lambda_2' n_2}{\lambda_2'},$$

where

$$\lambda_1' = \lambda_1 - \lambda_3, \quad \lambda_2' = \lambda_2 - \lambda_3, \quad \text{and} \quad S = \frac{\lambda_1' - \lambda_2'}{\lambda_2'}.$$

The accuracy obtainable in wave-length measurements from prism spectrograms depends principally on the dispersion, and under the best conditions the limit is about 0·01 A. Spectroscopic work with prisms is, of course, limited to the range of wave-lengths for which transparent prism materials are available. The lower limit is set by fluorite, which transmits to 1200 A, and sylvine marks the upper limit at about 23 μ or 230000 A.

§ (6) WAVE-LENGTH MEASUREMENTS IN THE SCHUMANN REGION.—The most precise determinations of light waves exist for the range from about 2000 to 9000 A, that is, in the region of the spectrum which is most easily photographed. It is very difficult to work with shorter waves because of the strong absorption of their energy by the air and by the gelatine of the photographic emulsions. Schumann (32) first overcame these difficulties with a vacuum spectrograph, fluorite prism, and special photographic plates. Consequently, these short waves are commonly called Schumann waves.

The first successful attempt at accuracy in length measurements of Schumann waves was made by Lyman (33). The wave-lengths of the hydrogen lines in this Schumann region were measured to serve as standards. The method used is briefly as follows:

Two illuminated slits S and S′, placed on a circle whose diameter is the grating's radius of curvature, will give images at I and I′, and spectra corresponding to each (*Fig.* 9). The two first-order spectra will be shifted with respect to each other by an amount depending on the distance between the slits. At a given point on a photographic plate between I and I′ the light brought to a focus from S will be of shorter wave-length than that from S′. The amount of this shift was determined by comparing known lines of the aluminium and iron spectra at one end of the plate. Then the longer wave portion of the iron spectrum (3100 to 2400 A) was superposed on the shorter wave portion (1900 to 1200 A) of the hydrogen spectrum and the wave-lengths in the former reduced by the shift. The accuracy in this region does not surpass 0·2 or 0·3 A.

The shortest waves observed by Schumann himself were about 1200 A. Lyman extended the spectrum down to about 600 A, and has collected the important tables of wave-lengths and other optical data relating to the Schumann region in a monograph entitled *Spectroscopy of the Extreme Ultra-violet.* Very recently Millikan has pushed the wave-length limit an octave lower, so that a gap of less than five octaves remains between the shortest ultra-violet waves and the longest X waves thus far observed.

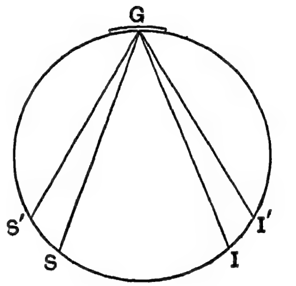

Fig. 9.

§ (7) Wave-length Measurements in the Infra-red.—Beyond the photographic limit, investigation of the infra-red spectrum by means of the heating effect of the rays has been carried on with the aid, chiefly, of thermopile, radiometer, radio-micrometer, and bolometer. The thermopile consists of a number of junctions of dissimilar metals, *e.g.* bismuth and antimony, iron and constantin. If radiation falls on alternate junctions a galvanometer in the circuit will give a deflection proportional to the heating effect.

The radiometer is a modification of the instrument devised by Crookes in which mica vanes, accurately mounted on a central spindle *in vacuo*, rotate when placed in the path of radiant energy. The radio-micrometer[1] invented by Boys and d'Arsonval simultaneously is a type of galvanometer. A single thermocouple is suspended by a quartz fibre with the plane of the couple in the line joining the poles of a magnet. When radiation falls on a junction the current generated causes the couple to turn in the magnetic field. In 1881 Langley (34) announced his actinic balance or bolometer,[2] which measures the temperature of a very fine strip of metal in terms of the change of electrical resistance. Two similar strips are placed in two of the arms of a Wheatstone bridge. When radiation falls on one of them the resistance changes and causes a deflection of the galvanometer.

In connection with this method of spectrum investigation the name of Langley (35) became famous. His bolometer was an exceedingly great advance upon any of the apparatus which had previously been constructed. With a bolometer strip 0·5 mm. broad and ·002 mm. thick he reached a sensitiveness of 10^{-6}° C. With such instruments he investigated the heat spectrum of the sun and the absorption of the earth's atmosphere. In his final work on the solar spectrum Langley used a fixed-arm type of spectrometer, with lenses and prisms of rocksalt, and the spectrum was made to pass over the bolometer strip by rotating the prism. The galvanometer readings were recorded on photographically sensitive paper whose motion was co-ordinated with that of the prism. From the known dispersion of the prism the wave-length of any spectrum line shown upon the record could be found, and also, from the length of the galvanometer throw, its intensity estimated. Langley thus mapped the solar spectrum as far as 5·5 μ, and observed 700 lines between A (·7604 μ) and this limit.

For more than a decade Langley was practically the only worker in this field. In 1892 Rubens (36) began to measure the dispersion of various substances for long wave-lengths. With a bolometer he measured the dispersion of crown and flint glasses, water, and various liquid hydrocarbons to 3 μ, and of quartz, rocksalt, and fluorite to 3·5 μ. Later he extended the work on fluorite to 6·48 μ.

In 1894 Paschen (37) went out to 9·3 μ by using a fluorite prism, and Rubens (38) and Trowbridge in 1897 pressed forward to 23 μ by using prisms of rocksalt and sylvine. The continuous spectrum was thus extended to thirty-nine times the wave-length of sodium yellow, or five octaves into the infra-red. A further extension in this manner seemed impossible, because no substances were known which were more transparent than sylvine to the long waves. The extreme limit of prism

[1] See "Radio-micrometer and other Instruments," Vol. III.

[2] See "Radiant Heat, Instruments for the Measurement of," § (18).

transmission is fixed by sylvine at 23 μ. With rocksalt and fluorite the limits are already reached at 15 μ and 9 μ respectively. It is an interesting fact that the absorption which makes it impracticable to use these substances further as prism material furnished the key to still greater penetration into the infra-red region.

The presence of these absorption bands is attributed to a resonance phenomenon which

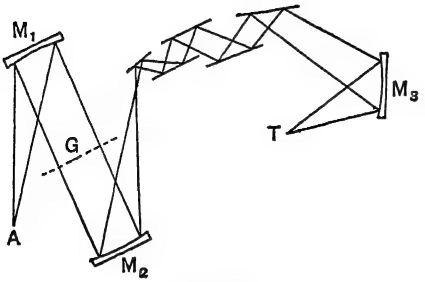

FIG. 10.

causes a large part of the incident radiation to be re-emitted, so that the particular substance shows metallic (*i.e.* high) reflection at these points. This fact is the basis of the method of isolating long waves which was worked out by Rubens (39) and Nichols in 1899. If the radiation of a source falls upon a plate of rocksalt, for example, all wave-lengths are transmitted except in absorption regions; the wave-lengths corresponding to the maximum absorption are almost wholly reflected. The diagram (*Fig.* 10) of Rubens' apparatus shows light from an incandescent Welsbach burner A passing through a wire grating G and undergoing several successive reflections before being focussed on thermopile T. The final radiations thus obtained by successive reflections from a substance were called "Reststrahlen" or residual rays, and possess the greatest energy for almost the same wave-lengths as the maxima of the absorption bands for the substance. For example, the absorption bands computed by means of the Ketteler-Helmholtz dispersion formula are at 35 μ for fluorite, 56 μ for rocksalt, and 67 μ for sylvine. Rubens and Nichols found experimentally for fluorite 24 μ and 34 μ, for rocksalt 52 μ, and for sylvine 63·4 μ; very good agreement if one considers that the dispersion formula requires the reflection maximum at somewhat shorter wave-length than the absorption. It was suspected that for other substances, especially those with larger molecular weight, still longer waves could be found. This was confirmed by Rubens, and is shown in the following table:

Substance.	Mean λ of Reststrahlen.	Molecular Weight.
Rocksalt (NaCl) . . .	52·0 μ	58·5
Sylvine (KCl) . . .	63·4	74·6
Silver chloride (AgCl) .	81·5	143·4
Potassium bromide (KBr)	82·6	119·0
Thallium chloride (TlCl)	91·6	239·5
Potassium iodide (KI) .	94·1	166·0
Silver bromide (AgBr) .	112·7	188·0
Thallium bromide (TlBr)	117·0	284·0
Thallium iodide (TlI) .	151·8	331·0

The infra-red spectrum was thus pushed to nearly 8 octaves above the visible. Because of the limited energy of sources, further extension to longer waves by the Reststrahlen method is difficult in spite of the refinement of modern apparatus.

A still further improvement in the method of isolating very long waves was made by Rubens (40) and Wood in 1911. The method is based on the selective refraction and selective absorption of quartz. Quartz has an absorption band beginning at 4·5 μ which reaches far out into the infra-red, but for wave-lengths longer than 70 μ it becomes transparent.

At the same time, in consequence of its anomalous dispersion, quartz has a very large index of refraction for 70 μ; at 63 μ, $n = 2{\cdot}19$ and approaches 2·14 with longer wave-lengths. For visible and short heat waves its index of refraction ranges from 1·43 to 1·55. A quartz lens, therefore, has a much shorter focal

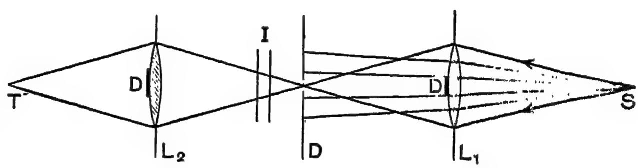

FIG. 11.

length for extremely long waves than for the shorter ones. This principle was used by Rubens and Wood in their apparatus, *Fig.* 11, in which the long waves are selected from the source S by means of the quartz lenses L_1 and L_2 and opaque screens D which stop the short waves. The long waves pass through an interferometer I and are focussed on a thermopile T. The great advantage of this method of focal isolation is that large angular apertures can be used and the radiation is weakened only by reflection and absorption by the two quartz lenses. Its only disadvantage is that all the radiations for which n approximates 2·14 pass through. The wave-lengths are determined

TABLE OF WAVE-LENGTHS

from "visibility" curves obtained by plotting increasing separation of the interferometer plates as abscissae and corresponding energy readings as ordinates. In this way it was found that the radiation from a Welsbach incandescent mantle contains waves over 150 μ long, the maximum radiation being about 100 μ. Rubens (41) and von Baeyer in 1911 investigated by this method the long waves from a quartz mercury lamp and found an emission region between 200 and 400 μ with maxima at 218 μ and 342 μ. Here is a light wave 1/3 mm. in length, or over 500 times the length of the yellow sodium ray. This is the longest wave isolated to date, and is only 2¼ octaves from the shortest electric waves ($\lambda = 2$ mm.) obtained by O. von Baeyer. The rapid progress in the knowledge of the region between the visible spectrum and electric waves in the last 30 years justifies the hope that the remaining gap will soon be filled up. An effort in this direction was made in 1914 by Rubens (42), and Schwarzschild, who tried to find solar radiation between 400 and 600 μ by the quartz lens method. Calculation predicted that radiation could be measured if the sun were assumed a black body at 6000° C. and if the atmosphere were transparent. However, not a trace of deflection could be observed. The explanation is probably that the water-vapour in the earth's atmosphere, whose absorption spectrum is complex and full of bands below 400 μ, also possesses strong absorption for still longer waves.

Standards of wave-length in the infra-red part of the spectrum have been determined with considerable accuracy by Paschen (43) and by Randall (44), using thermopiles with which to explore the normal spectrum of concave gratings. Their investigations cover the arc spectra of a large number of the chemical elements. The measurements extend to wave-lengths of 30 to 40 μ, and are probably not more than a few tenths of an Ångström in error.

§ (8) Table of Wave-lengths.—The charts on pages 893-894 show the entire range of wave-lengths of electromagnetic waves which are within the domain of scientific investigation at the present time.
